These immunochemical observations are in agreement with information obtained on the structure of CA and its metal complexes by other techniques. Previous investigations on the metal-binding activity of CA have demonstrated that FeCA is significantly more resistant to proteolysis, thermal denaturation, as well as to chemical modifications, as compared with CA (refs. 11 and 12). Investigations of optical rotatory dispersion have demonstrated an anomalous effect for FeCA, as compared with a plain rotatory dispersion for CA (ref. 13). This suggests that the interaction of metal with CA produces important changes in the protein molecule which affect its specific metal-binding functional groups as well as its overall structure.

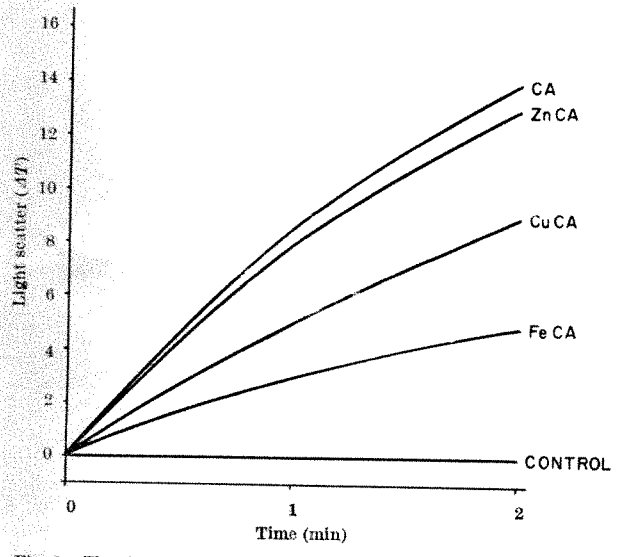

Fig. 1. The change of light scatter in the reaction of CA and its metal complexes with ACA. Protocol: 1·0 ml. antibody + 0·1 ml. antigen $\frac{\text{mixed}}{\text{in 3–5 sec}}$ light scatter recorded. Antibody: 25 × diluted ACA in 0·1 M borate buffer pH 8·2 ($0{\cdot}1 \times 10^{-4}$ μmole/ml. antibody protein, 3·2 mg/ml. total serum protein). Antigen: CA, FeCA, CuCA or ZnCA ($1{\cdot}87 \times 10^{-4}$ μmole/ml. in 0·1 M borate buffer, pH 8·2). The experiments were conducted at 21° C. The curves shown are redrawn from actual recorded tracings

The present investigation offers evidence for a change in the antigenic reactivity of a protein on metal binding. The light scattering technique, although it measures the secondary antigen–antibody interaction, is an even more sensitive method for the detection of changes in the antigenic reactivity than techniques which measure the primary antigen–antibody interactions[14]. Investigations are being carried out to determine whether or not this change in antigenic reactivity is caused by configurational or conformational change in the protein molecule.

This investigation was supported by the U.S. Public Health Service.

MICROBIOLOGY

Inhibitory Effect of *Lactobacillus acidophilus*

SABINE[1] demonstrated the antibiotic-like effect of *Lactobacillus acidophilus* by growing it in a solid medium in holes cut in a plate seeded with a staphylococcus and *Escherichia coli* as test organisms. He stated that the inhibition observed was not a result of acidity, since there was no difference in the *p*H of the agar in the cup, in the inhibition zone or in the outer zone. The antibiotic substance was said to be extremely labile and had not yet been isolated.

We examined the inhibitory effect of *L. acidophilus* (Aplin and Barrett, Ltd., Yeovil) against *E. coli* by a procedure based on that of Ritter[2]. 50 ml. of milk agar was poured into a 6-in. plastic Petri dish and allowed to solidify. Another 30 ml. of milk agar inoculated with 3 ml. of a 10^{-4} dilution of 1–2-day-old nutrient broth culture of *E. coli* I was then poured on top of the solidified agar and allowed to set. Using a sterile hollow steel borer, 15 mm in diameter, the required number of holes were cut into the medium and the bottom of each hole was sealed with a few drops of milk agar. 0·3 ml. quantities of the test solutions were then pipetted into these holes. After 3 h of pre-diffusion at 5° C the plates were incubated for 18 h at 30° C.

Using this technique we found that a 48-h-old *L. acidophilus* culture in a tomato dextrose broth (TDB) was usually about *p*H 3·5 and inhibitory. Raising the *p*H reduced the inhibition, which almost disappeared above *p*H 4·5. A neutralized and non-inhibitory TDB became inhibitory again on reacidification with lactic acid, but far less so when hydrochloric acid was used. The inhibitor was found to be present in a cell-free (membrane-filtered) filtrate and to be heat-stable. We photographed a plate (Fig. 1) showing the inhibitory effect of sterile TDB adjusted with either lactic acid or hydrochloric acid to

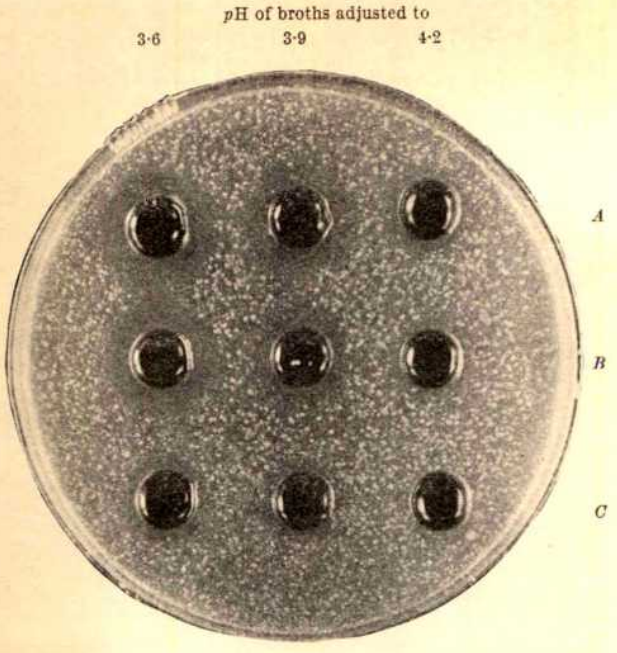

Fig. 1. Inhibition of *E. coli* by various broths. Plate seeded with *E. coli*; cups filled with broth. Prediffusion for 3 h at 5° C followed by 18 h at 30° C. *A*, Cell-free filtrate from *L. acidophilus* culture in tomato dextrose broth; *B*, tomato dextrose broth acidified with 2·3 N lactic acid; *C*, tomato dextrose broth acidified with 0·5 N hydrochloric acid

*p*H 3·6, 3·9 and 4·2, and also that of a cell-free filtrate of an *L. acidophilus* culture of *p*H 3·6 and adjusted with caustic soda to 3·9 and 4·2. As can be seen, the zones of inhibition diminish markedly when the *p*H of the broths is raised in fairly small stages. While the inhibitory effect of the *L. acidophilus* filtrate is almost unequalled by that of the broth acidified with lactic acid, the broth acidified to corresponding *p*Hs with hydrochloric acid produces only little inhibition. By incorporating a mixed indicator consisting of 0·25 per cent methyl red and 0·5 per cent bromthymol blue (1 : 1) it was found that the zones of inhibition coincided with the extent of spread of acidity from the cups as judged by the orange colour of the indicator. The lactic acid spreads much farther into the medium than the hydrochloric acid–acidified broth, apparently governing the size of the zones of inhibition observed.

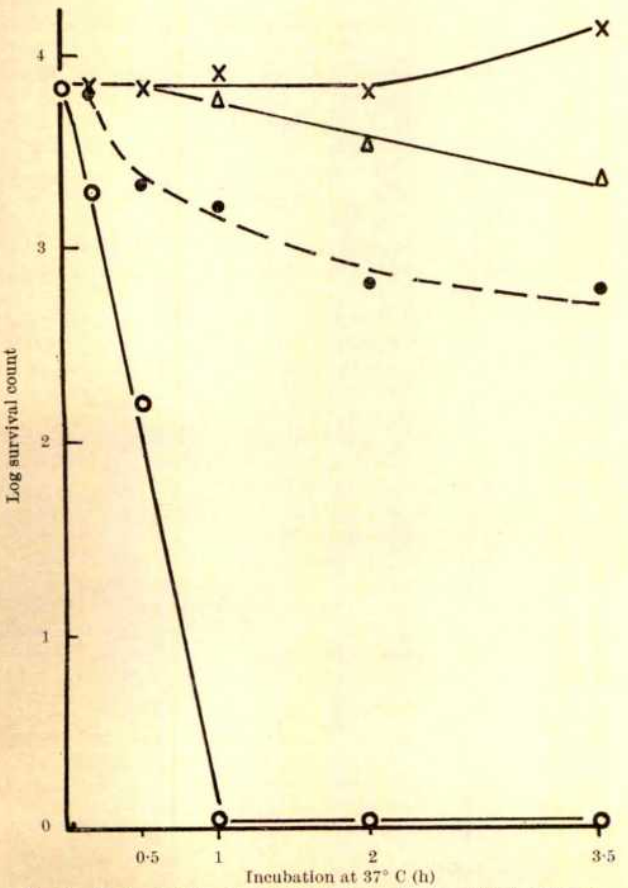

Fig. 2. Survival of *E. coli* in tomato dextrose broth acidified with lactic acid to *p*H 3·6 (○), 4·2 (△), and 4·9 (×) and with hydrochloric acid to *p*H 3·6 (●)

However, if the incubation time was extended beyond 18 h or the incubation temperature raised to 37° C, the *p*H of the whole agar changed gradually towards alkalinity with only some diminution of the zones of inhibition. Thus the time of measuring the *p*H is fairly critical, and Sabine's finding (after 24 h at 37° C) that the *p*H was the same throughout the plate may well be explained in this way.

Since the zones of inhibition produced by lactic acid remained clear even though the whole plate had become uniformly slightly alkaline, we next examined the relative lethal effect of lactic acid and of hydrochloric acid on *E. coli*. TDB acidified with either acid was inoculated and plate counts were carried out after incubation at 37° C. The results given in Fig. 2 show that lactic acid at *p*H 3·6 causes practically 100 per cent mortality of *E. coli* in TDB at 37° C in 1 h, whereas hydrochloric acid at the same *p*H reduces the viable count by only 60 per cent in that time and by 90 per cent in 3·5 h. Only very little, if any, kill occurred at 5° C in 3·5 h with either acid. These results are in good agreement with some earlier findings of Shillinglaw and Levine[3].

Lactic acid is thus shown to be strongly germicidal and possibly largely responsible for the inhibitory effect of *L. acidophilus*. Our plate cup experiments, notably the small inhibition zone produced by *L. acidophilus* culture even when its *p*H is raised to 4·2, suggest the possibility that some other inhibitor is also formed.

Incidence of *Clostridium botulinum* Type *E* in Fish Products in the United Kingdom

UNLIKE other areas of the world, such as the United States, Japan and Scandinavia, the British Isles, until recently, appeared to be free from the presence of *Clostridium botulinum* type *E*. Early surveys by Meyer and Dubovsky[1], Leighton and Buxton[2], Haines[3], and more recently by Dolman[4] and Cann *et al.*[5], failed to demonstrate its presence either in soil in the British Isles or in sea muds and fish from traditional British fishing grounds. A recent examination by Hobbs *et al.*[6] of more than two hundred commercial vacuum-packed fish purchased in the United Kingdom and of the intestines of a hundred fresh North Sea herring gave no toxic samples. Nevertheless, type *E* botulism could arise from the ingestion of fish imported from areas where there is a high incidence of *Cl. botulinum* type *E*.[5,7].

In continuing a survey of fish and fish products in the United Kingdom for the presence of *Cl. botulinum* type *E*, 646 samples of vacuum-packed fish and samples of fresh herring were examined. The vacuum-packed fish were purchased at random from shops in England. The techniques of examination are reported elsewhere[8]. The herring were part of cargoes landed at British ports

by foreign vessels thought to have been fishing in areas where there is a high incidence of *Cl. botulinum* type *E*. These were sampled in two ways. In the first, contents of the lower intestine of each fish were cultured anaerobically after dissection under aseptic conditions and the broths were incubated for 3–6 days at 30° C. In the second, herring were vacuum-packed whole and incubated for 6 days at 30° C before testing for the presence of toxin.

Of the 646 samples of vacuum-packed fish examined, five contained *Cl. botulinum* type *E*. These were kippers which were all purchased in the same area in early summer 1965. Further attempts to isolate *Cl. botulinum* type *E* from fishery products met with no success until February 1966, when out of one sample of twenty-six Storsild herring, landed at Aberdeen by a Scandinavian carrier ship, eleven were toxic, and out of a second sample of sixteen herring five were toxic.

One of these catches is known to have been taken just off the coast of Norway east of the Viking bank. In spring and early summer there is a large herring fishery off the coast of Norway and it is possible that the five positive isolates of *Cl. botulinum* type *E* made in 1965 came from herring landings from this area.

Table 1. INCIDENCE OF *Clostridium botulinum* TYPE *E*

Source	Type of sample	No. tested	No. containing *Cl. botulinum* type *E*
Shops in Britain	Vacuum-packed fish	646	5
Skagerrak	White fish (intestines)	130	0
Skagerrak	White fish (whole)	130	0
North Sea	White fish (intestines)	96	0
North Sea	Herring (intestines)	200	0
Norwegian Sea	Herring (whole)	29	19
Norwegian Sea	Herring (intestines)	14	0
Viking Bank	Herring (whole)	18	8
Viking Bank	Herring (intestines)	8	3
Fish room of Swedish trawler carrying contaminated fish	Swabs and ice samples	16	0
North Sea west of Haugesund	Herring (whole)	12	0

As a consequence of the demonstration of such a high incidence of *Cl. botulinum* type *E* in the Storsild herring, further batches of fish landed by Scandinavian trawlers were examined. The results are shown in Table 1. The incidence of the organism was sufficiently high to attempt viable counts using 'most probable number' techniques with the demonstration of toxin in a culture indicating the presence of at least one viable spore. Of six fish tested, one gave a count of one spore/16 g and two gave counts of one spore/200 g of whole fish.

Previous work on the distribution of *Cl. botulinum* type *E* in sea-bottom deposits had shown the organism to be present off the coast of Norway so far north as 59° 59′ N., 4° 53′ E. (unpublished data) but had not covered the areas in which the above-mentioned fish were known to have been caught. The research trawler, *Sir William Hardy*, was therefore sent to sample the off-shore areas between the Viking Bank and the towns of Ålesund and Kristiansund. In all, twenty-eight samples of sea bottom deposit were examined with negative results.

The source of contamination of the herring, therefore, is not known, but the sporadic incidence of *Cl. botulinum* type *E* in herring indicates the probable presence of the organism in the sea in concentrated pockets, and although it is still true to say that *Cl. botulinum* type *E* has not been demonstrated in materials indigenous to Britain there is now no doubt that the organism is present in some fish sold in British shops.

There is little danger of botulism due to the ingestion of this type of product, as the cooking times recommended by manufacturers will generally inactivate any toxin which may be formed as a result of bad storage (unpublished data). The main danger lies in products such as smoked salmon which are eaten without further cooking. It is, therefore, essential that all fish products, whether vacuum-packed or not, should be stored below 4° C or preferably frozen from the time they are processed until they are eaten, and all packs should be clearly labelled to this effect.

An Enrichment Method for Auxotrophic Yeast Mutants using the Antibiotic 'Nystatin'

ENRICHMENT methods have greatly facilitated the work of geneticists in obtaining desired mutants. The various methods in use depend on the selective removal or killing of growing cells relative to non-growing mutants. Moat *et al.*[1] showed that several antifungal agents could be used with yeast to increase the proportion of mutant survivors in artificial mixtures of mutant and wild-type cells. Although 'Nystatin' was not so effective as 'Endomycin' or 'Amphotericin *B*' in their experiments, it seemed a desirable antibiotic with which to undertake further work, as a great deal is known about the physiology of its action on yeast[2–4] and especially as it had been reported that actively metabolizing cells take up much more of it than glucose-starved cells[5].

Preliminary experiments were carried out to determine the killing action of 'Nystatin' on growing and non-growing cells. Haploid strain *S288C* of *Saccharomyces cerevisiae* (obtained from Dr. R. K. Mortimer) was grown with shaking at 30° C until stationary phase in YEP (1 per cent yeast extract, 2 per cent Bacto-peptone, 2 per cent glucose). The culture was washed twice with water, resuspended in a synthetic minimal medium (Difco yeast nitrogen base, without amino-acids) from which the nitrogen source, ammonium sulphate, was omitted, and incubated for a further 6 h. After washing twice with water, the nitrogen-starved culture was adjusted to about 10^8 cells/ml. 1 ml. of this suspension was added to a flask containing 8·0 ml. of the minimal medium with ammonium sulphate (S medium), and to a second flask containing 8·0 ml. of the nitrogen-free medium (S—NH_4 medium). The two flasks were incubated for 3·5 h before 1·0 ml. of a 100 μg/ml. 'Nystatin' solution was added to each. The 'Nystatin' solution (Squibb) was made by diluting a 1 mg/ml. solution in 95 per cent alcohol 1 : 10 with sterile distilled water, and was used without additional sterilization. Samples were removed at 0, 20, 40 and 60 min, and plated for viability in YEP agar. The results are given in Table 1. The viability of the cells in S—NH_4 dropped about 20 per cent after 60 min, but only 0·003 per cent of the cells in S were alive after 40 min, and less than 0·0005 per cent were alive after 60 min.

Table 1. VIABILITY OF NITROGEN-STARVED YEAST CELLS EXPOSED TO 10 μG/ML. 'NYSTATIN' IN MINIMAL MEDIUM WITH AND WITHOUT NITROGEN

	'Nystatin' treatment before plating (min)	Viability (per cent)
Cells in S—NH_4 medium	0	100
	20	85
	40	85
	60	81
Cells in S medium	0	100
	20	0·04
	40	0·003
	60	< 0·0005

Several experiments were carried out to determine the best conditions for killing prototrophic cells. The following are our conclusions. (1) At least 3 h of nitrogen starvation should be given, but the period may be extended to 24 h if desired with no significant loss of viability through starvation. (2) Starvation for glucose for 6 h did not prevent killing by the antibiotic—presumably the cells were still metabolizing sufficiently to be sensitive to its action. (3) Maximum killing was found when 3–4 h growth in S was allowed between nitrogen starvation and addition of 'Nystatin'. During this time, cell number increased 10–15 per cent, and microscopic examination showed that most cells had started budding. (4) An exposure of at least 1 h to the antibiotic should be given. Longer treatments (up to 2·5 h) resulted in somewhat greater killing, but they also resulted in increased killing of non-growing cells and possibly some mutants may be lost. (5) The amount of killing is rather less at 10^8 cells/ml. than at 10^7/ml.; however, even with the higher cell concentration viability was reduced by almost thirty after treatment for 1 h.

To determine whether the proportion of mutant cells could be increased relative to wild-type, an experiment similar to those of Moat *et al.*[1] was undertaken. *S288C* and a red adenine-requiring strain of the same mating-type (*A708C*) were separately grown in YEP and treated as before. After nitrogen starvation and washing they were mixed by volume in the proportion of one mutant to 1,000 wild-type cells, and then suspended in S. The *A708C* cells would not grow because the medium lacked adenine. After incubation for 4 h in S, 'Nystatin' was added to a final concentration of 10 μg/ml. as before, and platings were made at intervals of 30 min on to S-agar supplemented with 20 μg/ml. adenine. On this medium, the red adenine-requiring colonies could easily be distinguished from the white wild-type colonies. Our results are given in Table 2 as the change in ratio of red to white colonies. There was a maximum calculated enrichment of about 10,000-fold for mutant cells relative to wild-type cells. However, this figure is not very reliable as there were very few red colonies in the 0 min platings. A more reasonable estimate would be at least a 1,000-fold enrichment for mutants among survivors.

It thus became necessary to determine whether the method could be used with newly induced mutants. *S288C* was grown in YEP as before, washed, suspended at 10^7 cells/ml. in *tris* buffer at *p*H 7·4, and ethylmethanesulphonate (EMS) was added to a final concentration of 1 per cent. After 3 h incubation the cells were washed, suspended in 6 per cent sodium thiosulphate for 10 min, and washed twice more. Survival after treatment with EMS was about 50 per cent. The treated cells were suspended in YEP and grown for about 18 h, then subjected to nitrogen starvation and 'Nystatin' selection as before. Survival after treatment with 'Nystatin' was 0·61 per cent. Platings of suitable dilutions were made on YEP agar. Almost 10 per cent of the resulting colonies failed to grow when replicated to S-agar. The requirements of the various auxotrophic strains isolated were satisfied by arginine, histidine, leucine, lysine, isoleucine, isoleucine + valine, methionine, phenylalanine, threonine, tryptophan, tyrosine and adenine. Because an intermediate growth period in YEP was allowed, many of the colonies which required a particular substance were without doubt clonal repeats of one mutational event.

The method can be used to select specific auxotrophic mutants by allowing growth after mutagen treatment in S supplemented with the specific growth factor. One cycle of 'Nystatin' selection may be sufficient in such cases, but if the mutation is rare it is advantageous to go through a second selection cycle (after washing and a second intermediate growth period) in order to increase the mutant yield. When using this two-cycle method to select specifically for histidine auxotrophs, 5–10 per cent of surviving colonies regularly proved to be the required mutant types.

Table 2. CHANGE IN THE PROPORTION OF ADENINE-REQUIRING (RED) TO WILD-TYPE (WHITE) COLONIES IN A 1 : 1,000 MIXTURE (BY VOLUME) TREATED IN MINIMAL MEDIUM CONTAINING 10 μG/ML. 'NYSTATIN'

'Nystatin' treatment before plating (min)	Ratio red : white colonies	Enrichment factor
0	1 : 470	—
30	1·24 : 1	580
60	9·2 : 1	4,300
90	25·2 : 1	11,800
120	11·7 : 1	5,500

The proportion of petite colonies is increased after 'Nystatin' selection, but in practice this has not been a serious disadvantage. They can be eliminated by plating on a medium containing a non-fermentable carbon source such as glycerol, or identified by replicating to such a medium.

A period of growth after mutagen treatment seems necessary to 'fix' the mutation. No auxotrophs were obtained in one experiment in which 'Nystatin' selection was used immediately after EMS treatment. The desirability of intermediate growth has also been noted when using the penicillin method with bacteria[6]. As is also the case with penicillin selection, it is desirable to allow the prototrophs to grow vigorously before the antibiotic is added (Moat, personal communication). Lampen *et al.*[4] have shown that log phase cells bind more 'Nystatin' than stationary phase cells.

The uptake of 'Nystatin' by yeast is influenced by *p*H, the maximum being at about *p*H 4 (ref. 5). Because the minimal medium used had a *p*H of about 4·2, no adjustment was made. If media with higher *p*H's are used adjustment would probably be necessary to ensure that the antibiotic has maximum effect.

The 'Nystatin'-selection method is analogous to the penicillin-selection method widely used in bacteria[6–8]. Although the mutant yield does not reach that of the penicillin method, 'Nystatin' selection has nevertheless proved a convenient way to isolate a wide variety of auxotrophic yeast strains.

PHYSIOLOGY

Kininase Activity in Experimental Pancreatitis

THE role of vasoactive polypeptides as humoral mediators in acute pancreatitis has been the subject of much recent speculation. Both trypsin and kallikrein, normally present in the pancreas in an inactive form, are activated in acute pancreatitis, and these enzymes are able in turn to split the polypeptides bradykinin and kallidin from the alpha 2 globulins to which they are bound in the blood. The active peptides have well-known pharmacological properties which include pain production, increased capillary permeability, smooth muscle stimulation, production of hypotension and leucocyte aggregation. The severe pain, unique retroperitoneal oedema, hypotension, and shock encountered in acute pancreatitis suggest the presence of such a substance.

The kinins are rapidly destroyed in the normal subject by peptidases which split off a terminal peptide leaving

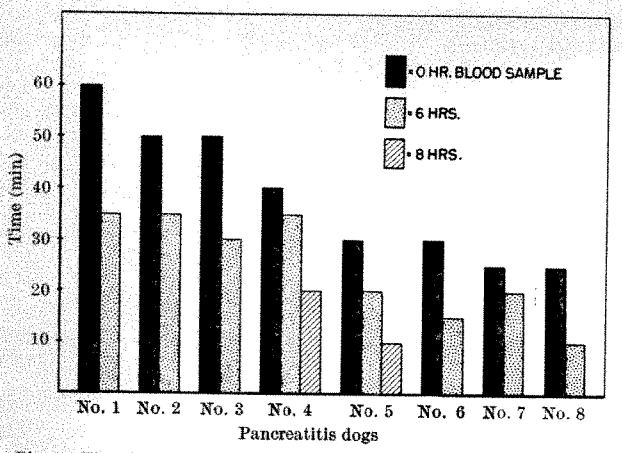

Fig. 1. Time for complete inhibition of 0·05 mcg of bradykinin in 0, 6-h, and 8-h blood samples from eight dogs with bile pancreatitis

an inactive form[1]. The balance between available kininase and kinin production thus becomes extremely important in this disease.

Reports have been made of increased kinin activity[2-4] and of decreased kinin precursor[3] during experimental pancreatitis in the dog, but to our knowledge changes in plasma kininase levels have not been studied.

Eight mongrel dogs were anaesthetized with sodium pentothal (10·5 mg per lb.). Bile pancreatitis was produced by injecting 10 c.c. of the bile of the dogs into the major pancreatic duct under pressure. The portal vein was cannulated through the splenic vein and blood was collected at 0, 2, 4 and 6 h; in two dogs a specimen was also collected at 8 h.

5 c.c. of oxalated blood was centrifuged at 37° C and 40,000 r.p.m. for 15 min; 0·5 c.c. of plasma was then diluted with 19·5 c.c. of buffered saline solution, and 5 c.c. of this mixture was incubated with an equal amount of a standard solution containing 0·05 mcg of bradykinin (kindly supplied by Sandoz Pharmaceuticals, Hanover, New Jersey). In a rat uterus bioassay system, unresponsive to histamine, serotonin and catecholamines, vasoactivity of the incubated mixture was determined at 5-min intervals until no activity was detectable.

Plasma kininase levels increased during the first 8 h of pancreatitis in all the dogs. The time for total inhibition of 0·05 mcg of bradykinin decreased from a mean control time of 39 min to a mean of 23 min in the 6-h pancreatitis specimen (Fig. 1). No change in the level of plasma kininase was detected during sham pancreatitis.

This investigation was supported in part by funds from the U.S. Public Health Service.

Alveolar Deposition of Aerosols on the Moon and in Outer Space

IT was recently suggested[1] that, on the Moon, man will be more susceptible to infection by aerosols containing bacteria because the smaller gravitational field will lower the filtration efficiency of the upper respiratory tract. The reduction in upper respiratory tract deposition will be caused by a reduction in the sedimentation velocity

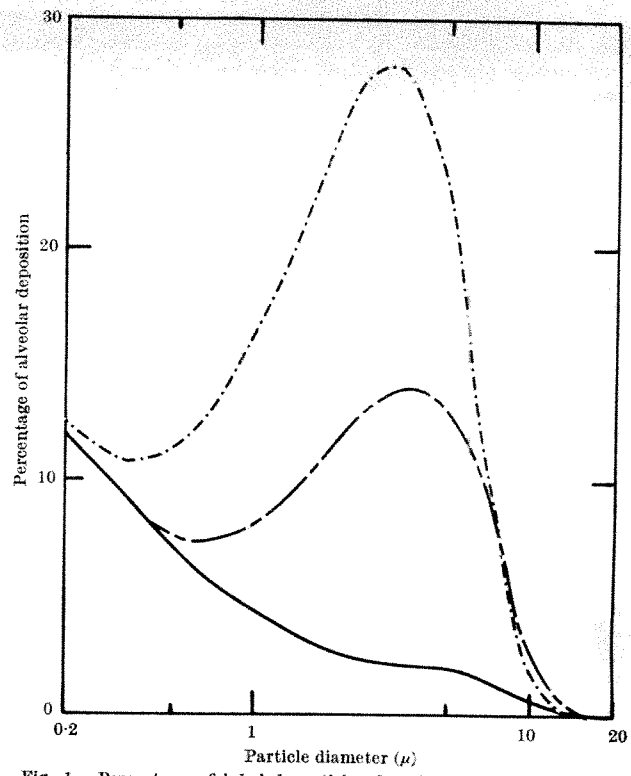

Fig. 1. Percentage of inhaled particles deposited in the alveolated regions of the lung as a function of particle size, for unit density spheres. *Upper curve*, Terrestrial deposition; *middle curve*, lunar deposition; *lower curve*, deposition in the absence of gravity

of the aerosol particles. The other mechanisms for upper respiratory tract deposition, Brownian diffusion and impaction, will be unaffected, but the former is of negligible importance for particles greater than about 1μ.

I recently published details of a method for calculating alveolar deposition as a function of particle size[2,3]. The computations were performed on an electronic computer, and recalculations based on a different gravitational acceleration were easily performed. The results are shown in Fig. 1, for a tidal volume of 500 c.c., a 3-sec linear symmetrical breathing cycle without pauses, and a functional residual capacity of 2 l. It is seen that alveolar deposition on the Moon does exceed terrestrial alveolar deposition, as predicted, in the region of particle-sizes greater than 7μ. However, the difference is not so great as might have been expected, and this is due to the fact that, on the Moon, a higher proportion of those particles which penetrate the upper respiratory tract are exhaled from the lower respiratory tract without being deposited there. This is even more true in the complete absence of gravity, and alveolar deposition in this case is everywhere lower than it would be on either the Moon or the Earth.

Technique for investigating Binding of Labelled Thyroxine by Human Serum

TECHNIQUES using two-dimensional electrophoresis for the investigation of the proteins of human serum have been reported in the past[1,2]. However, these techniques are rarely used because they do not offer advantages over other procedures[3]. The present communication contains a report of a new two-dimensional technique of paper electrophoresis which was used to achieve a better separation of the proteins of human serum. The same technique

was afterwards used to investigate the binding of thyroxine labelled with iodine-131 (T4*) by human serum proteins.

The new technique is based on the ordinary hanging-strip paper electrophoresis procedure in a 'Spinco' cell, with some modifications. A special 30 × 30 cm sheet of Whatman 3 *MM* paper was prepared to replace the eight paper strips which go in the folding rack. Eight holes were punched in the sheet on each of the four sides coinciding with the pegs of the folding rack. Also, for the first-dimensional electrophoresis, one of the edges of the sheet was folded under to allow for the introduction of one narrow paper strip in the folding rack in addition to the sheet. The purpose of the paper strip was to have a control of the migration of the serum proteins in the first-dimensional electrophoresis. It also became important to choose proper buffers for the procedure. Veronal and *tris*-maleate[4], both at *p*H 8·6, were chosen. These buffers were interchanged at different steps of the procedure. Veronal was selected for the second-dimensional electrophoresis when *tris*-maleate had been used in the first dimension and vice versa.

In the first-dimensional electrophoresis, the folding rack with the sheet and one paper strip was placed in the 'Spinco' cell; the papers were then wetted with the buffer, and electrophoresis was started after equilibration. After approximately 16 h, the procedure was stopped, and the papers were taken out of the cell and dried at room temperature. Only the paper strip was stained and fixed in order to obtain information on the migration of the proteins of the serum in the first-dimensional electrophoresis.

In the second-dimensional electrophoresis, the sheet of paper was unfolded, rotated through 90° and placed back with the folding rack in the 'Spinco' cell. The alternate buffer, as stated before, was used. Every step in this part of the procedure followed exactly those of the first procedure. After 16 h of electrophoresis, the sheet was taken out from the cell, dried and stained[3]. The staining revealed five bands in the sheet. These represented albumin (A), alpha 1, alpha 2, beta and gamma globulin when veronal was used as the first and *tris*-maleate as the second buffer (Fig. 1). Only four bands identified as albumin (A), alpha, beta and gamma globulin were stained when *tris*-maleate was the first and veronal the second buffer (Fig. 2). It became evident from this part of the experiment that separation between alpha 1 and alpha 2 globulins could only be obtained under one of the experimental conditions, namely, when veronal was the first buffer and *tris*-maleate the second. The reason for the different behaviours of the proteins of the serum with the two buffers is unknown at present.

It has been shown in the first part of this experiment that the new two-dimensional electrophoretic method produced a distinct separation in two dimensions of the proteins of human serum. This separation is, of course, better than the one obtained in one dimension only.

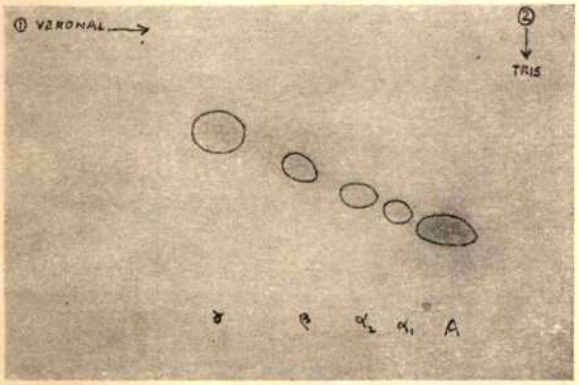

Fig. 1. Two-dimensional electrophoretogram of human serum with veronal as the first and *tris*-maleate as the second buffer, both at *p*H 8·6

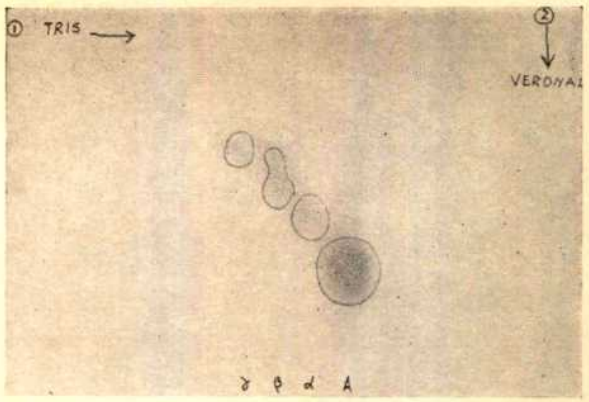

Fig. 2. Two-dimensional electrophoretogram of human serum with *tris*-maleate as the first and veronal as the second buffer, both at *p*H 8·6

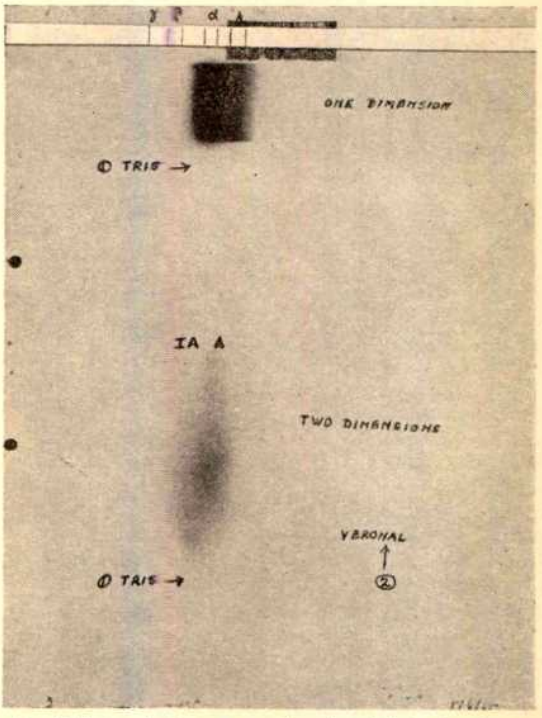

Fig. 3. At the top is shown a one-dimensional electrophoretogram of human serum in *tris*-maleate buffer at *p*H 8·6. Immediately below is the autoradiogram of a one-dimensional electrophoretogram of human serum plus iodine-131-labelled thyroxine in *tris*-maleate buffer. In the lower part is the autoradiogram of a two-dimensional electrophoretogram of human serum plus iodine-131-labelled thyroxine with *tris*-maleate as the first and veronal as the second buffer, both at *p*H 8·6

These results encouraged us to undertake the second part of this experiment, in which binding of iodine-131-labelled thyroxine (T4*) by the proteins of human serum was investigated in two-dimensional electrophoresis.

For this purpose a fresh batch of T4*, specific activity 42·8 mc./mg (0·0049 mg T4/ml.), was purchased from Abbott Laboratories, Oak Ridge, Tennessee. 3 μc. of this T4* were then mixed thoroughly in a test-tube with 1 ml. of normal human serum, and 10 μl. of the mixture were used for each of the two dimensions of the electrophoretic procedure. The materials and methods used were the same as those previously described. Another step was introduced which consisted of the preparation of autoradiograms from the electrophoretograms[5]. It was found necessary to take 2–4 days over this process if clear and defined autoradiograms of the electrophoretograms were to be obtained. In the autoradiograms, T4* was bound in three areas which corresponded to the pre-albumin (PA), albumin (A) and inter-alpha (IA) regions of the human serum when veronal was the first buffer

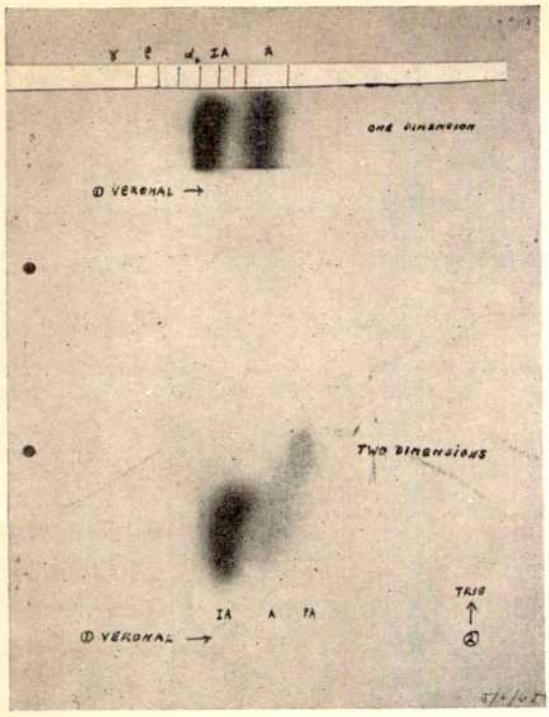

Fig. 4. At the top is shown a one-dimensional electrophoretogram of human serum in veronal buffer at *p*H 8·6. Immediately below is shown an autoradiogram of a one-dimensional electrophoretogram of human serum plus iodine-131-labelled thyroxine with veronal buffer at *p*H 8·6. In the lower part is the autoradiogram of a two-dimensional electrophoretogram of human serum plus iodine-131-labelled thyroxine with veronal as the first and *tris*-maleate as the second buffer, both at *p*H 8·6

used and *tris*-maleate the second (Fig. 3). Poor separation between the bands of albumin (A) and inter-alpha (IA) globulin was obtained when *tris*-maleate was the first buffer and veronal the second. No binding of T4* could be detected in this instance in the pre-albumin area (Fig. 4). It is known that T4* binds in the albumin and inter-alpha regions when veronal is the buffer[6], and that T4* also binds in the pre-albumin area when *tris*-maleate is the buffer. It is the first time, however, that T4* has been shown to bind in the pre-albumin area in two-dimensional electrophoresis using veronal as the first and *tris*-maleate as the second buffer. Since pre-albumin shows T4* binding in *tris*-maleate buffer, the results are not surprising. The second run merely washed all veronal away with the *tris*-maleate buffer so that the inhibitor of T4* binding by pre-albumin (that is, veronal) was no longer present.

More experiments are now in progress in which the binding of T4* by the human serum and tissues is under investigation with the aid of the new two-dimensional electrophoretic technique. In these studies autoradiograms of the electrophoretograms are made and counting of the radioactivities in the sheets is also carried out. It is expected that more progress in this field will be made in the future with the new technique.

BIOLOGY

Translocation of Amino-acids in Sugar Beet

STUDIES of translocation have been largely concerned with movement of sugars or photosynthate, and investigations of transport of nitrogenous material have been limited. Organic nitrogen has been found in root exudates[1,2], but these consist of material transported in xylem. Analyses of phloem contents have revealed nitrogenous material[3], but large samples are difficult to obtain. Indirect methods for investigation of phloem transport must often be used. An earlier report[4] described specific movement of amino-acids from roots to young leaves in phloem. Further experiments on nitrogen movement are now reported.

Sugar beet were used for this work, although some similar phenomena were observed with seedlings of cucumber, tobacco and vine. Methods of growth and detection of radioactivity were as described earlier[4,5].

When supplied to the roots of intact plants, a hydrolysate of carbon-14-labelled protein (complete mixture of protein amino-acids) was translocated preferentially to young leaves over periods of 6–24 h, as were glutamine and glycine, reported earlier[4]. Sarcosine, betaine and β-alanine were more generally distributed to all leaves, as reported for α-amino-isobutyric acid. In an attempt to investigate the mechanism of selective distribution, intact plants were supplied for 30 min with carbon-14-labelled protein hydrolysate, then subjected to the treatments shown in Table 1. In the subsequent 2·5 h in unlabelled nutrient solution considerable amounts of carbon-14 were translocated into young leaves. Removal of old leaves had relatively little effect on accumulation of carbon-14 by young leaves, whereas removal of roots markedly decreased translocation of label (transfer of material to the insoluble fraction accounts for the fact that the soluble fractions in treatment 4 are lower than in 1). It is likely, therefore, that the specific distribution involves discrimination and transfer to phloem in the roots, rather than a general transport to all leaves and redistribution from old to young. However, this latter mechanism could be made to operate in abnormal circumstances. When seedling tops were supplied with amino-acids through the cut hypocotyl, all leaves became labelled in the first 30 min and there was a subsequent redistribution of label to young leaves.

Phloem translocation of amino-acids from older leaves could be demonstrated. Carbon-14-labelled glutamate, -glycine and -protein hydrolysate, applied in drops to the upper surface of leaves, were translocated into growing leaves. After 24 h the typical distribution was to the nearest young leaf, often only the adjacent half, as shown in Fig. 1. This resembles the distribution of photosynthate from mature leaves[5]. A greater proportion of the absorbed activity was translocated when the treated leaf was nearing senescence. 5–12 per cent of the absorbed amino-acid was translocated from the treated leaf in 18 h. Translocation was stopped by petiole steaming. The non-protein amino-acids α-amino-isobutyric acid and D-alanine were absorbed by treated leaves but very little was translocated to young leaves.

The date presented here and earlier show that phloem transport of organic nitrogen is readily carried out by the plant, and that the mechanism and resulting distribution

Table 1. RADIOACTIVITY IN LEAVES OF SUGAR BEET SEEDLINGS (EIGHT LEAF STAGE) AFTER SUPPLYING ^{14}C-AMINO-ACID MIXTURE TO THE ROOTS

Amino-acids were supplied for 30 min, then plants were treated as shown. Leaves were extracted with hot 70 per cent ethanol

	Radioactivity (c.p.s.)			
	Leaves 1–3 (growing)		Leaves 4–6 (mature)	
Further treatment:	Soluble fraction	Insoluble	Soluble fraction	Insoluble
(1) Immediate harvest	1,097	827	2,008	1,470
(2) Transferred to inactive nutrient for further 150 min	3,402	4,533	1,736	1,267
(3) As 2, but older leaves (4–8) removed	3,054	—	(1,850 at 30 min)	—
(4) As 2, but fibrous roots and lower tap root removed	551	—	1,158	—

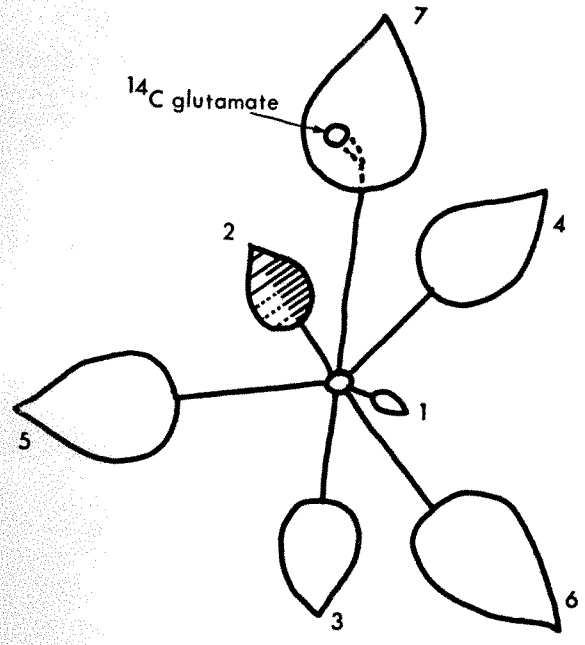

Fig. 1. Translocation of carbon-14 to a young leaf after supplying carbon-14-labelled glutamate to a mature leaf of beet for 18 h. The glutamate solution was placed in a small well (a ring of 'Tygon' tubing) sealed to the leaf with lanolin, and covered with cellulose acetate film to restrict evaporation. Diagram based on autoradiographs

are quite different from those of xylem transport. It remains to be shown whether phloem translocation of amino-acids can contribute a significant amount of nitrogen for young leaf growth.

Variations in Gestation Length of Mink (*Mustela vison*)

MINK reproduction is characterized by several remarkable features, among which the variability of gestation length is of outstanding interest. Hansson[1] and Enders[2] have emphasized this variability (from 37 to 91 days) in their classic studies on mink reproduction. It is generally accepted that this range in gestation length is due to varying periods of delayed implantation, when the fertilized ova reside in the uterus for an extended period of time before nidation occurs. This communication reports some investigations which I made of the normal variations of gestation length in four modern colour phases (strains) of mink and the effects of the age of the female, the date of mating and litter size on gestation length.

Ninety mink of the four colour phases were used. The genetic formulae of these colour phases were: 'Pearl' (*pp bpbp alal*), 'Cameo' (*alal bm^{H}bm^H*), 'Dawn Pastel' (*bb bsbs*) and 'Violet' (*pp alal bmbm*). The mink were raised under normal ranch conditions in the Great Lakes region of the United States. All mink received a standard ration consisting of 55 per cent meat, 12 per cent cereal and 33 per cent water. This ration was supplemented with vitamin A (1,560,000 I.U. per ton of dry feed) and a bacterial-fungal enzyme (Nopco Chemical Co., Harrison, New Jersey) (1·8 kg per ton of dry feed). Some of the mink received an additional supplement of ethylene dichloride extracted wheat germ oil (Dukelow[3]). This treatment did not significantly affect gestation length, and therefore data from mink receiving this treatment were pooled with data from untreated mink.

Table 1. GESTATION LENGTH OF YEARLING AND OLDER MINK OF FOUR COLOUR PHASES

Factor	No. of gestations	Mean gestation length (days)
(1) Colour phase		
(*a*) 'Pearl'	41	52·5 ± 4·0
(*b*) 'Cameo'	20	50·8 ± 5·2
(*c*) 'Dawn Pastel'	22	53·3 ± 3·9
(*d*) 'Violet'	7	52·0 ± 5·1
(2) Age of female		
(*a*) Yearling	60	52·0 ± 4·1
(*b*) Older	30	52·9 ± 4·5

Table 2. GESTATION LENGTH OF MINK BASED ON TIME OF BREEDING

Date of breeding	No. of gestations	Mean gestation length (days)
March 10–14	12	56·8 ± 2·3
March 15–19	46	53·0 ± 2·7
March 20–24	25	50·3 ± 4·5
March 25–29	7	46·4 ± 4·4

Table 3. GESTATION LENGTH OF MINK IN RELATION TO LITTER SIZE

Gestation length range (days)	No. of gestations	Mean gestation length (days)	Mean litter size
42–45	8	43·1	4·00 ± 1·82
46–49	11	47·5	4·00 ± 2·14
50–53	33	51·5	3·88 ± 2·18
54–57	29	55·1	3·59 ± 2·21
58–61	9	58·7	3·33 ± 1·66

Matings were started on March 10, 1963. All females were mated only once and did not accept mating at a later date. Because of this procedure it can be assumed that these mink were of higher fertility than the remainder of the herd which afterwards accepted a later mating. The gestation length was measured from the date of mating to the date of birth. All data were treated by analysis of variance. Differences in gestation length between colour phases and yearling and aged females were not statistically significant (Table 1). Hansson[1] reported gestation length means of 51·3 ± 5·4 days for 'Eastern' mink and 49·0 ± 4·2 days for 'Alaskan' mink. The lack of a significant difference between yearling and older mink in gestation length is in agreement with Apelgren[4], but conflicts with Enders[2], who believed that the gestation length was longer in yearlings than in the same individuals when older. A highly significant difference ($P < 0.01$) was observed between gestation lengths based on the date of mating (Table 2). Generally, the later in the breeding season that mating occurred, the shorter was the gestation period.

Hansson[1] reported that the length of gestation decreases greatly when the date of mating is moved forward. He also reported a decrease in gestation length from matings on March 10–March 29 of 6·5 days compared with 10·4 in the present investigations. Table 3 illustrates the relationship between the length of the gestation period and the number of kits born. The shorter gestations tended to be associated with larger litters. Hansson[1] showed a similar but irregular tendency. The cause of this phenomenon is not known. Early workers believed that the presence of a larger number of foetuses resulted in an earlier stimulus to parturition and a shorter gestation length. However, modern endocrinological theories of the onset of parturition are in conflict with this. A more logical explanation lies in the higher mortality of zygotes during the period of delayed implantation associated with longer gestations.

I thank Mr. Nobe Hall, Woodland Mink Ranch, Grand Rapids, Minnesota, for his assistance and co-operation in these studies.

Ascent of Calcium in Intact and De-rooted Bean Plants

CALCIUM ions are known to be practically immobile in the phloem of plants and are thus not re-translocated from older leaves[1]. Other elements manifesting low phloem mobility are zinc, boron and iron; the last-mentioned is also immobilized in the xylem in various circumstances[2]. Apparently, it has not been suggested that elements other than iron may be immobilized in the xylem[2].

Fig. 1. Autoradiographs of (*A*) intact bean plant, and (*B*) similar but de-rooted bean plant. Both absorbed calcium-45 from a labelled 10^{-4} *N* calcium chloride solution during 24 h, at 25° C, in a photoperiod of 18 h light and 6 h darkness

In the present investigation, upward movement of calcium in de-rooted and in intact bean plants (*Phaseolus vulgaris* L.) was compared. Calcium was delivered to the whole plant when absorbed by roots of intact plants; it was, however, retained in the basal stem segment when absorbed by cut surfaces of similar but de-rooted plants (Fig. 1). Other mineral ions such as chloride[3], sulphate and potassium, as well as an acid dye—fuchsin—were found to be distributed throughout the whole plant when absorbed by de-rooted beans. Immediate microscopic examinations of hand-sections made from stems of de-rooted plants after absorption of acid fuchsin showed that the flow of the solutions was restricted to the xylem vessels. These observations seem to indicate that the mobility of calcium ions in the xylem vessels of bean plants is increased by the passage of these ions through the roots.

Iron chelates have been found in exudates from soybean[4] and tobacco[5] plants; it was therefore suggested that chelated iron is the form translocated in intact plants. The effect of bean roots on the mobility of calcium ions in the xylem may also result from the binding of these ions to organic ligands during permeation of the roots, and thus translocation in the xylem as metal organic calcium compounds. This hypothesis seems to be confirmed by further experiments, the results of which will be published in detail elsewhere.

RADIOBIOLOGY

Roles of Phosphate and Respiration in Nuclear Damage in Irradiated Rat Thymocytes

THE highly radiosensitive thymic lymphocyte (or thymocyte) suffers true physiological death shortly after irradiation with relatively low doses of X-rays. The most striking symptom of radiation damage is the loss of nuclear structure (pycnosis); the prominent chromatin granules and threads of the interphase nucleus disperse and form a structurally homogeneous basophilic mass[1].

The development of nuclear homogeneity is prevented, or reduced, by the inhibition of respiration either with inhibitors such as cyanide and high concentrations of nicotinamide, or by incubating the irradiated cells in an anaerobic environment[2,3]. Changing the phosphate concentration of the medium also has a profound effect on the post-irradiation rate of nuclear homogenization[1,4]. This communication describes the relationships between respiration rate, phosphate concentration and nuclear structural homogenization (pycnosis). It also presents evidence to support the hypothesis that nuclear homogenization is caused by phosphate.

Thymocytes (from 1-month-old Sprague–Dawley rats) were suspended in a glucose-phosphate medium buffered at *p*H 7·2 with *tris* (hydroxymethyl) aminomethane. Phosphate was added in the form of sodium monohydrogen phosphate, and variation of its concentration required that the concentration of sodium chloride also be varied to keep the total Na^+ concentration at 130 m.equiv./l.; the rate of nuclear homogenization is strongly influenced by the concentration of sodium ions[1]. This medium and the method of preparing thymocyte suspensions have already been described in full[1,2,4,5].

Thymocyte suspensions were irradiated at 37° C with 1,000 r. (at 100 r. min^{-1}) of 250-kV X-rays produced by a Seifert 'Isovolt' X-ray machine. After irradiation, 2 ml. samples were removed from the suspensions (containing about 1×10^8 cells/ml.) and placed in respirometer flasks. After irradiation, oxygen consumption was measured for 2 h with a Warburg constant volume respirometer. The gas phase in the flasks was air. The cells were then fixed in neutral formalin and stained with Delafield's haematoxylin according to the method developed by Whitfield *et al.*[1].

The relation between respiration rate and nuclear homogenization was determined by suspending irradiated cells in medium containing 15 mM sodium monohydrogen phosphate and varying their respiration rate by incubating them at various temperatures from 25° to 37° C. The rate of nuclear homogenization was very sensitive to changes in the respiration rate between 8 and 24 μl. oxygen consumed per 10^8 cells/h (Fig. 1). When the oxygen consumption fell below 8 μl./10^8 cells/h, the development of nuclear homogeneity was completely inhibited.

Therefore, when the phosphate concentration is constant, the rate of nuclear homogenization is determined by the respiration rate. However, experiments with 2,4-dinitrophenol clearly showed that respiration itself was not directly responsible for the nuclear changes. When dinitrophenol was added to cell suspensions (in 15 mM phosphate medium; incubated at 37° C) at a concentration

of 10^{-4} M immediately after irradiation, there was no inhibition of respiration, but the development of nuclear homogeneity was strongly inhibited. For example, the respiration rate in the presence of dinitrophenol was 24·1 μl. oxygen/10^6 cells/h while in the control it was 20·6. However, dinitrophenol reduced the percentage of cells with homogeneous nuclei 2 h after irradiation from the control value of 25·0 per cent to 1·9 per cent. Higher concentrations of dinitrophenol (5×10^{-4} and 10^{-3} M) halved the respiration rate and inhibited nuclear homogenization.

Concentrations of dinitrophenol which do not inhibit respiration inhibit the active transport of inorganic phosphate[6]. Because active transport of phosphate into cells and mitochondria is driven by respiration[7,8] and the post-irradiation rate of nuclear homogenization is strongly affected by the concentration of inorganic phosphate in the medium[1,4,5], it is very likely to be the phosphate which is somehow responsible for the nuclear changes. Respiration would influence nuclear changes only indirectly by way of its role in active transport of phosphate.

To relate the respiration and phosphate effects, we incubated irradiated cells at 37° C in media containing various concentrations of sodium monohydrogen phosphate. Raising the concentration of sodium monohydrogen phosphate from 0 to 2·0 mM increased the respiration rate (Fig. 2*A*), but there was no change in the rate of nuclear homogenization (Fig. 2*B*). However, the rate of nuclear homogenization was directly and linearly proportional to the phosphate concentration between 2·0 and 30·0 mM while the respiration rate remained essentially constant (Fig. 2*A* and *B*). Therefore, it is probable that phosphate is directly responsible for nuclear homogenization.

On the basis of cytological[1,4,5,9] and biochemical[10–13] observations, we have already suggested[1,2,5] that nuclear homogenization in irradiated thymocytes arises from a phosphate-induced separation of the chromatin-condensing histones from the deoxyribonucleic acids of the nucleoproteins which constitute the chromatin. It has, in fact, been clearly and directly shown that phosphate compounds are responsible for structural homogenization in isolated nuclei[9,12].

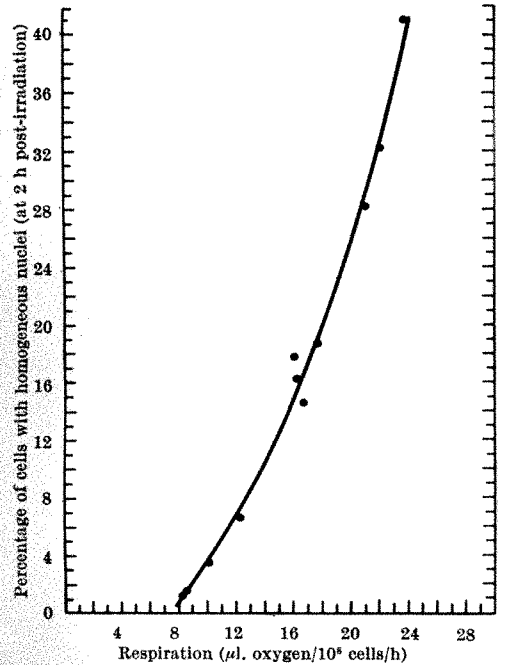

Fig. 1. Relation between the rates of nuclear homogenization and respiration in irradiated cultures of rat thymocytes. The respiration rate was varied by incubating the cells at different temperatures (25° – 37° C)

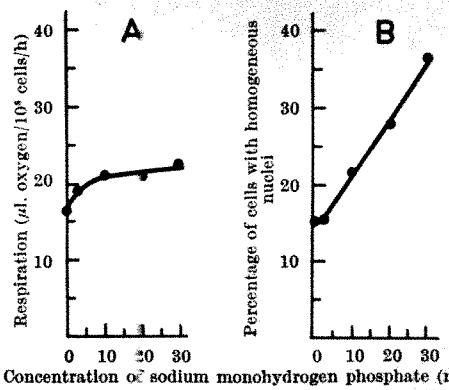

Fig. 2. Effect of varying the phosphate concentration in the culture medium on (*A*) the respiration rate and (*B*) the rate of homogenization of nuclear structure in populations of irradiated rat thymocytes

A satisfactory explanation of the present observations could therefore be formulated in the following way. During the first hour after irradiation, respiration[2] and phosphate uptake[14] proceed normally; however, the ability of the irradiated nuclei to combine inorganic phosphate with adenosine diphosphate to form adenosine triphosphate is impaired or inhibited[14,15]. For this reason, free phosphate accumulates and releases the histones from the irradiated, and thus unstable[16], deoxyribonucleoproteins of the chromatin aggregates. Therefore, variation of the respiration rate affects the post-irradiation development of nuclear changes indirectly by way of a change in the amount of phosphate which is drawn into the cell during the first hour after irradiation.

Strontium-90 in Finnish and some Imported Cereals during the Harvest Period 1963–64

MILK and cereals provide the major part of the calcium, and consequently of the strontium-90, in the Finnish diet. According to the statistics of the Food and Agriculture Organization[1], the contribution of cereals to the calcium supply is calculated at 6 per cent; this is much less than the corresponding figure for milk, 87 per cent. However, the ratio of strontium-90 to calcium is so much greater in cereals than in milk that the cereals approach milk in importance as a supplier of radio-strontium, especially in a country like Finland, where no calcium is added to cereals.

Samples of wheat and rye from the 1963 harvest (harvest period 1963–64, the main part being consumed during 1964) were delivered by the State Grain Storage

from four storage sites (Districts Nos. 1, 2, 3 and 4). District No. 1 is an area which contributes about 80 per cent of all Finnish wheat production, and nearly half the rye production. The proportion of wheat from District No. 2 is about 6 per cent. Districts 3 and 4 represent only local production in a narrow area. The State Grain Storage also collected the samples of imported cereals; these samples were taken from cereals imported during the winter 1963–64—their histories are unknown apart from their countries of origin, namely, the U.S.S.R., the United States, Canada and Argentina.

The determinations were made in respect of whole grain and flour. The flour was separated in a laboratory mill with a yield of 55 per cent for wheat flour and 80 per cent for rye flour. The analyses were made as double determinations. 1 kg of flour and 0·5 kg of whole grain were taken for each determination. The analytical method used, with some modifications, is given in ref. 2. The yttrium daughter of strontium-90 was precipitated as oxalate, and the radioactivity was counted in an anti-coincidence β-counter, of which the background was about 0·7 c.p.m. and the efficiency about 50 per cent for yttrium-90. The chemical yield of strontium was determined with an atomic absorption spectrophotometer, and the yield of yttrium determined gravimetrically.

It can be seen that there is a distinct difference between the strontium-90 activities of the Finnish and the imported cereals. The reason for this is not clear, as the histories of the imported samples are unknown. These may be from the harvests of earlier years. If this were the reason for lower levels of activity, they should have been harvested in 1961 or earlier—Finnish cereals of the 1962 harvest[3] were of appreciably higher activity than the imported material of 1963–64 examined in this investigation. When the levels of activity of the 1963 Finnish harvest are compared with the Danish results from the same year, it is found that the level of strontium-90 in Danish wheat is very similar to the activity found in the Finnish wheat; the mean level of strontium-90 in whole grain according to the Danish determinations[4] was 846 S.U.—the corresponding Finnish value was 890 S.U. In the Danish rye, on the other hand, the strontium-90 content was appreciably higher than in the Finnish: 1195 and 637 S.U. respectively. The West German results from 1962 (ref. 5) are also rather similar to the corresponding Finnish figures for the same year. Thus, at least so far as the neighbouring countries are concerned, the contamination of cereals is rather similar to that

in Finland, and it seems probable that the reason for the lower levels of contamination of the imported cereals depends not so much on a difference in location but rather on a difference in the time of harvesting.

We thank the State Grain Storage for the important contribution it made to this investigation in collecting the samples.

ENTOMOLOGY

Chromosome Numbers of some Psocid Genera (Psocoptera)

PSOCID chromosomes have been studied by Boring[1], who has described in detail the behaviour of the chromosomes of *Cerastipsocus venosus* (Kolbe) during meiosis in spermatogenesis. The chromosome number for this species of the family Psocidae was established as $2n = 16 + 1$ in the male. We have examined testis squash preparations of a number of Hong Kong species, both in order to verify Boring's description and interpretation of the mechanism of sex determination, and also to establish the chromosome numbers of representatives of as many genera and families as possible.

Specimens of twenty-one species, representing seventeen genera in twelve families of Psocoptera, were collected in Hong Kong throughout the year. Males were used in this investigation; female oogonial meiosis and embryonic mitotic figures were attempted, but without success.

The insects were lightly etherized, and the testes were removed by dissection in 0·7 per cent sodium chloride containing a little detergent to reduce surface tension, and transferred into a drop of aceto-carmine to fix and stain for 20 min on an albuminized slide[2]. The testis squashes were made according to the method described

Table 1. DIPLOID NUMBER OF CHROMOSOMES OF VARIOUS SPECIES OF HONG KONG PSOCIDS

Sub-order	Division	Family	Species	2n in male
Trogiomorpha	Atropetae	Trogiidae	*Lepinotus inquilinus* Heyden	16+1
		Psoquillidae	*Psoquilla marginepunctata* Hagen	18+1
	Psocatropetae	Psyllipsocidae	*Psocatropos* sp.	28+1
Troctomorpha	Amphientometae	Amphientomidae	*Seopsis* sp.	14+1
Psocomorpha	Caecilietae	Caeciliidae	*Caecilius singaporensis* Enderlein	16+1
			Caecilius sp.	16+1
			Dypsocus sp.	16+1
	Homilopsocidea I	Mesopsocidae	*Mesopsocus hongkongensis* Thornton	16+1
		Philotarsidae	*Haplophallus orientalis* Thornton	16+1
	Homilopsocidea II	Peripsocidae	*Ectopsocopsis cryptomeriae* (Enderlein)	16+1
			Ectopsocus maindroni Badonnel	16+1
			Peripsocus fasciatus Thornton	16+1
			Peripsocus quercicola Enderlein	16+1
			Peripsocus sp.	16+1
		Hemipsocidae	*Hemipsocus* sp.	16+1
		Pseudocaeciliidae	*Pseudocaecilius hirsutus* Thornton	16+1
		Archipsocidae	*Archipsocus* sp.	16+1
	Psocetae	Psocidae	**Cerastipsocus venosus* (Kolbe)	16+1
			Psococerastis sinensis Thornton	16+1
			Ptycta incurvata Thornton	16+1
			Trichadenotecnum medium Thornton	16+1
			Trichadenotecnum nudum Thornton	16+1

* Boring's determination.

by Darlington and La Cour[3]. The slides were made permanent by removing the cover glass using dry ice[4].

The chromosomes of psocid spermatogonia are short and small (Fig. 1), and it was not possible to interpret their morphology from the preparations.

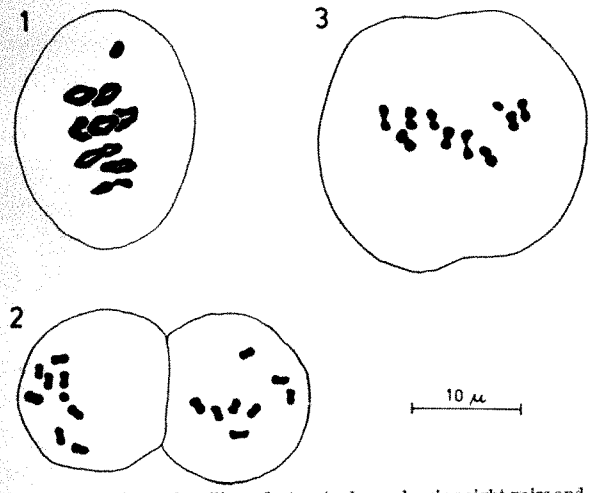

Fig. 1. (1) *Lepinotus inquilinus*, first metaphase, showing eight pairs and one odd chromosome. (2) *Hemipsocus* sp., second metaphase, showing eight chromosomes in one cell, nine in the other. (3) *Psoquilla marginepunctata*, first metaphase, showing nine pairs and one odd chromosome. All drawings to same scale

In all species examined an odd chromosome was present. Boring's interpretation of the sex-determining mechanism is therefore confirmed, and it seems likely that the *XO* type of sex determination is general in the Psocoptera.

The chromosome numbers found for the different species are listed in Table 1, in which the classification adopted is that of Badonnel[5].

The constant number of $2n = 16 + 1$ for eighteen representatives of fourteen genera of eight families of the sub-order Psocomorpha is noteworthy, particularly in view of the fact that departures from this were found in the two remaining sub-orders.

The three sub-orders are regarded on morphological grounds as fairly discrete taxonomic groups; the present investigation would appear to confirm this, although an investigation of more representatives of other families of the Trogiomorpha and Troctomorpha, usually regarded as more primitive than the Psocomorpha, is needed before any evolutionary conclusions can be drawn.

A Neural Fat-body Sheath in a Phytophagous Insect (*Carausius morosus*)

RECENT experiments have demonstrated rapid exchanges of inorganic ions and molecules between the haemolymph and the tissues of the central nervous system in insect species[1–3]. These exchanges occur through the peripheral cellular and fibrous nerve sheath, which in most species is bathed directly by the surrounding haemolymph. In certain regions, however, as in the cockroach, the surface of the abdominal nerve cord may be overlaid by patches of fat-body. Electron microscopic investigation has shown that in the cockroach the fat-body cells exhibit a very close relation with the underlying neural lamella[4]. In view of the relative permeability of the neural lamella it was suggested[4] that the metabolic processes of the fat-body cells might be intimately linked with those of the underlying perineurium, which is thought to be involved in the mobilization of nutrient substances by the central nervous system[5].

In an insect such as the cockroach, the deposits of closely adhering fat-body cells are confined as small patches on the surface of ganglia and are absent from the inter-ganglionic connectives. Recent investigation has shown that in the stick insect (*Carausius morosus*), however, the fat-body cells are modified to form a continuous sheath which completely encloses both the ganglia and connectives of the ventral nerve cord (Fig. 1). The fat-body cells overlying the ganglia tend to be thinner and less closely packed than those associated with the connectives; the continuity of the sheath is, however, maintained by the basement membrane. The ultrastructural organization of these fat-body cells is essentially similar to those found in other parts of the insect. The disposition of the fat-body cells appears to differ from that found in the cockroach ganglia in that they do not seem to be closely applied to the surface of the neural lamella. The environment contained between the fat-body sheath and the neural lamella has also been found to contain haemocytes.

The discovery of the neural fat-body sheath surrounding the central nervous system in *Carausius* is of interest in view of the extremely specialized composition of the haemolymph in this insect. The haemolymph of this phytophagous species is characterized by an extremely low sodium content, of about 20 mmole/l. (refs. 3, 6–9), and a relatively high magnesium level, averaging 60 mmole/l. The haemolymph is also relatively dilute, with a freezing point depression of only 0·53° C (ref. 8). It is possible that this neural fat-body sheath may be involved in the ionic regulation of the central nervous tissues. It might, for example, contribute to the relatively large, rapidly exchanging, sodium fraction demonstrated in a previous investigation[3]. Preliminary experiments have shown that there is a potential gradient of between 15–20 mV across the fat-body sheath, the inner surface being positive with respect to the exterior. The un-

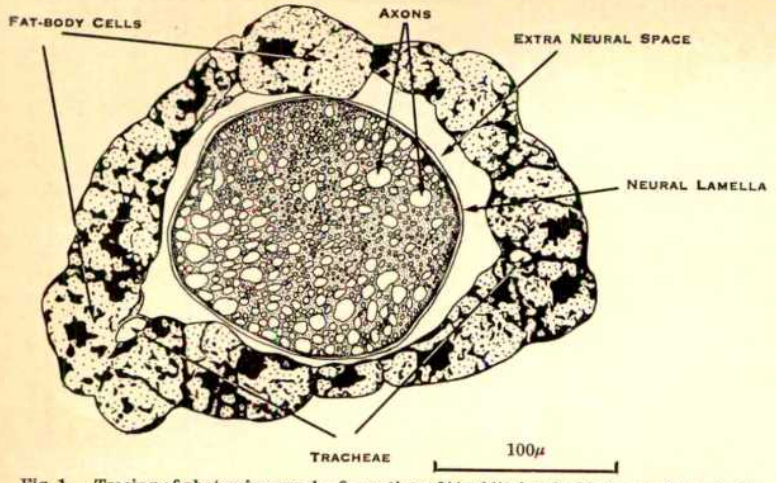

Fig. 1. Tracing of photomicrograph of a section of 'Araldite'-embedded material stained with methylene blue (ref. 10). The diagram shows the sheath formed by fat-body cells around a connective between pro- and meso-thoracic ganglia

specialized nature of the fat-body cells in this sheath is, however, difficult to correlate with any extensive role in ionic regulation. Furthermore, nervous conduction has been shown to occur in the absence of the fat-body sheath in preparations bathed in low sodium solutions.

The possibility exists that this fat-body sheath may represent a device to maintain an adequate concentration of appropriate nutrient molecules in the immediate vicinity of the nerve cord surface. Such a specialization might also be correlated with the relatively low osmotic concentration of the haemolymph in this species.

AGRICULTURE

Influence of the Level of Nitrogenous Fertilizer on the Yield and Dry Matter Content of Marrow Stem Kale at Various Sowing Dates

ALTHOUGH nitrogen appears to be the major element affecting the yield of kale[1], there is marked variation in response[2], which depends on the level of soil fertility[3], rainfall[4] and the dates of harvesting[4,5] and sowing, some authors finding a greater response to nitrogen when sowing occurs after early June[2]. It is also known that higher rates of nitrogen reduce the dry matter content[4,5] and increase the number of lodged and rotted plants in marrow stem kale, especially with very late harvesting[5]. In 1962, 1963 and 1964 the effects of nitrogen level and plant population on the yield and dry matter content of Cannells marrow stem kale were investigated in respect of varied dates of sowing and two dates of cutting (Table 1). Five levels of nitrogen were used: (*a*) no nitrogen, 1963 and 1964; (*b*) 2 cwt. nitro-chalk (21 per cent nitrogen) per acre, late sowing 1964; (*c*) 4 cwt. nitro-chalk/acre, 1962, 1963 and 1964; (*d*) 6 cwt. nitro-chalk/acre, early sowing 1964; (*e*) 8 cwt. nitro-chalk/acre, 1962, 1963 and 1964. All nitrogen was broadcast immediately after drilling and each treatment received a basal dressing of 5 cwt./acre of a 20 per cent phosphorus pentoxide compound, 20 per cent potassium monoxide compound which contained no nitrogen. Graded seed was precision drilled at 1 and 2 in. spacings in rows 8, 16 (1962) and 24 in. apart.

In all years the response to nitrogen level obeyed the law of diminishing returns, but the magnitude of the response depended on the date of sowing and declined as sowing was delayed. The actual yield of dry matter (Table 1) and the response in terms of lb. dry matter/unit nitrogen applied (Table 2) were thus very large with the early sowings and lower rates of nitrogen application, but were small or even negative with late sowing and a high rate of nitrogen application. The response to a high nitrogen level was also greater at the second harvest, except for (*e*) in 1963.

The visible effects of nitrogen on growth depended on sowing date and on season. The plots sown late and receiving no nitrogen (*a*) were affected only mildly, but the corresponding plots sown early exhibited severe symptoms of nitrogen deficiency and hard stunted growth. This effect was accentuated by severe drought in July, August and September 1964, when only 3·95 in. of rain fell, compared with 9·59 and 7·14 in. in 1962 and 1963 respectively. The 1964 drought also affected autumn growth with early sowing, when only the (*d*) and (*e*) levels of nitrogen gave any further increase in weight of dry matter at the second harvest. The yield of the (*a*) and (*c*) levels was actually lower.

Dry matter content was affected by date of sowing and nitrogen level, although differences were far greater in the stem than in the leaf. Dry matter content was greatest at the early sowings and the lowest nitrogen level, and declined as sowing was delayed and as nitrogen increased. The effect of the date of harvest depended on the season. In all sowings except the early sowing in 1964 when drought advanced maturity excessively, the content of dry matter rose substantially at the late harvest.

The effects of spacing, relative to nitrogen, were usually small and there were no significant interactions between the two. However, closer spacing gave a somewhat higher content of dry matter and a shorter crop; this is an important consideration when grazing kale.

This investigation shows that in conditions of field practice the level of nitrogen application to marrow stem kale should be related to the date of sowing so that the level is reduced as sowing is delayed. The results obtained in 1964 suggest that, in an arable rotation, 126 units is likely to be the maximum amount profitable for sowings before mid-May, while for sowings in early July the nitrogen should be restricted to about 60 units. If the crop is sown at the latter date, high levels of nitrogen result in severe reductions in the content of dry matter in the stem and reduced production of dry matter may occur in a normal year. However, in an extremely dry year higher rates of nitrogen application give a slightly better response. With late sowing it is normally better to drill closely rather than to give heavy applications of nitrogen.

We thank Dr. D. A. Boyd of the Rothamsted Experimental Station for advice on layout and analysis of data, and Mr. J. L. Jemmett of the National Institute of Agricultural Botany for the provision of facilities for estimating dry matter.

Absorption of Ethylene by Self-indicating Soda-lime

During investigations on the effects and interactions of carbon dioxide and ethylene on the physiology of flowers after cutting, an absorbent was required which would remove respiratory carbon dioxide but not ethylene. Investigations by Walls[1] and Potter and Griffiths[2] indicated that soda-lime absorbs fruit volatiles but probably not ethylene. Petri dishes of carbon dioxide absorbents (150 g) were placed in large glass tanks of capacity about 70 l., sealed, and then injected with sufficient ethylene through a rubber cap ('Suba-seal') to give a concentration of approximately 1·0 p.p.m. After allowing time for mixing, gas samples (1·0 ml.) were withdrawn at intervals and the concentration of ethylene determined by gas chromatography using a flame-ionization detector as described by Meigh[3]. The absorbents investigated were soda asbestos, sodium hydroxide, and self-indicating ('Carbosorb', BDH; 'Indicarb', Hopkin and Williams) and non-indicating soda-limes. Sodium hydroxide proved the most suitable for the investigation in hand.

However, it became clear that there was a substantial difference between the two soda-lime formulations; the self-indicating forms rapidly absorbed the ethylene, whereas the non-indicating forms did not. These observations were confirmed by repeating the experiments using small quantities of soda-lime (2·5 g) wrapped in cotton cloth inserted into winchester quart bottles. The bottles were then stoppered with 'Suba-seals' and treated with ethylene and sampled. The results are shown in Fig. 1.

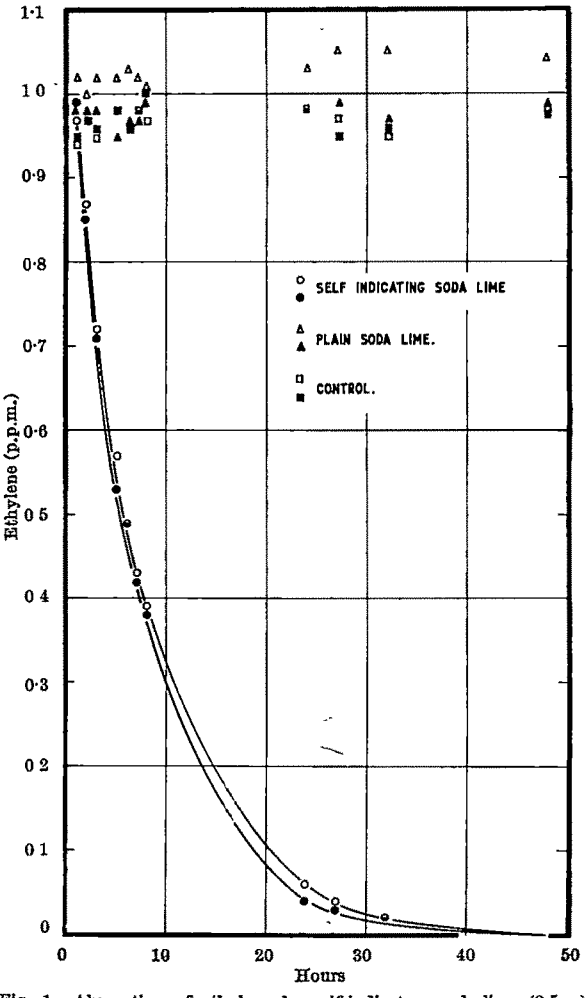

Fig. 1. Absorption of ethylene by self-indicating soda-lime (2·5 g) enclosed in winchester quart bottles. Initial concentration of ethylene approximately 1·0 p.p.m (≏2·75 μl.)

Two chemical supply houses suggested that there were no physical or chemical differences in their soda-limes apart from the addition of the indicator. One of the firms disclosed that the indicator is a manganate. A possible explanation of the phenomenon is that ethylene is oxidized to ethylene glycol, either by the manganate or by permanganate formed in the presence of carbon dioxide and water.

The important point is that recently there has been considerable interest in the physiological interaction of carbon dioxide and ethylene[4]. This is well recognized for fruits and has been reported for cut flowers[5], and is supported by work in this laboratory. Thus the observation that the commonly used self-indicating form of soda-lime absorbs both carbon dioxide and traces of ethylene at concentrations which are physiologically active may indicate a possible source of error in interpreting results in investigations in this field. The possibility of using some form of manganate for absorption of ethylene would merit further investigation.

We thank British Drug Houses Ltd. for disclosing and allowing us to publish the indicator in 'Carbosorb'.

PSYCHOLOGY

Obstacle Detection using Ambient or Self-generated Noise

OBJECT ranging can be achieved by humans using the sound reflected or scattered from obstacles. For a range of wave-lengths short compared with the size of its surfaces, and long compared with the size of the irregularities in these surfaces, specular reflexion will be obtained and an acoustic image of the sound source will be formed analogous to an optical image. In many situations, however, such as the approach of an external corner, an acoustic image may not be audible from the observer's position. In these cases sound scattered from the edges and irregularities may, or frequently may not, give the necessary warning. Such signals are, however, weak compared with those of the acoustic image with which we are chiefly concerned.

In the neighbourhood of such an obstacle, sound reaches the ears of an observer both directly and by reflexion from the obstacle, as if originating from the acoustic image. Interference between these signals introduces a series of maxima and minima into the frequency spectrum, the spacings of which depend on the path difference. A sound of broad bandwidth develops a characteristic tone the pitch of which becomes higher as the obstacle is approached[1–3]. This tone is not normally perceived as such; blind subjects generally claim to 'feel' the presence of an obstacle directly[4]. It is, however, readily perceivable under laboratory conditions.

Blind people are reputed to find difficulty in negotiating obstacles in the immediate vicinity of intense noise sources[5]. There would appear to be several reasons for this difficulty.

First, people accustomed to using self-generated noises such as their own footsteps may find such noises masked and be unaware that reflexion of the extraneous noise itself could give them the information that they require.

For people who normally make use of the ambient noise, there are some further causes of difficulty when the source is nearby. The depth of modulation of the spectrum as they approach an obstacle will depend on the relative amplitude of the direct and reflected waves. For large source distances and high reflexion coefficients, these will be nearly equal and the depth of modulation will be high. Nearby sources, however, in which the ratio of the path lengths is large may give modulation depths below threshold.

The pitch itself may also be very different from that obtaining for a distant source so that, for example, while maintaining a parallel course with a wall they would hear a changing pitch. Naturally, this could lead to the disorientation of the observer. Moreover, when the source lies between the observer and the obstacle, it can be seen that the pitch will be determined predominantly by the position of the source and very little by the position of the observer. This is, however, unimportant in practice as the reflecting surface would not be considered as an obstacle until the source of sound itself had been negotiated.

The main object of this article is to point out the potential importance of rates of change of pitch in giving additional ranging information, enabling several ambiguities to be overcome. The first of these is the occurrence of octave mismatches when this type of signal is matched in pitch to a sine wave, indicating the possibility of more than one estimate for the distance. The second arises when the source of sound lies at an angle remote from the normal to the reflecting surface, giving a higher value of pitch than for angles near the normal ($f = \frac{c}{2x\cos\theta}$ where c is the velocity of sound, x the distance of the observer's ear from the plane of the reflecting surface, and θ the angle between the source of sound and the normal to the surface).

In both cases, if pitch is defined in the musical sense of log frequency, it can be seen that the rate of change of pitch with movement of the observer, $\frac{df/f}{ds}$, will lead to unique evaluation of the distance of the obstacle in the direction of motion. Specifically, $\frac{df/f}{ds} = -\frac{1}{s}$ regardless of the angle of approach; so that the motion required to change the pitch by a given small amount is a direct measure of obstacle distance. This will, of course, be true only if the distance of the source from the surface is large compared with that of the observer. For distances that are comparable, the expression for the path difference is more complex; but, as before, the rates of change can be calculated by differentiating this. Despite the apparent complexity of this expression, the rate of change of pitch tends toward the simple value given above as the obstacle is approached.

It would seem then that, although a blind man must inevitably encounter difficulty and disorientation in the neighbourhood of a sound source, nevertheless if he is prepared to carry on his original course the appropriate ranging information will reappear and become more definite and more accurate as he gets nearer to the obstacle.

At higher speeds of travel, greater distances will be covered before the observer can come to a halt. The higher speeds, however, will also lead to greater rates of change of pitch with respect to time or conversely to a greater distance at which a predetermined rate of change is achieved.

As the rate of change of pitch is proportional to velocity, and inversely proportional to distance in the direction of motion, it follows that once a certain critical value of rate of change of pitch has been reached, the observer, whatever his velocity, will have a constant time, T, before collision if he maintains this velocity. An experiment of Leonard and Wycherley[6] gave stopping distances proportional to speed up to 5 m.p.h., at about 1 ft./m.p.h. (0·7 ft./ft./sec). The critical value for rate of change for this subject would therefore be about 2 octaves/sec, giving him 0·7 sec before collision if he takes no avoiding action or, assuming uniform retardation, 1·4 sec to stop.

The human auditory system is likely to be particularly sensitive to rates of change of this order, as they lie well within the range of rates encountered in the rise and fall of the formant frequencies of speech. It is interesting to note that, in the case of the cat, cortical neurones have been found that respond only to certain ranges of changing pitch[7]. Although the frequencies are much higher than can be perceived by humans, the rates of change concerned are comparable (1–5 octaves/sec).

Furthermore, most subjects have expressed the opinion that the pitch of this type of signal is much more readily perceived when it is changing.

It would appear that our auditory system and possibly those of some animals are well suited to the problems of detection and avoidance of obstacles.

I thank the Science Research Council for supporting this work.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, July 13

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (at University College, Gower Street, London, W.C.1), at 2.30 p.m.—Symposium on "What are the Criteria by which the Content of Sixth Form Mathematics Syllabuses should be Judged?"

BRITISH INTERPLANETARY SOCIETY (in the Botany Lecture Theatre, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Academician A. A. Blagonravov and Mr. S. N. Vernov (U.S.S.R.): "The Soviet Space Programme".

Monday, July 18—Friday, July 22

ROYAL MICROSCOPICAL SOCIETY (at Imperial College, London, S.W.7), at 10 a.m. daily—Conference on "The Role of the Microscope in Scientific Investigation".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

JUNIOR LECTURER (graduate with medical or science qualifications in pharmacology, biochemistry or physiology) IN PHARMACOLOGY—The Registrar, King's College (University of London), Strand, London, W.C.2 (July 11).

LECTURER IN EXPERIMENTAL PHYSICS—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey (July 12).

EXPERIMENTAL OFFICER (graduate in geology, physics or chemistry) IN THE DEPARTMENT OF GEOLOGY, to take charge of and operate the X-ray laboratory, including scanning electron probe microanalyser and X-ray diffractometer—The Registrar, The University, Leicester (July 14).

LECTURER IN THE DEPARTMENT OF CIVIL ENGINEERING—The Registrar, The University, Liverpool, quoting Ref. CV/118/N (July 15).

LECTURER or ASSISTANT LECTURER (with a good honours degree in an appropriate subject and experience in the field of either experimental pharmacology or biochemical pharmacology) IN PHARMACOLOGY in the School of Pharmacology—The Registrar, Bradford Institute of Technology, Bradford, 7 (July 15).

SENIOR DEMONSTRATOR (graduate, preferably with a higher degree and research experience in industry, a university or government research establishment) IN THE SCHOOL OF PHYSICS, to undertake original research in collaboration in one of the research groups operating in the School of Physics and to take an active part in the undergraduate and postgraduate teaching programmes—The Registrar, The University, Newcastle upon Tyne, 2 (July 15).

SENIOR LECTURER (medically qualified) IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Liverpool, 3, quoting Ref. CV/119/N (July 15).

ASSISTANT LECTURER IN MATHEMATICAL LOGIC AND THE THEORY OF PROBABILITY IN THE DEPARTMENT OF HISTORY AND PHILOSOPHY OF SCIENCE—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (July 18).

DEMONSTRATOR (preferably with a special interest in taxonomy or ecology) IN THE DEPARTMENT OF BOTANY—The Registrar, University College of Wales, Aberystwyth (July 18).

LECTURER or ASSISTANT LECTURER (graduate in fuel science or technology, chemical engineering, physics or physical chemistry) IN THE DEPARTMENT OF FUEL SCIENCE, The Houldsworth School of Applied Science—The Registrar, The University, Leeds, 2 (July 18).

LECTURER (with a special research interest in genetics) IN THE DEPARTMENT OF BOTANY—The Deputy Secretary, The University, Southampton (July 18).

LIBRARIAN (graduate with a professional qualification in librarianship, and appropriate senior experience)—The Secretary, Royal College of Advanced Technology, Salford, 5, Lancs, quoting Ref. LY/19 (July 18).

TECHNICIAN IN THE ELECTRON MICROSCOPE LABORATORY at the Hammersmith Annexe, working mainly in the fields of biology and polymer physics—The Superintendent of the Physics Laboratories, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (July 18).

ASSISTANT LECTURER or LECTURER (with a good honours degree and experience in the fields of digital computers and electronics) IN THE DEPARTMENT OF ELECTRICAL AND CONTROL ENGINEERING—The Academic Registrar (LFG), Battersea College of Technology, London, S.W.11 (July 22).

LECTURER or ASSISTANT LECTURER (with good qualifications in astronomy with some research experience, or qualifications in mathematics or physics with experience in astronomy) IN ASTRONOMY—The Secretary, University College, Gower Street, London, W.C.1 (July 22).

ASSISTANT LECTURER (preferably with theoretical or experimental experience in plasma or laser physics) IN THE DEPARTMENT OF NATURAL PHILOSOPHY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1, quoting Ref. 27/66 (July 23).

LECTURER (with a good honours degree and professional and/or research experience) IN CIVIL ENGINEERING—The Secretary, The University, Aberdeen (July 23).

LECTURER (with qualifications in entomology and preferably research experience in ecology) IN ENTOMOLOGY at the University of Auckland, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 25).

SENIOR LECTURER, LECTURER or ASSISTANT LECTURER (honours graduate) IN MATERIALS SCIENCE/PHYSICAL ELECTRONICS; and a LECTURER or ASSISTANT LECTURER (preferably with experience in modern semiconductor circuit design) IN COMMUNICATIONS ENGINEERING—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (July 25).

CHAIR OF MATHEMATICS; and CHAIR OF PHILOSOPHY—The Registrar, University of York, Heslington, York (July 29).

SENIOR LECTURER or LECTURER (suitably qualified and interested in any of the following research topics: solid state studies, radio investigations of the upper atmosphere such as meteor distribution, auroral zone detection and studies of air-glow and of the lower ionosphere) IN PHYSICS at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 29).

TECHNICIAN (with a pass degree, A.I.M.L.T., H.N.C. or equivalent qualifications, interested in intermediary metabolism and willing to handle large farm animals) IN THE DEPARTMENT OF BIOCHEMISTRY—The Secretary, Institute for Research on Animal Diseases, A.R.C., Compton, Near Newbury, Berkshire (July 30).

LECTURERS/ASSISTANT LECTURERS (with a degree in medicine or science, suitable teaching and research experience, and preferably with a special interest in enzymology or biophysical chemistry) IN BIOCHEMISTRY at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, July 31).

MICROBIOLOGIST (with a first- or upper second-class honours degree with microbiology or bacteriology as one of the main subjects, together with research experience and preferably a Ph.D.) at the Food Research Institute, Norwich, for fundamental research concerning food spoilage bacteria—The Secretary, Low Temperature Research Station, Downing Street, Cambridge, quoting Ref. 66/2 (July 31).

READER/SENIOR LECTURER or LECTURER/ASSISTANT LECTURER (graduate in electrical engineering or any other related discipline with research experience in the field of electronic engineering) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING SCIENCE—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (July 31).

SENIOR LECTURER or LECTURER IN PREHISTORY IN THE DEPARTMENT OF ANTHROPOLOGY, University of Auckland, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 31).

RESEARCH ASSISTANT (with a good honours degree in zoology and preferably with interests in palaeontology, sedimentary petrology or structural geology) IN GEOLOGY IN THE DEPARTMENT OF BIOLOGY AND GEOLOGY—The Secretary, Norwood Technical College, Knight's Hill, London, S.E.27 (August 1)

SENIOR LECTURER (preferably medically qualified pharmacologist) IN THE DEPARTMENT OF PHARMACOLOGY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 1).

VETERINARY OFFICERS (men and women aged at least 23, M.R.C.V.S., with at least one year's appropriate postgraduate experience) with the Ministry of Agriculture, Fisheries and Food, for posts in various parts of the country—Civil Service Commission, Savile Row, London, W.1, quoting Ref. 130/66/1 (August 1).

LECTURER IN BIOCHEMISTRY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 5).

LECTURER (preferably with experience and interests in the fields of control engineering or energy conversion) IN ELECTRICAL ENGINEERING at the University of Adelaide, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, August 8).

LECTURER (preferably with several years postgraduate experience and specialized in the field of theoretical elementary particle physics, and capable of supervising M.Sc. and Ph.D. students) IN MATHEMATICAL PHYSICS at the University of Adelaide—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the University (Australia, August 8).

LECTURER (graduate of a British Commonwealth University or of equivalent status, preferably corporate member of the Institution of Mechanical Engineers, and teaching experience at university level) IN MECHANICAL ENGINEERING at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, August 15).

LECTURER or ASSISTANT LECTURER (preferably with research experience in plant metabolism including radio-tracer techniques) IN BOTANY—The Registrar, University College of North Wales, Bangor, North Wales (August 15).

LECTURER (preferably with a special interest in high energy nuclear physics) IN EXPERIMENTAL PHYSICS—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (August 15).

SENIOR LECTURERS/LECTURER IN PHYSICS in the School of Mathematics and Physics, Macquarie University, Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 26).

CHAIR OF MATERIALS SCIENCE at Monash University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Academic Registrar, Monash University, Clayton, Victoria, Australia (Australia and London, August 31).

CHAIR OF PSYCHOLOGY at the University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

LECTURER or ASSISTANT LECTURER IN THE NEW DEPARTMENT OF CERAMICS, Houldsworth School of Applied Science—The Registrar, The University, Leeds, 2 (August 31).

LECTURER (preferably with an interest in material science, physical electronics or monolithic circuits) IN ELECTRICAL ENGINEERING at the University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

SECOND CHAIR OF ELECTRICAL ENGINEERING at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

SENIOR LECTURER IN PHYSICS at the University of Cape Town, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (August 31).

SENIOR LECTURER (with wide research experience in ionospheric or radio physics) IN THE DEPARTMENT OF PHYSICS (R.A.A.F. Academy), University of Melbourne, Australia, to engage full-time in research and postgraduate training—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 3).

ASSISTANT LECTURER (with experience either in the biochemistry or reproduction in vertebrates or in mechanisms of photosynthesis) IN BIOCHEMISTRY, to participate in the teaching and research programmes of the Department—The Registrar, University of Strathclyde, George Street, Glasgow, C.1, quoting Ref. 26/66.

ASSOCIATE PROFESSOR IN THE FIELD OF MOLECULAR BIOCHEMISTRY—Prof. B. E. Conway, Chairman, Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada.

BIOCHEMIST (preferably graduate in chemistry or biochemistry) IN THE PATHOLOGY DEPARTMENT—The Group Secretary, Princess Margaret Hospital, Swindon, Wiltshire.

BIOCHEMIST (well-qualified with suitable research experience) IN THE PHYSIOLOGY DEPARTMENT to lead a small group investigating the biochemistry of the mammary gland and related topics—The Secretary, National

Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 66/N/15.

DEPARTMENTAL DEMONSTRATOR (preferably with some experience in X-ray crystallography or in physical methods of rock and mineral analysis) IN MINERALOGY—The Reader in Mineralogy, Department of Geology and Mineralogy, University of Oxford, Parks Road, Oxford.

EDITOR OF *Chemistry in Britain*—The Secretary and Registrar, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

LECTURER (preferably with the ability to assist with biochemistry) IN MICROBIOLOGY to teach the subject to university degree level—The Principal, College of Technology, Headington, Oxford.

MATHEMATICIANS to work on a wide range of problems arising from research into the utilization and distribution of electricity (topics include: arc physics, electro-chemical reaction kinetics, solid state devices, magnetism, electrical distribution systems, heat transfer, and the application of mathematics to life science)—D. C. Page, Head of Personnel Services, The Electricity Council, Research Centre, Capenhurst, Chester, quoting Ref. N/29.

READER (with high academic qualifications, together with an established record of research in an appropriate field such as vibrations, materials, applied thermodynamics or fluid mechanics) IN MECHANICAL ENGINEERING—The Academic Registrar, Hatfield College of Technology, Hatfield, Hertfordshire.

RESEARCH ASSISTANT OR EXPERIENCED SENIOR RESEARCH TECHNICIAN IN THE PHYSIOLOGY DEPARTMENT (Division of Biochemistry) for research on lipid and carbohydrate metabolism—The Assistant Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1.

RESEARCH FELLOW IN CHEMISTRY for work which will involve the application of far infra-red spectroscopy to problems in inorganic and physical chemistry, under the direction of Dr. A. Finch—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

HOW MUCH SCIENCE?

DECIDING what part of a nation's resources should be spent on scientific research and development remains unfortunately just beyond the reach of rational discussion. Though there is now a great volume of public literature on the various problems of estimating and allocating scientific resources, and though no self-respecting nation will embark on a year of public administration without some declaration of its intentions towards science, rules of thumb are still as conspicuous as more objective yardsticks in the making of scientific budgets. Recently the most familiar, and the most fashionable, of all these rules is the doctrine that total expenditure on research and development should amount to a certain proportion of the Gross National Product. In Britain, for example, this proportion is something like 2·7 per cent, and those who fashion science policy comfort themselves that this is only a little less than the corresponding proportion in the United States, and that it exceeds the percentage of the Gross National Product being spent on development in other European countries. But one nation's comfort is another's goad, and it is in this spirit that the most recent edition of the French Plan declares that expenditure on research and development must be at least 2·5 per cent of the Gross National Product by 1970.

The most obvious difficulty, of course, is that the percentage of a nation's Gross National Product being spent on research and development is only a rough-and-ready guide to the real volume of its scientific activity. Much depends, for example, on how much of the total is spent on military research and development, for in such activities it is known that qualified scientists can run through comparatively large sums of money in a year. The balance between academic and industrial research can also vary enormously within the confines of a fixed proportion of the Gross National Product, which also suggests that the use of the Gross National Product as an indicator can conceal great variations in the real volume of a nation's scientific effort—and great differences in the consequential benefits which it is entitled to expect. All this implies that yardsticks constructed from the Gross National Product have strictly limited value.

They can probably be used with confidence to suggest that nations spending a mere 0·3 per cent of their wealth on research and development are probably being too niggardly, and that nations spending—or trying to spend—30 per cent of their Gross National Product in the same way are being unreasonably ambitious. They are probably no more valuable than other indices—such as those which indicate the allocation of a nation's skilled manpower to different kinds of activities—in deciding whether the balance of activity is right or wrong. Indeed, the index based on the Gross National Product is likely to be misleading, and dangerously so, when used to suggest that all must be well with a nation's policies because the proportion of its Gross National Product being spent on research and development is such and such a percentage.

But if the Gross National Product is an insufficient yardstick for deciding science policy, what yardsticks should be used instead ? This was one of the questions implicit in the recent report of the Council on Scientific Policy in Britain, for it is plain that the Council's argument with the Treasury in the months ahead is going to depend in a crucial manner on the degree to which its claims on behalf of scientific research can be sustained by objective arguments. The question has also been raised explicitly in the United States, and one response has been the great volume of detailed study, under the National Academy of Sciences, which has now led to the publication of assessments of the various branches of science and of possibilities which the immediate future has to offer. Among these documents the report on chemistry (the Westheimer Report) stands out because of its calculation that the economic importance of the chemical industry in the United States should somehow be reflected arithmetically in the funds devoted to academic chemical research at American universities. On the face of things, this looks like the design of an objective yardstick of a novel kind, though in the event only the chemists have welcomed it wholeheartedly. In general, of course, the attempt to indicate where opportunities now exist for investing profitably in scientific research must be as much an embarrassment as a help to those who must allocate resources, for there is nothing to suggest how priorities should be decided among the possibilities which have been described.

The construction of objective yardsticks is plainly a problem of international importance. How is it to be begun ? The ideal, of course, would be some grand theory linking the investment of funds in scientific research and development with the economic value of the consequences. If only it were possible to show that a million dollars spent on research in high-energy physics must eventually result in, say, the addition of ten million dollars a year to that nation's Gross National Product, the difficulties of financing scientific research would melt away. The trouble is that the connexion between research and economic prosperity is by no means simple. Research is not always profitable. There are, for example, some circumstances in which it may be economically profitable not to carry out research but to use results obtained by other people, at least in the short run. There may also be circumstances in which a rapidly growing research programme may drain skilled people away from productive jobs, and may thus diminish a nation's productivity—in the short run, again.

The use of educational principles in constructing an objective yardstick for deciding expenditure on university research is perhaps a more hopeful possibility.

In Britain, thanks to the detailed description of the university system provided by documents such as the Robbins Report, there are good foundations for calculating how many people must be employed on science faculties at universities. For example, with an undergraduate population similar to that in 1964, and on the assumption that one undergraduate in three stays on to do research, it is easy to conclude that university research in Britain should cost something like £130 million a year, at least on the assumption that each member of a scientific faculty costs roughly £10,000 a year by the time he has been provided with a salary, somewhere to work and with adequate assistance and materials. As it happens, this figure is not very different from that which the British Government at present spends on university research, either through the grants of the research councils or by the subventions of the University Grants Committee. The immediate interest, however, is that this line of argument could in principle be made to yield a link between the nation's demand on the educational system and the cost of scientific research in the universities. It would in particular show that the greatest cost in increasing the population of post-graduate students will be that of providing the students and those who teach them with opportunities for research.

Another yardstick could in principle be designed to ensure that a nation could hold on to a certain proportion of its senior scientists. Though not enough is known about the reasons why people leave nations in Western Europe to take permanent jobs in the United States for example, there is no question that one of the decisive factors is the availability of facilities for research. It follows that a nation wishing to keep a greater proportion of its skilled people at home must spend more on competitive facilities. With persistence, this line of argument could be made to yield criteria for deciding how much money should be spent on capital equipment of various kinds. Like the educational yardsticks, those based on attempts to prevent emigration at a certain level would necessarily be incomplete. They would, however, have the advantage of being ways of linking the cost of scientific research with tangible decisions about public policy in a wider field. At a time when the gross yardsticks based on Gross National Product are evidently too crude, and when treasuries everywhere are anxious to see further growth of science justified objectively, they obviously have great value.

ELDO RECONSTITUTED

THE new agreement on ELDO (European Launcher Development Organization) reached at Paris on July 8 seems to have papered over the cracks previously apparent in the structure of that organization, at least so far as the members are concerned. At the same time, the reputation of the British Government has been saved because the new agreement, operative from January 1, 1967, ensures that the British share of the cost will amount to 27 per cent, or just about two-thirds of the original levy. The fact that the West German contribution will, in future, be the same should further help to make it appear as if the Government has been fighting for nothing but the interests of its taxpayers in the past few months. In reality, however, the so-called apogee–perigee system to which British representatives were objecting vigorously on grounds of cost only a few months ago is now firmly written into an extended programme that will run until 1970.

The heads of the agreement at Paris include a determination to extend the ELDO programme so as to make possible a stationary communications satellite system of the kind proposed by the European Conference on Satellite Communications (CETS). On to the original ELDO-*A* programme are to be grafted a number of subsidiary programmes, including some work on inertial guidance, the development of a launching site near the Equator in French Guiana (which has done little to comfort the Australians), and the development of two rocket systems to be fired at the perigee and then the apogee of an elliptical orbit so as to carry a load of as much as 200 kilograms into a stationary orbit about the Earth. It is expected that the cost of the four years of work from January 1967 will amount to 330 million dollars, or rather more than the sum that will have been spent by the end of 1966. By way of a watchdog, ELDO is to be provided with a force of financial inspectors. The central organization will in future be free to place contracts directly with potential contractors, but will have to suffer more frequent meetings of its controlling committees.

To the extent that an efficiently managed programme is better than one that is muddled, the last of this reorganization of ELDO is obviously something of a gain. Yet the suspicion remains that ELDO is awkwardly incomplete and inadequately constructed. For one thing, there is no guarantee and only a small likelihood of a commercial demand in 1970 for the kinds of communications satellites that ELDO will then be able to construct. And whatever successes the years ahead may bring, much more will be determined by what happens within the COMSAT organization in the United States, and in the development of its international links with other nations. In this sense, there is much in the view that the best insurance of European freedom in international telecommunications will be to drive tough bargains on landing rights from communications satellites—not to follow the American development of communications satellites proper. This is probably too cynical an argument, and may be wrong as well, but it would be a great mistake if the new excitement about ELDO were to blind its sponsors to the need for working out practical but permanent arrangements for European participation in international satellite communications, if necessary without the participation of European rockets.

NEWS AND VIEWS

Successful Physics

THE Institute of Physics and the Physical Society seems to have had a successful and busy year. In its annual report for 1965, the Institute says that membership increased by 1,086 to a total of 11,273 at the end of the year. This is a larger increase than in recent years, and is attributed in part to the energy which has been devoted to recruitment and in part to the introduction of the new licentiate grade of membership. The buoyant membership has been reflected in a buoyant revenue, and the Society was able to transfer more than £9,000 to its general reserve during 1965. It is proving to be particularly successful as a publishing organization and showed a surplus of some £50,000 on the sales of books and journals during 1965—a figure that should comfortably cover the cost of salaries and other overheads. Even the annual exhibition of instruments produced a cheerful surplus of more than £5,000, though in this respect 1965 was not so successful as 1964.

These surpluses are evidently not going to be wasted. During 1965, the Institute of Physics and the Physical Society finally acquired the Fulmer Research Institute and thus set up in business as a research contractor in its own right. It also provided its members with advice on what are described as "various aspects of professional conduct". Though the four documents concerned are supposed to be confidential to the membership, enquiry shows that they are concerned with the terms of employment which working physicists should be prepared to accept, the terms and conditions on which outside consultancy work should be carried out, the rules to be followed by physicists wishing to write for the Press or to appear on television, and the precautions to be taken by those about to sign contracts with publishers. Clearly, the Institute of Physics and the Physical Society now feels able to pass on to its membership some of the secrets of its own success in combining business with learning. It remains curiously anomalous that this go-ahead organization still cannot settle for one half or the other of its composite title, and cannot call itself either the Institute of Physics or the Physical Society.

World Atmospheric Study

THE meteorologists have tentatively settled on 1972 for a comprehensive study of weather patterns and their predictability in both hemispheres to be known as the Global Atmospheric Research Programme. The decision was taken at the second meeting of the Committee on Atmospheric Sciences of the International Union of Geodesy and Geophysics (IUGG) held in Geneva at the end of April. According to Prof. P. A. Sheppard of the Imperial College of Science and Technology, a member of the IUGG Committee, the aim is nothing less than an observation of the whole atmosphere up to 30 km in order to determine how far ahead—perhaps a few weeks—the evolution of weather systems can be worked out from data available at a given instant. "We see the possibility and we should try to turn it into fact."

Talk of the research programme has been in the air for the past two years. Part of the stimulus for it has been a wish to see whether the atmosphere is really determinate on larger time scales as some theories of numerical prediction now suggest. Weather satellites provide further opportunities. Because of the planning which has to be done, 1972 is the earliest year in which the experiment can be mounted. It is intended that intensive studies in that year will be well co-ordinated with the World Weather Watch being sponsored by the World Meteorological Organization. The atmospheric programme is, however, intended to be very much more complete and, indeed, it owes its existence in part to the impatience of some meteorologists with the difficulty of using the work of the World Weather Watch to make a critical assessment of the value of their theories in computer programmes.

It is probable that by 1972 there will be in operation a number of meteorological balloons, able to drift at fixed heights of up to 30 km, and equipped to transmit information by means of communications satellites. According to one plan, these balloons would be launched into eight or nine distinct levels in the atmosphere; they would be sufficiently permanent, and their spacing sufficiently close, to provide the detailed information about the free atmosphere on which accurate long-range computer forecasting must eventually be based.

Atomic Energy in Latin America

THE Organization of American States appears to be doing some constructive work at last. The Inter-American Nuclear Energy Commission of the Organization met for its sixth annual meeting in Washington, D.C., at the end of June. Five resolutions were passed encouraging research and co-operation in the economic uses of atomic power, but the Organization has not yet chosen to back these resolutions with hard cash. Before the June meeting, the approved programme for 1966–1967 provided only for the holding of a conference on radiochemistry and a special legal committee meeting. At the meeting itself, four countries pledged 35,000 dollars, including 20,000 from the United States, and other member states stated their intention to make contributions during the year. The additional funds will be used for technical conferences on radioisotopes in agriculture and food preservation, reactors for the production of electric power and water, and problems related to health and radiological protection. Some funds will also be available for assisting member states in the fields of insect control, the assessment of water resources, food preservation and the determination of soil needs. Additional funds would make it possible to expand these programmes, to implement study groups to deal with specific topics, and to initiate training programmes in accordance with interests expressed by the member states.

The meeting agreed that "the importance of these programmes may not have been adequately recognized at all stages of the budgetary process of the Organization of American States" and resolved "to recommend that the Secretary-General of the Organization give greater consideration to the growing importance of science and technology in the balanced development of the countries of the hemisphere, and particularly to more adequate support of reasonable programmes in the field of nuclear energy". The 1967–1968 budget that the meeting submitted for approval includes

68,000 dollars to support conferences, study groups, training, and assistance to member states—a slightly larger figure.

National Academy *versus* Fat

THE United States National Academy of Sciences has now published a further edition of the report of the Committee on Fats of the Food and Nutrition Board, and has in the process moved a tiny step closer to a declaration against fatty acids and phospholipids as components of human diet. Without saying in as many words that dietary fat disposes a person to atherosclerosis, the report wags a finger at diets containing excessive fat—a category which can be counted as including the American diet, with 40 per cent of its calories derived from fat. Though it lends some support to the view that there is a link between the concentration of cholesterol in the blood and the likelihood of contracting atherosclerosis, this evidence is described as "considerable but not conclusive".

On the issue of whether poly-unsaturated fats are the best fats to eat, the report comes down, without much emphasis, on the side of those who hold that margarine is better than butter. First, it acknowledges the validity of the dietary experiments which show that the substitution of "unsaturated vegetable oils for animal fats" leads to a reduction in the concentrations of cholesterol in the circulating plasma. The report goes on to argue, however, that there is no evidence to show whether some unsaturated acids are more effective than others in bringing about a reduction of plasma cholesterol, and no evidence to show which natural animal fats are most productive of high concentrations of cholesterol. There is also continuing uncertainty about the extent to which the concentration of cholesterol, as distinct from the concentration of triglycerides in plasma, or some combination of them both, may be relevant to the causation of atherosclerosis. The evidence of epidemiological studies is, at the same time, inconclusive; in some parts of the world where all the fats in diet are animal fats, the amounts of cholesterol in the blood are low. In the circumstances it is no wonder that the report comes out most strongly against over-eating as such.

Material for Materials Science

TWO new journals have stepped in to fill what they feel is a gap in the literature. The *Journal of Materials Science* and *Materials Science and Engineering* have appeared within five months of each other; the *Journal*, first published in February, states that its purpose "is to promote an inter-disciplinary approach to the study of the relationships between the structure, properties and uses of materials". The editorial staff is based in England with Prof. R. W. Cahn, professor of materials science at the University of Sussex, as chairman. The first issue of *Materials Science and Engineering* came out this May; its sub-title is "An International Journal" and its associate editors and advisory board represent the United States, Britain, The Netherlands, Germany, France, Italy, the Soviet Union, Japan, Australia, Canada, Sweden, and Argentina. Prof. Robert Madden, director of the School of Metallurgical Engineering of the University of Pennsylvania, is editor-in-chief; Dr. A. H. Cottrell is a member of the Advisory Board. Like the *Journal*, *Materials Science* "has been founded in the belief that much depends on a deeper understanding of the structure and synthesis of materials, and of their engineering application. . . . It is their [the editors and publishers] hope that *Materials Science and Engineering* will become the chosen publication medium for significant and forward-looking work in this broad field."

If these two journals are to become complementary and not merely competitive, the operative word in the above statement must be 'broad'. And from the introductory issues there is some hope that this will be the case; *Journal of Materials Science* seems to be concentrating more on the chemical properties while *Materials Science and Engineering* is placing more emphasis on physical and engineering aspects of the science.

Parliament in Britain

IN a written answer in the House of Commons on June 26 to a request for a list of advanced technical and scientific projects which Great Britain is undertaking in collaboration with European nations, Mr. G. Thomson, on behalf of the Secretary of State for Foreign Affairs, listed twenty-five projects. Three of those are under the European Nuclear Energy Agency, four under the European Space Research Organization, in addition to the Sounding Rocket Programme 1964–67, four aviation projects in collaboration with France, and two natural gas projects. The list also includes the *Vulcain* project, the European Launcher Development Organization, the European Organization for Nuclear Research, the Channel Tunnel, an Anglo–Dutch project, *Sea Dart*, an Anglo–French–German project for a lightweight jet lift engine, an Anglo–German–Canadian project for a reconnaissance drone system, the International Agency for Research on Cancer, and the Cross-Channel Current Link. There are also close relations between many British and European bodies in the field of advanced science and technology.

IN reply to questions in the House of Commons on June 28, the Prime Minister, Mr. H. Wilson, said that it was the duty of the Committees on Manpower Reserves for Science and Technology to look at the whole field, including manpower employed in defence. Although much work was due on this subject in relation to the National Plan, there was no special entry or section dealing with it. Sir Solly Zuckerman was now looking intensively at all questions arising out of the co-ordination of scientific and technological matters, and manpower was one of them. It was the Government's policy to transfer far more scientific reserves to civil purposes from defence, and the transfer of much of the Ministry of Aviation to the Ministry of Technology would further this process. Expenditure on civil research and development had increased in 2 years from £194 million to £289 million on the Civil Votes.

IN replying in an adjournment debate on water supplies for Manchester in the House of Commons on June 27, the Minister of Housing and Local Government, Mr. R. Crossman, stated that after the new Water Order at present with the printers, there would be no further abstraction from Ullswater in the Lake District, and no more artificial resources such as was

proposed for the Winster Valley. In adding that it was necessary to look at the lower reaches of the rivers in this region, he appeared to have accepted an earlier recommendation of the Nature Conservancy. Mr. Crossman went on to say that it would be sensible to rule out barrages across Morecambe Bay and the Solway Firth as sources of water supply before 1980. Mr. Crossman said also that the Water Resources Board had a Northern Committee which was assessing long-term demands and resources for the whole of the north of England, and at his request this Committee was preparing a short list of schemes for Manchester and south-west Lancashire on which urgent detailed investigations must be concentrated. This Committee was also doing the exploratory work which formerly had been left to individual water undertakers or had been neglected.

IN a written answer in the House of Commons on June 27, the Secretary of State for Education and Science, Mr. A. Crosland, listed thirty-two institutions registered by him as charities whose purposes concerned him in connexion with his general functions relating to education. The list included the Battersea College of Technology, the Bradford Institute of Technology, Bristol College of Science and Technology, Chelsea College of Science and Technology, College of Aeronautics, Institute of Electronics, Institute of Transport, Loughborough College of Science and Technology, Royal Aeronautical Society, Royal College of Advanced Technology, Salford, and Woolwich Polytechnic.

University and College News:

Battersea College of Technology

DR. P. R. DAVIS, reader in anatomy in the Royal Free Hospital School of Medicine, has been appointed to the chair of human biology.

Heriot-Watt

DR. B. GLOVER has been appointed to the chair of chemistry in succession to Prof. F. Bell.

Massachusetts Institute of Technology

GIFTS exceeding 40 million dollars have been received by the Massachusetts Institute of Technology during the past year, according to Dr. James R. Killian, jun., chairman of the Corporation. This is the largest sum ever received in one year and exceeds the total amount received by the Institute during its first fifty years. Reflecting on the growth of the Institute, Dr. Killian said that the academic staff has grown from 300 to 2,800 in fifty years, that graduate enrolment has increased 50 times, and that expenditure is 250 times larger than half a century ago.

Nottingham

PROF. A. D. M. GREENFIELD, at present professor of physiology in St. Mary's Hospital Medical School, has been appointed first dean and professor of physiology in the new University of Nottingham Medical School.

Sheffield

DR. W. GALBRAITH, at present group leader, High Energy Physics Group, Nuclear Physics Division, Atomic Energy Research Establishment, has been appointed professor of physics.

Appointments

PROF. K. DUNHAM, at present professor of geology in the University of Durham, has been appointed director of the Institute of Geological Sciences in succession to Sir James Stubblefield.

DR. D. W. KENT-JONES has been appointed chairman of the Council of the British Industrial Biological Research Association, in succession to Sir Owen Wansbrough-Jones.

DR. S. Q. DUNTLEY has been appointed president of the Optical Society of America to fill the unexpired term for 1966 of the late Dr. Van Zandt Williams.

Announcements

AT the ordinary meeting of the Royal Society of Edinburgh on July 4 the following were elected honorary fellows of the Society: PROF. P. M. S. BLACKETT, emeritus professor of physics in the University of London; DR. F. H. C. CRICK, member of staff of the Medical Research Council Laboratory of Molecular Biology; SIR PETER MEDAWAR, director of the National Institute for Medical Research; LORD TODD OF TRUMPINGTON, Master of Christ's College, Cambridge; PROF. F. BLOCH, Department of Physics, Stanford University; PROF. K. KURATOWSKI, Faculty of Mathematics and Physics, University of Warsaw; PROF. J. MONOD, Faculty of Science, University of Paris at the Sorbonne; DR. T. B. NOLAN, formerly director, United States of America Geological Survey; PROF. L. C. PAULING, Santa Barbara, California; ACADEMICIAN N. N. SEMENOV, director of the Institute of Chemical Physics, Moscow.

AT the annual general meeting of the Institute of Physics and the Physical Society on July 5, the following were elected to honorary offices and as members of the Council: SIR JAMES TAYLOR, president; DR. J. V. DUNWORTH, vice-president; P. T. MENZIES, honorary treasurer; DR. R. PRESS, honorary secretary.

AT the annual meeting of the Board of Trustees and the members of the Corporation of the Woods Hole Oceanographic Institution held during June 22–23, the following were elected officers of the Corporation: P. M. FYE, president of the Corporation; N. B. MCLEAN, chairman of the Board of Trustees; E. D. BROOKS, JUN., treasurer.

MR. C. COCKERELL has been awarded the gold Albert Medal of the Royal Society of Arts for 1966, in recognition of his work in connexion with the technical development of the hovercraft.

THE eighth international conference on "Semiconductors" will be held in Kyoto during September 8–13. Further information can be obtained from Dr. M. G. Hatoyama, The Research Institute of Sony Corporation, c/o Japan Physical Society, P.O. Box 28, Hongo Post Office, Tokyo.

AN international symposium on "Atherosclerosis and Reticulo-Endothelial System" will be held in Como during September 8–10. Further information can be obtained from Prof. R. Paoletti, Institute of Pharmacology, 32 Via Vanvitelli, Milan.

THE ninth international Congress of Internal Medicine will be held in Amsterdam during September 7–10. Further information can be obtained from the Secretariat of the Congress, c/o Holland Organizing Centre, 16 Lange Voorhout, The Hague.

THE ninth congress of the International Society of Geographical Pathology will be held in the State University at Leiden during September 7–10. Further information can be obtained from the Secretariat of the Congress, c/o Holland Organizing Centre, 16 Lange Voorhout, The Hague.

A SYMPOSIUM on "Synthesis" will be held by the Organic Division of the Chemical Institute of Canada at the University of Alberta, during August 31–September 2. Further information can be obtained from Dr. F. W. Bachelow, Symposium Secretary, C.I.C., Department of Chemistry, University of Alberta, Calgary, Alberta.

THE third international congress of psychosomatic medicine on "The Psychosomatic Approach to Fatigue" will be held in Paris during September 15–18. Further information can be obtained from the Société Française de Médecine Psychosomatique, Hôpital Cochin, 27 rue du Faubourg-Saint-Jacques, Paris 14.

THE inaugural meeting of the new Radiochemical Methods Group of the Society for Analytical Chemistry will be held jointly with the Microchemical Methods Group at the University of Kent, Canterbury, during September 16–17. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

A TWO-DAY meeting, organized by the Mass Spectroscopy Group, will be held in the University of Birmingham during September 14–15. Further information can be obtained from R. M. Elliott, Associated Electrical Industries, Ltd., Scientific Apparatus Department, Barton Dock Road, Urmston, Manchester.

THE seventh international Machine Tool Design and Research Conference will be held in the University of Birmingham during September 12–16. Further information can be obtained from the Organizing Secretary of the Conference, Department of Mechanical Engineering, The University, Edgbaston, Birmingham 15.

A CONFERENCE on "Electrical Network Theory and Design" will be held in the University of Newcastle upon Tyne during September 11–18. Further information can be obtained from Dr. A. G. J. Holt, Department of Electrical Engineering, Merz Court, The University, Newcastle upon Tyne 1.

A CONFERENCE on "Instrumental Optics and Optical Design", arranged by the Optical Group of the Institute of Physics and the Physical Society, will be held at Chelsea College of Science and Technology during September 19–21. Further information can be obtained from the Meetings Officer, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A TWO-DAY conference on "Use of Rubber in Engineering Applications", organized by the Natural Rubber Producers' Research Association, will be held at the Imperial College of Science and Technology during September 15–16. Further information can be obtained from the Natural Rubber Producers' Research Association, 19 Buckingham Street, London, W.C.2.

THE second decennial conference on "Advances in Cell, Tissue, and Organ Culture", sponsored by the Tissue Culture Association and supported in part by the American Cancer Society, will be held at Bedford, Pennsylvania, during September 11–15. Further information can be obtained from Dr. V. J. Evans, National Cancer Institute, Bethesda, Maryland.

THE sixth international conference on "Microwave and Optical Generation and Amplification", sponsored jointly by the Electronics Division of the Institution of Electrical Engineers and the Institution of Electronic and Radio Engineers, will be held in the University of Cambridge during September 12–16. Further information can be obtained from the Joint Conference Secretariat, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

A CONFERENCE on "Radiation Measurements in Nuclear Power", arranged by the Berkeley Nuclear Laboratories of the Central Electricity Generating Board in collaboration with the Institute of Physics and the Physical Society, will be held at Berkeley during September 12–16. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE annual meeting of the Conference on Electrical Insulation of the National Academy of Sciences–National Research Council will be held in Pocono Manor, Pennsylvania, during October 4–5. Further information can be obtained from Mr. D. W. Thornhill, Staff Executive, Conference on Electrical Insulation, National Academy of Sciences, 2101 Constitution Avenue, N.W., Washington, D.C.

CORRESPONDENCE

Independence for Universities

SIR,—Much of your leader of July 2, 1966, is timely and will find support in the universities. A few points call for comment, however.

The main point which will not find support is the suggestion that the vice-chancellors must represent the universities in the outside world, unless all you mean by that is that, in a given area, it is the local vice-chancellor who will be the main P.R.O. for his university. It is undoubtedly time that there was a body which could state the case for the universities, and this body should contain representatives of the committee of vice-chancellors as top administrators and of my Association as the actual teachers who bear the brunt of work-pressures with inadequate facilities in too many cases. At the moment anyone, whether he be malicious or well-intentioned, can make any criticism of the universities without drawing an official comment or explanation: this is sheer folly on the part of the universities, in my view. The fact remains, however, that the committee of vice-chancellors alone can never speak for the universities, nor would they claim to do so. Many apparently administrative matters are in the last resort dependent on academic decisions and the voice of the academic should be clearly heard in any public pronouncements.

May I add a few other points briefly? The 'really big' university, if that means the American-type mammoth organization, presents major problems of student/staff relations in the context of the British concept of university education. This Association did, it should be noted, submit to the Robbins Committee that there was room for some large universities in our system, but may not have meant by 'large' what you have in mind. As for the staff/student ratio, this does in fact differ very much from faculty to faculty and from subject to subject.

You raise a most important question at the end of the article. Robbins estimated the need for university places on the basis of student demand, because that was the only basis sufficiently documented at the time—and that is still largely true to-day. That student demand and national needs must sooner or later be reconciled is obvious, and my Executive has promised to prepare and submit to the University Grants Committee at a later date some observations on this and on possible methods of reconciling them. The main problem may be to avoid suggesting to the unfortunate sixth-former that he may be directed to study a subject which he has no desire to study. Much long-term planning (and publicity) is required to avoid universities and schools reacting to trends in such a way as to produce permanent imbalance of need and demand.

Yours faithfully,

AND

DR. R. LANGRIDGE†
Children's Cancer Research Foundation, Massachusetts, and Harvard Medical School, Boston

THIS article presents a preliminary account of X-ray diffraction studies of helical RNA molecules and of how they crystallize. The results lead to suggestions of how helical regions in RNA molecules may play an essential part in protein synthesis.

The first diffraction patterns of RNA were obtained by Rich and Watson[1]. These patterns were not very well defined but suggested that RNA had a helical structure with some resemblance to that of DNA. Improved, semicrystalline patterns (Fig. 1) were obtained by some of us[2] from yeast RNA which was first believed to be intact transfer RNA but which was later shown by one of us to be fragmented RNA[3] probably of ribosomal origin[4]. The conclusions drawn from these patterns were that there are strong similarities between the helical structure of RNA and the *A* conformation of double-helical DNA, and that the helices are very similar in all kinds of RNA. By analogy with the *A* DNA structure and because there was a faint 2·5 Å reflexion on the meridian or close to it, the internucleotide spacing was taken as 2·5 Å. The helix-pitch varied from 28 Å to 30 Å as the humidity varied from 66 per cent to 92 per cent, implying eleven to twelve nucleotide pairs per helix turn. The base tilt (angle between the normal to the base-pair plane and the helix axis) appeared to be about 20°. Much more accurate and detailed structure analysis became possible when Langridge and Gomatos[5] obtained crystalline diffraction patterns from reovirus RNA. Their preliminary analysis[5] indicated that the RNA helix might be ten-fold (that is, with ten nucleotide pairs per helix turn) with internucleotide spacing of $3{\cdot}05 \pm 0{\cdot}05$ Å and base tilt of 10–15°. Similar results were obtained by Tomita and Rich[6] with wound tumour virus RNA and by Langridge *et al.* with *MS*2 virus replicative intermediate RNA[7]. The present, more extensive, analysis of reovirus RNA patterns shows that an eleven-fold helical model (base tilt 17°) is in as good agreement with the data as a ten-fold model (base tilt 11°).

It appears that viral RNA has two crystal forms, which we call α and β. RNA diffraction patterns of α-type (Fig. 2) have already been published[5,6] and indexed[6]. The β-form obtained by one of us (R. L.) with reovirus RNA (Fig. 3) has crystalline perfection approaching that of DNA (Langridge and Gomatos, to be published). Recently, using rice virus RNA, similar α- and β-patterns have been observed and analysed[8]. (We thank Prof. M. Tsuboi for kindly showing us his results before publication.) There is no appreciable difference between the overall diffraction intensity distributions in the crystalline patterns of α- and β-RNA and in the less-well-defined patterns of fragmented yeast RNA. This shows that the helical structure is, within small limits, the same in all three cases. We give here a preliminary account of quantitative diffraction data obtained in two dimensions from the yeast RNA patterns and in three dimensions from α and β reovirus RNA patterns. The molecular packing in RNA crystals is more complicated than for DNA and the analysis required to determine the crystal structure and the precise molecular conformation is more elaborate than that previously applied to fibre diffraction patterns. Preliminary molecular models derived from these data are described. In fibres of α- and β-RNA, the molecules are

† Present address: Department of Biophysics, University of Chicago, Chicago, Illinois.

arranged in groups of three which appear to be the same in both cases. We find many indications that hydrogen bonds hold the molecules together in these groups. We suggest the possibility that such hydrogen bonds may be involved in the interaction of transfer RNA (*t*RNA), messenger RNA and the ribosome.

Analysis of the Diffraction Patterns of Fragmented Yeast RNA

Densitometry of the pattern shown in Fig. 1 gives the X-ray intensity data shown in Fig. 4. The lattice is hexagonal with three molecules passing through the unit cell at positions $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$, $(\frac{2}{3}, 0, \frac{2}{3})$, $(0, \frac{2}{3}, 0)$. The crystallinity is optimum when the fibre humidity is between 75 per cent and 92 per cent; at 75 per cent the unit cell dimensions are $a = 40{\cdot}7 \pm 0{\cdot}2$ Å, $c = 29{\cdot}0 \pm 0{\cdot}2$ Å, the c axis being in the helix axis direction. Because of disorder, the outer parts of the pattern consist of continuous diffraction. Measurements of this part were related to those of the sharp spots in the inner part by a procedure[9] applied to DNA patterns. As a result, curves were derived of the scattered intensity from a single molecule (Fig. 4).

When the relative humidity surrounding the RNA fibres is increased the fibre swells and the separation between molecules increases. The resulting considerable variations of intensity of the 110 and 220 reflexions show that the molecular scattering curve passes through zero at $R = 0{\cdot}05$ Å^{-1} and $0{\cdot}10$ Å^{-1} approximately, as is the case for *A* DNA[10].

Preliminary molecular models. The similarity of the diffraction patterns of helical RNA and *A* DNA strongly suggests that the RNA helix is basically like that of DNA[2]: it consists of two anti-parallel polynucleotide chains joined by Watson–Crick base pairs, a conclusion supported by the base ratios of the viral RNAs[13,14]. A series of maxima and minima on the scattering curve on the equator (including the zeros referred to in the previous paragraph) and on the second layer line shows, as for *A* DNA, that the phosphate and sugar groups in RNA are both at a radius of about 9 Å[10]. When molecular models are built and adjusted to fit the X-ray data (using procedures already described[11]) it becomes clear that the middle of the base-pairs is displaced about 5 Å from the helix axis and that the phosphates in the two chains almost superimpose when viewed parallel to the helix axis.

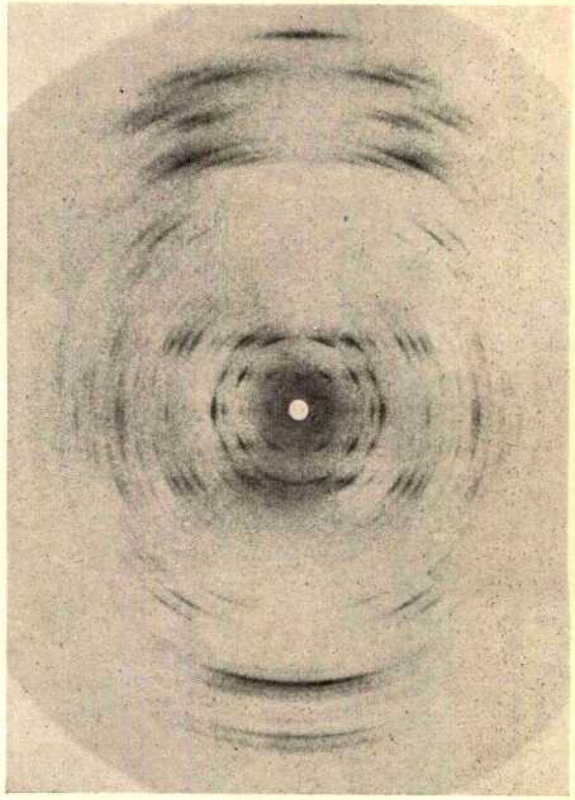

Fig. 3. Diffraction pattern of reovirus RNA (prepared by Dr. P. J. Gomatos), β-type fibre at 76° to X-ray beam. 75 per cent relative humidity. Obtained at Children's Cancer Research Foundation by R. Langridge

Because the upper layer lines of the fragmented yeast RNA pattern are diffuse it is not possible to derive unambiguously from the pattern the number of nucleotide pairs per turn of the helix. It was first suggested[2] that the number lay between eleven and twelve (depending on the relative humidity) and that the base tilt was about 20°. The crystalline reovirus RNA patterns were much sharper; and the fact that on the tenth layer line there was a reflexion which appeared to be meridional strongly suggested that there were ten nucleotide pairs per turn[5,6], and preliminary consideration of models suggested[5,6] that the base-pairs were tilted at 10°–15°. However, when we built various types of models we discovered, rather to our surprise, that very similar intensity distributions could be produced with different degrees of twisting and extending of the helix. Except for the meridional reflexions, the effect of changing the helix twist could largely be

compensated by changing the tilt and position of the bases. It is true that the meridional reflexion appeared on different layer lines for different twists, but it was not strong. Unless a meridional reflexion is strong, it cannot reliably be used to identify the number of residues per helix turn because we cannot safely assume that all the unit cell contents are in a regular helix. For these reasons and because the observed reflexion on the tenth layer line is not unambiguously meridional, the number of nucleotide pairs per turn could not be established with certainty. Nevertheless, the allowed variation of helix twist is small enough for the relative arrangement of the atoms in each nucleotide to be determined to within a few tenths of an Ångström. In this sense the conformation of the molecule is already fairly well defined. Fig. 5 shows a preliminary ten-fold model built on the basis of the fragmented yeast RNA data (and taking into account the published analysis[5,6] of α-RNA crystalline patterns and the general appearance of the unpublished reovirus β-pattern obtained by one of us (R. L.)), and an eleven-fold model developed during the present analysis of crystalline reovirus RNA data. Comparison of observed and calculated diffraction is shown in Fig. 4.

The free OH group. One feature of the RNA models is of special interest. Although helical models can be constructed with the ribose OH hydrogen-bonded to another part of the same molecule, so far we have not succeeded in building a model of this kind which is both stereochemically satisfactory *and* compatible with the X-ray data. Therefore, although not yet firmly established, it appears very likely that the OH does not form intramolecular hydrogen bonds. As a result, the OH is free to form external hydrogen bonds. Such bonds to phosphate groups on other RNA molecules could influence crystallization of helical RNA, as will be discussed later.

If the ribose OH hydrogen were to form a hydrogen bond within the RNA helix this would provide an explanation, which is otherwise so far lacking, of why RNA double helices are stable at higher temperatures than DNA double helices of equivalent base composition[15]. The present work concerns RNA structure in the solid state; we cannot exclude the possibility that the RNA helix in dilute solution (when its stability is assessed) contains intramolecular hydrogen bonds and that when the RNA solution is concentrated the helical conformation alters reversibly and intermolecular hydrogen bonds form.

The Crystalline Virus RNA Patterns

Three-fold arrangement of molecules. The best-defined diffraction patterns were obtained by one of us (R. L.) from reovirus RNA prepared by Dr. P. J. Gomatos[5]. One of the α-patterns measured (Fig. 2) has been published[5]. The β-pattern is shown in Fig. 3.

Both types of patterns can be indexed on hexagonal lattices:

for α, $a=b=43{\cdot}9\pm0{\cdot}2$ Å, $c=30{\cdot}0\pm0{\cdot}2$ Å (at 75 per cent relative humidity);

for β, $a=b=39{\cdot}8_7\pm0{\cdot}1_5$ Å, $c=29{\cdot}9_5\pm0{\cdot}1_5$ Å (at 75 per cent relative humidity).

The α-lattice is very similar to that already derived for wound tumour virus RNA[6]. The fact that the lattices are hexagonal suggests that the contents of the unit cells have trigonal or hexagonal symmetry. The intensity relations described below are consistent with this symmetry and support its assignment. The intensities exclude the possibility that the RNA molecule itself has three-fold symmetry. Therefore, because the unit cell is too small to accommodate six molecules, it appears that it has passing through it three molecules related either by a triad axis, or by a screw triad. Intensities were measured with a densitometer[11].

When the α- and β-patterns of reovirus RNA are carefully indexed special intensity relations become apparent. These are of key importance because they reveal the nature of the molecular packing and thus enable one to compare the observed diffraction intensities with those calculated for a given molecular model. The relations also show that only ten-fold and eleven-fold models need be considered.

Allowing for the form of the scattering curve for a single molecule, and particularly bearing in mind where the curve falls to zero, the intensities follow the rules:

When $l=0$, or 3 (for the inner part of the pattern) and when $l=5$, 8, for α, in the main, reflexions with both h and k even are strong and others weak; for β, reflexions with $h-k=3n$ are strong and others weak.

When $l=1$, 2 (for the inner part of the pattern) and when $l=7$, 9, for α, in the main, reflexions with both h and k even are absent and others present; for β, reflexions with $h-k=3n$ are weak and others strong.

The rules arise as follows. Assume that the unit cell contains three right-handed ten- or eleven-fold helical molecules. The diffracted amplitude from one molecule is given by the sum of Bessel function terms[12]. For the inner part of the pattern ($l=0$–3) only the Bessel function terms with $m=0$ (see ref. 12) are appreciable. When l is not much different from 10 or 11, only the terms with $m=1$ are appreciable (for our models this applies for $l=5$–11). The Bessel function terms from each of the three molecules interfere to give the various $F(hkl)$. Let the jth molecule be at position (ax_j, by_j, cz_j) in the unit cell. First let us consider the equator ($l=0$). It may readily be seen that when $x_j=y_j=\frac{1}{3}$ (as for some forms of DNA[9]) the intensity rules are $h-k=3n$ strong and $h-k\neq3n$ absent. For β-RNA the $h-k\neq3n$ reflexions are not absent, but are weak; this shows that $x_j\sim y_j\sim\frac{1}{3}$. The α-RNA rules apply when $x_j\sim y_j\sim\frac{1}{2}$.

Considering other layer lines, if it is assumed that the Bessel function terms with $m=0$ need only be considered when $l=0$, 1, 2, 3 and those with $m=1$ when $l=7$, 8, 9, it may be shown that the observed rules apply only for

three right-handed ten-fold helices related by a left-handed screw triad axis or for three eleven-fold helices related by a triad axis. Nine-fold and twelve-fold helices are excluded. These deductions can be made because in much of the pattern one set of Bessel function terms only is appreciable. When more than one set is appreciable (that is, on outer parts of layer lines) intensity rules are complicated.

The molecular packing and identity of molecular triads in α and β. The molecular packing is defined by the molecular dimensions, the dimensions of the molecular triad, its orientation in the unit cell and the orientation of the molecules in the triad. The geometry of the packing is essentially the same for both α- and β-crystals, but they differ in the value of x (see Fig. 6) which is about $\frac{1}{2}$ in α and about $\frac{1}{3}$ in β. In β-RNA the molecules are approximately hexagonally close packed. α-RNA has a surprising feature: there are large 'holes' in the structure—the structure may be regarded as approximately hexagonally close packed, with one quarter of the RNA sites occupied only by water and ions. Values of x, probably accurate to within 0·01, can be obtained from the diffraction data by least-squares analysis. This requires that a molecular model be assumed. However, the value of x was insensitive to the model chosen: in β-RNA a ten-fold model gave 0·360 and an eleven-fold gave 0·365. The value for α-RNA was 0·46. It was assumed that the triads were oriented so that, in both crystals, molecules lay on the unit cell edges and the short diagonal. That this was correct was confirmed by varying the triad orientation.

It is noteworthy that the molecular triads in the α- and β-crystals appear to be identical: although the values of a and of x are different for the two structures, the dimensions of the triads are the same, and there is good evidence that the orientation of the molecules is the same. This orientation was determined by comparing the agreement between

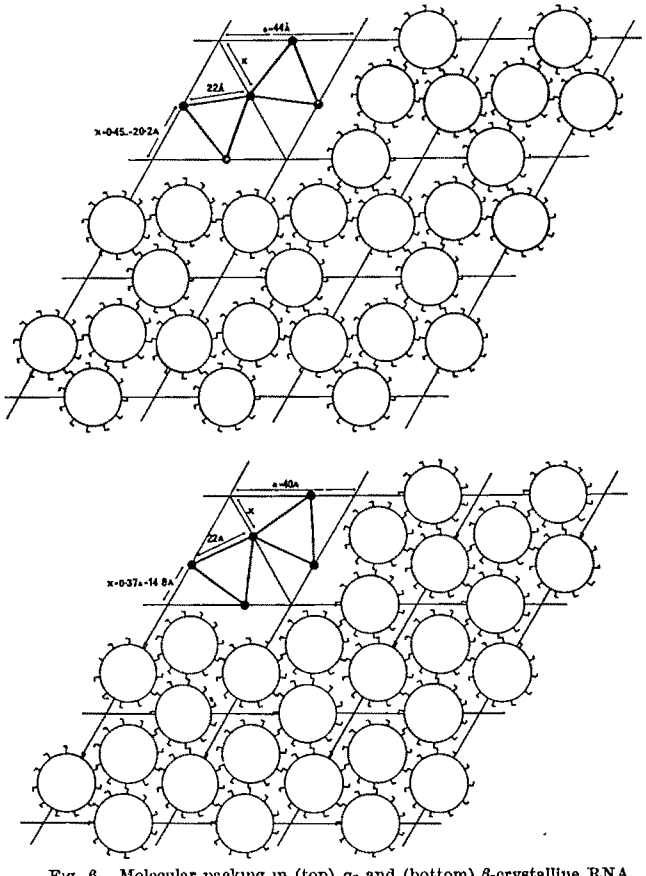

Fig. 6. Molecular packing in (top) α- and (bottom) β-crystalline RNA structures. Vacant sites may be seen in the α structure. The molecules are shown as eleven-fold

observed and calculated diffraction intensities (as measured by conventional crystallographic residual) for different molecular orientations. With an eleven-fold model the agreement varied markedly with orientation and the best orientation was defined within a few degrees for both α and β. For the ten-fold model the measure of agreement for both α and β varied little with orientation and therefore the best orientation was poorly defined. The best agreement which could be obtained for the ten-fold model in both α and β was slightly inferior to that obtained with the eleven-fold model. The difference was not sufficient to exclude the possibility that an improved ten-fold model could be built with better agreement than that obtained by an eleven-fold model.

In addition to the identity of the molecular triads in α and β, the crystals exhibit another special feature—one which may provide a clue to the origin of the two crystal forms. If an eleven-fold molecular model is assumed, it follows from the values of x established for both α- and β-RNA that every molecule in both crystal forms makes identical contacts with each of its four nearest neighbours. This equivalence of contacts is possible only for triadic arrangements where the triads are arranged so that the molecules lie on the unit cell sides and on minor diagonals where the values of x are related to the number of molecular residues per helix turn. A similar equivalence would occur for ten-fold helices only if x were 0·50 in α-RNA and 0·41 in β-RNA. It thus appears that only an eleven-fold helical RNA molecule gives the same contacts throughout both α and β crystals.

It was hoped that consideration of interatomic distances between molecules in close contact in α- and β-crystals might enable one to choose between ten-fold and eleven-fold models. Neither, however, could be eliminated. Intermolecular interatomic distances were calculated as a function of molecular orientation. The stereochemically permissible orientations (assuming normal van der Waals radii) were in agreement with those derived from the X-ray data for both ten-fold and eleven-fold helices.

Fourier synthesis. Fourier studies, particularly difference syntheses of the c-axis projection, were made using phases derived from both molecular models. The molecular orientation previously determined for the eleven-fold model was confirmed, but in some of the Fourier maps for the ten-fold model discrepancies persisted of a kind which suggested that no ten-fold model might be acceptable.

Is the RNA helix ten- or eleven-fold? The main reason for thinking that the helix might be ten-fold is that there is a fairly strong reflexion on the tenth layer line on or close to the meridian in both α- and β-patterns. Furthermore, the distribution of intensity on the seventh, eighth, ninth and tenth layer lines of the RNA patterns closely resembles that on the ninth, tenth, eleventh and twelfth layer lines of the pattern of the complex of polyinosinic and polycytidylic acids (poly I : poly C)[16] (also Langridge and Chamberlin, in preparation). The twelfth layer line of the poly I : poly C pattern is closely meridional and the helix is twelve-fold. It may be valid to compare corresponding parts of the diffraction pattern of a twelve-fold helix with that of a ten-fold. In the present case, such a comparison indicates that the RNA helix is ten-fold. However, we have shown that, if the helix is ten-fold, a screw triad axis must relate three molecules (though this cannot be proved exactly) and, as a result, the meridional (0,0,10) reflexion, due to the helices, on the tenth layer line must be absent. If a meridional reflexion is present it must be produced by some part of the structure other than the ten-fold helical molecule, (that is, ions, water, or perturbation of the helices) and, moreover, by a part of the structure which is not operated on by the screw triad axis (the same is true for a meridional reflexion on the second layer line of some α-patterns). A ten-fold helix could give (1,0,10) diffraction which would be difficult to distinguish from the true meridional (0,0,10),

because the patterns are not sufficiently well defined. While it does not appear that an unperturbed eleven-fold helix can give diffraction on the tenth layer line as close to the meridian as is observed (allowing for disorientation), a perturbed eleven-fold helix (as discussed later) could do so.

Other considerations relevant to the question—is the helix ten- or eleven-fold ?—may be summarized as follows. If the overall agreement between observed and calculated diffraction intensities is considered, there is no clear preference for the eleven-fold model. However, the geometry of the α- and β-crystals is neatly explained if the helices are eleven-fold but not if they are ten-fold. If one accepts the idea that RNA molecules should crystallize with only one intermolecular stereochemical relation between molecules in contact, then the structure must be eleven-fold and not ten-fold. However, such an argument cannot be relied on to establish the structure. To do this it is very desirable to obtain X-ray diffraction data of still higher resolution than those described here.

Hydrogen bonding in the RNA crystallites. The viral RNA crystallizes in forms more complicated than those of DNA. Intermolecular hydrogen bonding could be responsible for this. Calculation of interatomic distances between neighbouring molecules shows that, for both ten- and eleven-fold models, hydrogen bonding is likely. Because the positions of atoms may be in error by 0·2 Å or more, the results cannot be interpreted very strictly. However, they show that with eleven-fold helices oriented as indicated by the α and β X-ray data, two hydrogen bonds per helix turn between two molecules are possibilities. The distance between the relevant oxygen atoms of the ribose OH and phosphate groups is correct (~2·7 Å) for hydrogen bonding. Non-bonding atoms are in contact but not too close. By varying the orientation of the molecules by an amount within the error of the X-ray determination, one OH direction may be made to lie along one hydrogen bond. There is a deviation of 60° for the other. (Hydrogen bond angles were derived by Dr. J. H. Venable.) With a ten-fold model the situation is much the same. It does not seem possible to adjust a regular helical model so that the deviations from linearity of both hydrogen bonds are reduced to reasonable values, that is, less than 20°. We are, therefore, at present investigating the possibility that the RNA helix is distorted slightly by the hydrogen bonding. Reasonably linear hydrogen bonds could be achieved if the sugar phosphate chains in the region of the hydrogen bonds were displaced (~1 Å) in a direction parallel to the helix axis. Systematic distortions of a regular eleven-fold helix could also result in meridional diffraction on $l=10$ and broadening of the transform peaks on $l=7$, 8 and 9, as observed.

Possible Biological Implications

Study of the RNA crystallites in the fibre specimens suggests that helical regions of RNA molecules join together in a specific way by hydrogen bonding from a ribose OH group of one helix to a phosphate group of another. There is no direct evidence from the diffraction patterns of fragmented RNA that the molecules are hydrogen bonded together. However, the peaks on higher layer lines (particularly on $l=8$) are broadened as in the crystalline reovirus patterns. As already discussed, peak broadening could result from distortion of the regular helix. If this were so, it could be argued that distortion was unlikely to occur unless there were specific intermolecular interactions as in α- β-RNA. We will briefly discuss possible roles of this hydrogen bonding in protein synthesis. Specific attachment of a *t*RNA molecule to a ribosome carrying messenger-RNA is believed to involve Watson-Crick hydrogen bonding between the bases in the codon and in the anticodon. The RNA in intact ribosomes probably contains regular helical regions like fragmented yeast RNA helices. *t*RNA also contains helical regions. Some of the ribosomal RNA helices may be sufficiently free of protein to come in contact with the *t*RNA helices, especially when the repulsion between phosphates of the ribosomal RNA and of *t*RNA is reduced by cation concentration and presence of basic groups in ribosomal protein. Ribose OH hydrogen bonding might then occur between the helices of ribosomal RNA and of *t*RNA. Bonding of a *t*RNA molecule specific for a particular amino-acid would depend on the additional binding resulting from the codon-anticodon interaction. The inter-helix ribose OH hydrogen bonding would hold the *t*RNA molecule to the ribosome in a highly specific way; this might facilitate codon-anticodon interaction. Furthermore, ribose OH hydrogen bonding might be one of the factors involved in holding, in correct relation to the ribosome, the codon in the single-chain messenger RNA molecule. In order that inter-base hydrogen bonding should cause formation of Watson-Crick pairs and not others it may be necessary for the glycosidic bonds in each base pair to be held relative to each other at the correct angle and separation. This could be achieved by ribose OH hydrogen bonding of both *t*RNA and codon to the ribosomal RNA.

Conclusion

We find that both ten-fold and eleven-fold helical RNA models are in reasonable agreement with the X-ray data. Because these data are limited and the structures complex we cannot yet decide between the two types of model. Furthermore, our conclusion that there are hydrogen bonds between adjacent helical molecules is tentative. That these bonds exist is indicated by the following:

(1) In both ten-fold and eleven-fold models described here the ribose OH groups are not hydrogen bonded to any part of the same molecule.

(2) The distances calculated between atoms in neighbouring helices in virus RNA crystallites following derivation of the orientation of the RNA molecules in the reovirus RNA crystallites are such as to permit intermolecular hydrogen bonding.

(3) The geometry of the α- and β-crystal forms suggests that RNA helices have specific directional interaction.

If the inter-helix bonds exist, their discovery is probably the most significant part of this work. To obtain results which are more definite, diffraction patterns with still higher resolution should be obtained and analysed. The main obstacle to doing this is the lack of suitable RNA in sufficient quantities.

One of us (F. H.) held a Guggenheim Memorial fellowship at the time of the work. We thank Miss A. Kernaghan, Miss J. Graham and Mr. Z. Gabor for technical help. The work in Boston was supported by grants from the U.S. Public Health Service and National Science Foundation to R. Langridge. The reovirus RNA was prepared by P. J. Gomatos and the fragmented RNA by G. L. Brown.

BOOK REVIEWS

THE METHOD

The Methods of Contemporary Thought

By J. M. Bocheński. Translated from the German by Peter Caws. Pp. x+135. (Dordrecht: D. Reidel Publishing Company, 1965.) 18 D.fl.

In this slight volume we have everything essential for the understanding of the methods of rational thought and, moreover, completely up to date. As a subject, this is distinct from both philosophy and logic, and claims attention in its own right. Basically, methodology has not been enriched appreciably from British sources; its study and impact came largely from the Continent and the United States. The translator, Dr. Peter Caws, has produced a clear text to which he has added a few footnotes of his own, in one or two of which he has slight reservations about the original text to make. All this is to the good, resulting in a book of exceptional value, because of the author's erudition both as a historian of logic and as a teacher of wide experience. He never leaves the reader in the air, however difficult the theme may be. There are not too many examples: they occur at exactly the right place, not to make things easier, but to clinch the argument.

Before going into detail, a general point will be noticed at once, namely, that in science there is little need for a complex system of methodology; what is required is fairly obvious, and the means of obtaining it admit of little argument. In philosophy, however, method is more important, and may well determine the outcome. However, this is by no means all—the major scientific achievements of the twentieth century, the theory of relativity and the quantum theory, have thrown up problems which are fundamentally philosophical, and to advance in these fields a deliberate *methodik* is essential. Neither Prof. Bocheński nor the translator say so, but both classical thermodynamics (including Nernst's theorem) and Carathéodory's axiomatic surfaces of adiabatic isolation are in the same position; the traditional cycles are very clumsy, and the implications of the concepts of Kelvin and Clausius for a formal deductive process are still scarcely resolved.

All this renders essential a firmer grasp *au fond:* no amount of mere technological expertise will help in the least, nor will greater refinement of experimental skills, except in so far that events knowable in principle (that is, not physically meaningless, like velocities in excess of that of light) may in time become factual knowledge.

After a few pages of introduction, which are definitive for such necessary elements as terminology and so forth, *The Methods of Contemporary Thought* consists of four parts: the phenomenological method, semiotic methods, the axiological method, and reductive methods. At the end is an epilogue, containing a guide to future reading, a bibliography and a couple of indexes; everything, in fact, which a careful reader needs. At the outset, great emphasis is placed on the necessity to keep the disciplines of formal logic, methodology and the philosophy of logic separate. Confusion has arisen in the past on this score. Meanwhile, Prof. Bocheński's four divisions may be discussed in detail. The name 'phenomenology' seems to stem from J. H. Lambert's *Neues Organon* of 1764, but little of permanent moment appeared until E. Husserl first used it in an exact context, since when it has become largely the working creed of the existentialists. Methodologically speaking, this means seeing things intellectually, which lies at the root of all true cognition, the putting into practice of the German *ding-an-sich*. From the observer this demands a rigid type of contemplation, utterly devoid of any axiological content, still less of any teleological element. This does not entirely exclude value-judgments as such (as Scheler and Otto have demonstrated), but only that the basic detachment must be supreme. Incidentally, one suspects that herein lies the aesthetic appeal of phenomenology.

Husserl himself, always ready (perhaps a little too ready) to do battle with psychologism, was radical in his exclusion of knowledge by testimony, deductions, hypotheses and so forth. In a word, for him tradition was suspect, and that brought him nearly into line with a tenet already accepted some six centuries earlier when St. Thomas Aquinas gave the lowest rating to argument from human authority. It is noteworthy that in this, if nowhere else, modern thought clasps hands with the *philosophia perennis*.

We now proceed to the study of semistics, or the analysis of language Historically, this subject was known to the Stoics (next to nothing of whose contribution now exists), and to the scholastics, of whose work in this field little is known. As we regard it to-day, such learning is attributable to Charles Morris (1938). Among its conquests are acceptable solutions of several of the antimonies, including the famous paradox of the liar, a sore vexation since the time of Plato. It is now recognized that such sentences are incapable of resolution in terms of syntax alone: they entail the use of a meta-language. Why should this be? Because everything that needs to be said about a science is sayable (if at all) not in the language of that science, but in its meta-language. It is almost impossible to over-value the importance of this process. Perhaps the most telling illustration of its power is the well-known attempt of Hilbert to lay the foundation of mathematics by means of such a meta-discipline, only to be followed by Gödel's discovery of the impossibility of the completeness of an axiomatic system (for example, arithmetic), probably the greatest advance in logic since Aristotle.

This leads naturally to the consideration of the axiomatic method itself. Its history is revealed with great lucidity: Leibniz as a precursor, followed by Boole, de Morgan and others, culminating in *Principia Mathematica*. Then another leap forward, which produced results neither Aristotelian nor Stoic, namely, the many-valued logic of Lukasiewicz (1931), and the work of the intuitionists. Here occurs perhaps the only slight obscurity in the book, the 'natural logics' of Gentzen and Jackowsky, which consist of rules only. Surely, these have nothing to do with the 'natural logic' of p. 13, a naïve affair suited to the needs of elementary science. But we are not told in so many words what this is. However, an axiomatic system must be complete and consistent; the latter requires proof that no contradiction can occur: it is not enough to show that no contradiction is discoverable. Aesthetically, the urge is to reduce the number of axioms, perhaps even to one.

Finally come reductive methods, of special importance to the sciences, and again originating with Aristotle, in spite of his preoccupation with deduction. To us, the basis seems to be Francis Bacon's *tabulae*, but they were in fact scarcely such as to aid research or discovery. Broadly, with emphasis on induction, we witness the rise of natural science, and the establishment of history as a scientific activity, differing only (in principle) in the assessment of the stage at which protocol statements can be made.

In sum, this elementary treatise of Prof. Bocheński is a little masterpiece. There is no branch of learning, scientific or humanistic, into which methodology does not enter. Here is a specific contribution to the unity of knowledge.

F. I. G. RAWLINS

THEORY FOR EXPERIMENTALISTS

The Physics of Elementary Particles

By H. Muirhead. Pp. xv+737. (London and New York: Pergamon Press, Ltd., 1965.) 140*s*. net.

EXPERIMENTAL workers in elementary particle physics are almost always conscious of never having been able to devote the time they would have wished to mastering the basic theory of the subject. This is partly due to the inadequacy of the typical first degree course, which does not bring them to the stage where they can readily progress naturally to an understanding of the theory without the help and stimulus of formal postgraduate courses. Happily, these latter courses are now becoming more and more common. Also, in such a competitive and rapidly moving field where the student is invariably working in a fairly large team, there is a tendency for many students to be involved immediately in the development of advanced techniques and, at an early stage, to make an immediate contribution to an often complicated experiment, the choice of experiments being determined by the more senior members of the team.

It is therefore an event of great interest when a comprehensive treatise, written by an experimentalist for experimentalists, is published. It will be hoped that here is a book which can be used as a basis for postgraduate courses, and as a reference book by the students and indeed by their mentors. How far does Dr. Muirhead's book meet these expectations? As may be expected from the sheer size, it could certainly be called comprehensive. In addition to dealing with topics with which the fresh research student will be unfamiliar, an excellent résumé of the special theory of relativity is given and also the Euler-Lagrange equation and Hamilton's equations are derived starting from the Principle of Least Action. The bold statement of this principle, as the starting point of dynamics without further discussion, illustrates one of my main criticisms of the treatment. Other examples of an unstated axiomatic approach in which physical requirements follow from the mathematical formalism instead of determining that formalism are "Thus the invariance of the Lagrangian under gauge transformation of the first kind can lead to charge conservation", and "The linearity of the space also implies the principle of superposition. . . . This properly is of great importance in quantum mechanics". How different from Dirac! The principle of superposition is the physical reason for choosing the mathematical formalism of linear vector spaces.

Of the more difficult, less familiar parts of the theory, the author's stated intention to keep mathematics as simple as possible has not, despite some sacrifice of mathematical elegance, made for easy reading, and most experimental readers will have to work hard to master the subject. I have a slight feeling that an apparently more demanding, but more elegant approach may have been easier for the reader. This is not to imply that any effort made by the student will not be amply rewarded. I have learnt much from this book, not without some effort; the conservation of energy implies a minimum expenditure of effort to reach a given height, and free airline tickets are not easy to come by. To counteract the criticisms made above, the merits of the book should be clearly stated. Not only are there many excellent parts (Chapter 6, for example), but also the completeness of the treatment offers an excellent reference to the whole subject. Many parts are sufficiently self-contained to make for easy reference to, and brushing up of, particular topics. The book is relatively free from typographical errors, considering the size. A second edition could remove the more glaring and irritating of these and also the few examples of confusing English.

All in all, Dr. Muirhead is to be admired and congratulated on the industry and knowledge which have added such a useful volume to the literature.

E. H. BELLAMY

MODERN GAS DYNAMICS

Atomic Theory of Gas Dynamics

By John W. Bond, Jr., Kenneth M. Watson and Jasper A. Welch, Jr. (Addison-Wesley Series in Aerospace Science.) Pp. x+518. (Reading, Mass., and London: Addison-Wesley Publishing Company, Inc., 1965.) 136*s*.

IT is almost certain that a review of *Atomic Theory of Gas Dynamics* will betray, by its criticisms, the allegiance of the reviewer, for it is still usual to identify oneself by exhibiting a label of some kind, 'aerodynamicist' or 'physicist' or 'chemist' or 'applied mathematician', for example, even though such labels no longer define the occupation and interests of their owners with any degree of precision. Indeed, the book by Bond, Watson and Welch provides an illustration of the necessity nowadays for a good measure of expertise in all the disciplines mentioned here, since they have become so closely interwoven as a result of the exigencies arising, principally, from flight through the atmosphere at super- and hypersonic speeds, although, to be sure, the subject matter has many applications in other fields. The thirteen chapter headings will perhaps illustrate the point; they are, in order: "Thermodynamic Properties of a Gas"; "Shock Hydrodynamics"; "Continuum Hydrodynamics"; "Atomic and Molecular Physics"; "Equation of State"; "Kinetic Theory of Gases"; "General Theory of Transport Processes and Hydrodynamics"; "Dissociation and Ionization in a Gas"; "Kinetic Theory of Transport Processes in Multi-component Gases"; "Radiation Transport Theory"; "Opacity"; "Radiation Transport Applications"; and, finally, "Shock-Front Structure".

It is quite clearly not possible, within the compass of only five hundred or so pages, to satisfy all of the people all of the time where such a wide variety of topics is concerned. The specialist practitioner in one or other of the foregoing arts is almost sure to find some omission or imprecision in a book of this kind which will upset him, and it is sometimes necessary to exercise a more-than-average degree of tolerance in order to avoid criticizing the authors unfairly. Indeed it would be difficult to criticize those parts of the book which deal with the more physical aspects of the problem. The description of a wide variety of particle interactions and their cross-sections and of the associated rate processes constitutes a most useful and readable contribution to the subject. The same is true of the later chapters, which concentrate primarily on the problems arising in radiating gases, although, inevitably, the rapid advances being made in this area must leave the information contained therein rather dated. From my point of view, then, the exercise of tolerance was not necessary here. A mild application was required for the discussions of kinetic theory, since I felt that these were rather disjointed and would have benefited from a more unified treatment. This is especially true of the derivation of the equations of change from the Boltzmann equation. It is possible to carry this through with a very high degree of generality without ever entering into detailed discussions of the collision terms in the latter equation and without any implied restriction to binary collision processes, or implied approximation if ternary and higher-order collisions actually are involved. A matter of rather more importance is the quite unnecessary confusion of Δ, δ and d operators which

occurs in the earlier chapters. This lack of precision is also too evident to avoid comment in parts of the chapter on thermodynamics. For example, $p\delta V$ [*sic*] is only the work done in an infinitesimal expansion of the system when that work is done reversibly.

Thus far the criticisms are of a comparatively minor nature. It is when one comes to the chapters on shock and continuum hydrodynamics that the important deficiencies occur. At best these parts of the book are amateurish, at worst downright incorrect. Most especially I refer to the section on sound waves, where a particular solution of the inhomogeneous wave equation is derived on the basis of a gross confusion between what are commonly known as 'body forces' and the forces actually experienced by a body immersed in a continuum supersonic stream. The distinction between them is known to every undergraduate who has anything to do with fluid mechanics and the appearance of such an error in any text-book is unforgivable. To summarize, the present book can be read with profit for its atomic theory but can hardly be recommended for its gas dynamics. JOHN F. CLARKE

SOVIET OPERATIONAL CALCULUS

Integral Transforms and Operational Calculus

By V. A. Ditkin and A. P. Prudnikov. Translated by D. E. Brown. English translation edited by Ian N. Sneddon. (International Series of Monographs in Pure and Applied Mathematics, Vol. 78.) Pp. xi+529. (London and New York: Pergamon Press, Ltd., 1965.) 100*s*. net.

INTEGRAL transforms, as a technique for solving differential equations, are a familiar part of the education of every mathematician. The technique is only really effective for some amenable linear differential and integral equations and provided that the space-time boundary conditions of the problem are sufficiently specialized. It is not viewed with great favour by modern pure mathematicians, as it aims at producing results rather than understanding. Yet, despite these manifest limitations, it will always be studied and books about it will continue to be written, because it rapidly and elegantly yields formulae of basic importance throughout the whole of linear physics and engineering. Indeed, its theoretical foundations have recently been the object of intense study by Russian mathematicians. Operational calculus was developed systematically in the middle of the nineteenth century, and then successfully applied by Oliver Heaviside to the solution of various problems arising from electromagnetic oscillation theory. Heaviside's point of view was afterwards displaced by the integral transform methods of Bromwich (not mentioned in this book) and others. Now the wheel has turned full cycle, and, as the authors point out in their foreword, "A complete return to the original operator view-point was made by Mikusinskii. He has provided a strict operator basis for Heaviside's operational calculus without any reference to the theory of the Laplace transform. When describing his theory, it occurred to Mikusinskii to introduce different notations for a function and for its value at a given point. For instance, 2 is the number, while {2} is the function taking the constant value 2.

"The definition of convolution given in Chapter V differs from that of Mikusinskii in that there is no need to distinguish between constants and functions of a constant. Since the various transformations and calculations connected with finding the operational formulae are considerably simplified in a number of cases when the Laplace integral is used, an indication is given here of the connexion between our calculus and the Laplace transform."

This chapter, entitled "Operational Calculus", is by far the most recondite in the book, and is evidently addressed to a more exclusive audience than are the other chapters. It does, however, contain remarks on difference equations, and on differential equations with phase lag, that should be of general interest. The treatment throughout the book is fairly straightforward, though one may sometimes wonder what distinguishes a "theorem" from a "property", and why dates are mentioned in the enunciation of some theorems and not in others. Reasonable familiarity with the special functions of analysis is assumed: Bessel and Gamma functions appear without warning on page 23; Green's function appears without explanation on page 62; MacDonald's function is introduced without a definition on page 75. A number of minor errors and misprints will be spotted by the reader without difficulty.

These five chapters, taking up some 150 pages, comprise only Part I of the book. They are in effect an introduction to Part II, which is a 350-page compilation of well-classified transforms drawn up partly from existing tables and partly from the solution of concrete problems known to the authors. Most of the latter are probably unknown outside the Soviet Union. The tables are prefaced by a list of some 150 special functions encountered in the text. Russian functional symbolism is used, but differs only slightly from our own as indicated on p. 147. About 250 references are cited.

This is not a book for the beginner, or even for the amateur, but specialists should find it a mine of useful information about developments in this field.

M. A. JASWON

TECHNETIUM AND RHENIUM

The Chemistry of Technetium and Rhenium

By R. D. Peacock. (Topics in Inorganic and General Chemistry, Monograph 6.) Pp. ix+137. (Amsterdam, London and New York: Elsevier Publishing Company, 1966.) 55*s*.

The Chemistry of Technetium and Rhenium is a fascinating example of recent developments in inorganic chemistry, and the majority of the references cited at the end of each chapter are drawn from the literature of the past 15 years. Rhenium, discovered in 1925 by Noddack by means of its characteristic X-ray spectrum, is widely dispersed in nature and this factor undoubtedly delayed its discovery and impeded the study of its chemistry. In 1937 Perrier and Segre produced a radioactive isotope of element No. 43 by deuteron bombardment of molybdenum and appropriately named the element technetium. Earlier attempts to discover "primordial" technetium were thwarted by the instability of all its isotopes, although "natural" technetium-99, generated by spontaneous fission of uranium, has recently been detected. The development of large-scale nuclear reactors has produced reasonable quantities of technetium-99 as a by-product and has accordingly stimulated the investigation of the chemistry of this element.

Technetium and rhenium are transition elements *par excellence*, and show oxidation states from 0 to 7 and co-ordination numbers from 4 to 7 with a wide variety of ligands including fluoride, nitride, hydride, *π-cyclo*-pentadienyl, acetylacetonate, diarsine, triphenylphosphine oxide, cyanide and carbonyl, not forgetting some fascinating polynuclear chlorides containing metal–metal bonds.

Prof. Peacock has done justice to this interesting field with a concisely written monograph which is a mine of information and interesting to read. Following the two opening chapters on the discovery and isolation of the elements and their general and elementary properties, the descriptive chemistry of these elements is dealt with in a series of chapters on oxides, halides, cyanides, etc., and the final chapter summarizes analytical methods. For good measure there are appendixes on the laboratory handling of technetium, bibliography and further references. This method of organization seems successful,

and the subject index makes reference to particular compounds agreeably speedy. A valuable feature of this book is the critical approach adopted by the author to the material taken from the literature.

It seems a pity that with Colton's book, *The Chemistry of Rhenium and Technetium*, published in 1965, there are now two very similar books covering the same ground.

D. C. BRADLEY

GAS CHROMATOGRAPHY

Gas Chromatography 1964

Edited by A. Goldup. (Proceedings of the Fifth Symposium organized by the Gas Chromatography Discussion Group of the Institute of Petroleum held at Brighton, September 8–10, 1964.) Pp. xii+386. (London: The Institute of Petroleum, 1965.) 90*s*.

THIS is an account of the proceedings of the fifth symposium organized by the Gas Chromatography Discussion Group held at Brighton during September 8–10, 1964.

The book is on similar lines to previous volumes with the exception of an additional section dealing with the informal discussion periods which were an innovation at this symposium. The main content, however, is a collection of the twenty papers presented and verbatim reports of discussions following each paper. These papers are presented under three headings, dealing with (*a*) column design, (*b*) techniques of separation and identification and (*c*) exploitation of molecular interaction.

Apart from one paper dealing with the preparation and operation of high-efficiency columns, section (*a*) is devoted to theoretical aspects of column evaluation and design. Although bridging the gulf between theory and practice will present many formidable problems, the possibility of very-high-efficiency columns of the order of a million theoretical plates performing separations within minutes is fascinating. The theory is aimed in general at extending established principles and correlating them with practice. The non-mathematical student of gas-chromatography must sometimes be perplexed with the number of parameters required to express the theory and he is unlikely to welcome the addition to this list of a "performance parameter". This section also contains a comprehensive appraisal of packed capillary columns, a relatively new aspect of column technology.

The second section begins with a philosophical discussion of the gas-chromatographic process of separation in terms of the entropy of a hypothetical system. The remainder, in contrast, is entirely practical in aspect. For example, pyrolysis, normally a "finger print" technique, is discussed in a paper which describes an apparatus claimed to give better reproducibility than a mass spectrometer. Because of the time factor involved, normal elution chromatography is not always a satisfactory method when applied to process control, and a number of alternative techniques involving continuous sample flow through a column are discussed. Other papers include the complementary use of thin-layer chromatography and mass spectrometry. This symposium, which has always been a forum for the introduction of innovations, includes papers describing the adaptation of the flame ionization and argon detectors for monitoring the effluent of non-volatile substances in solid/liquid chromatography.

The third section on exploitation of molecular interaction is mainly concerned with the growing potential applications of gas/solid chromatography. Appreciations of present views on molecular interactions in liquids and solutions, and solid interfaces, are made, with particular reference to their application to the interpretation of gas solid chromatography. The relationship between the surface chemistry of solids and retention data is also discussed at some length. Considerable point is made that one of the great virtues of gas/solid chromatography is the stability of many of the types of absorbants over relatively wide temperature ranges. Several developments in this direction are described and the impression emerges that here there is a whole new area for research worthy of greater attention than has hitherto been given, particularly with modified types of absorbants.

The editor, A. Goldup, is to be congratulated on maintaining the high standard one has come to expect of this biennial publication. The book should be of great value both to research and analytical chemists, particularly those who wish to remain in step with developments in the sphere of gas chromatography

E. A. WALKER

A MODERN *LIBER DE ARTE DISTIL?*

Distillation

Edited by E. S. Perry and A. Weissberger. Second completely revised and augmented edition. (Technique of Organic Chemistry, Vol. 4.) Pp. xx+838. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1965.) 180*s*.

DESPITE the large number of books and papers published over the years on various aspects of distillation processes and apparatus, there is still room for works which either make an original contribution to the field or else provide a comprehensive account of the state of knowledge.

With the relatively few fundamental advances in distillation theory over the past 40 years, there has been a tendency to treat the details of the latest apparatus and techniques in some isolation, without presenting a critical appraisal of the application of theory to practical problems.

The appearance of a comprehensive work which covers the field of laboratory distillation in both its theoretical and practical aspects, and which includes a wealth of details of apparatus and operating techniques, is therefore particularly welcome.

The new edition of *Distillation*, volume 4 of the Interscience "Technique of Organic Chemistry" series, provides much useful material in addition to that given in the first edition published in 1951. This volume in its augmented form covers all aspects of experimental distillation theory and practice from laboratory to pilot scale, and not only constitutes a valuable and comprehensive handbook for all those directly involved in such experimental work but also presents an admirable and concise summary of basic distillation theory.

The contents cover basic distillation theory, with particular reference to laboratory distillation. The theoretical basis and experimental determination of vapour-liquid equilibria, apparatus and procedures for fractional distillation under a wide range of conditions from low-temperature to high-vacuum with particular emphasis in the latter case on ancillary apparatus and the special requirements of extractive and azeotropic distillation and sublimation, are all dealt with.

Of particular value are the new sections on continuous distillation, pilot plant distillation and automation in distillation.

The theoretical section, written by Arthur and Elizabeth Rose, occupies more than 200 pages and provides a thoroughly detailed account of the development of distillation theory and its application to the practical problems. Of particular importance is the emphasis on batch distillation and fractionation and the methods of determining the number and height of theoretical plates, with details of still sampling techniques, and the use of specialized test mixtures for which detailed vapour-liquid equilibrium, density and refractive index data are given. One further aspect which is dealt with and which is particularly important in laboratory work is the effect of hold-up on performance. This is of interest not only

in determining batch distillation performance but, more vitally, in the calculation of equilibration time for different types of column.

This aspect is extended to a general investigation of the effects of process variables in batch distillation and the recommendation of optimum operating conditions. It also covers the use of digital computers in calculating the separation of multicomponent mixtures. Typical of the thoroughness of this section is the comparison of the Lewis, Chilton and Colburn, Westhaven and Kuhn, the Cohen, Marshall-Pigford and Bowman equations governing the approach to equilibrium. The section concludes with an extensive bibliography.

The treatment by Deal of vapour-liquid equilibria is concise and yet contains a valuable survey of the relation between molecular structure and activity coefficients. The treatment of experimental techniques and the design of the equilibrium is still perhaps excessively brief, as is the coverage of consistency tests, which are so important in the assessment of the reliability of experimental data. Williams on the other hand gives a wealth of detail on the performance and construction of both wetted-wall, packed and plate columns and ancillary apparatus such as temperature controllers, pressure controllers and reflux dividers. The operating procedure is also covered in detail.

The section on extractive and azeotropic distillation by Carlson and Steward might have suffered from the problem inevitable in a book of this type, namely the duplication of material covered by other contributors. However, the treatment of equilibrium is still so much more comprehensive than Deal's that all one can do is to criticize the editor for the allocation of section headings. The actual techniques of extractive and azeotropic distillation are well covered, although one would like to see a more extensive list of specific solvents and entrainers and a more detailed analysis of the relative merits of the two separation systems.

The section by Tipson on vacuum distillation gives much useful information on column design and vacuum techniques including the application of mechanical stills. Perry provides a detailed account of molecular distillation which is complemented by Hecker's contribution on all aspects of the performance of the distillation apparatus and ancillaries under vacuum.

The three new sections in this edition provide a valuable extension to the literature of laboratory distillation. Continuous laboratory distillation is treated somewhat briefly by Williams but is particularly interesting despite the lack of details on reboilers, feed pumps and flow meters. Orgen's treatment of pilot plant distillation covers the sizing of plant and ancillaries and is therefore valuable in itself and also serves as an introduction to the engineering of distillation plant and thus serves as a useful bridge between chemists and chemical engineers. This is particularly important at the present time when the control of full-scale plants is changing from that of the simple physical parameters of temperature, pressure and flow to the more elaborate and challenging idea of direct control of product composition by means of chromatography, mass spectrometry and infra-red and ultra-violet spectrometry. In this area the chemists become directly involved in commercial scale processing techniques.

The final section by Williams on automation and control in distillation therefore serves as a fitting conclusion. The chemist should find the coverage of these control techniques of both interest and use. Fundamental to control is the phenomenon of the dynamic responses in fractionation columns which is also covered and is a much-needed reminder to all those involved in distillation that the operation of fractionating plant is essentially an unsteady state in stable equilibrium on which are superimposed transient responses to external conditions.

This book covers a very wide range of topics of interest and value to the worker in the field, and will certainly earn a place on his bookshelf. M. G. Royston

THE BALD FACTS

Die Menschliche Glatze im Altersformwandel der Behaarten Kopfhaut

Morphologische Studie. Von Klaus Goerttler. Unter Mitarbeit von Peter Gordel. (Zwanglose Abhandlungen aus dem Gebiet der Normalen und Pathologischen Anatomie, Heft 17.) Pp. viii+48. (Stuttgart: Georg Thieme Verlag, 1965.) 23 D.M.

This short monograph, an account of the way the "glatze" or bald pate develops during ageing, is based on a pathological investigation of 118 scalps of both sexes, classed by decade of life and ranging from birth to old age. The material was taken from several regions—top, sides and in-between—and examined not only by traditional histological methods but also by the preparation of epidermal sheets.

In the newly-born, it seems that the dermo-epidermal junction is uncorrugated, but as the lanugo is replaced by terminal hair, the interface becomes crenulated to form the pattern of the rete-pegs. This development reaches a maximum in the second and third decades, when even the hair follicles become involved in the interdigitation of dermis and epidermis. By the fourth decade there are already signs of decline in those regions which were previously most active; the hair bulbs still appear relatively strong, but the hair shafts become feeble. From the fifth decade onwards, first at the side and crown, later in the intermediate regions, the dermo-epidermal junction flattens and the hair follicles diminish and shorten. For a time the sebaceous glands resist change, or even enlarge, but ultimately they, too, succumb to ageing; only the sweat glands remain unaffected and continue to function in old age.

This work is beautifully illustrated with photographs and constitutes a classic anatomical description of the relentless ageing of the scalp, a field in which surmise has often been a substitute for evidence. A full understanding of the process in dynamic terms awaits other investigators. The prognosis may appear somewhat depressing, but a faint optimism may be engendered by the reports of Drs. Papa and Kligman of Philadelphia that, in spite of the undoubted implication of male hormones in the development of hereditary baldness, the process can sometimes be mysteriously reversed by the local application of androgens. And if the hair follicle of the scalp, of all human organs, appears to be the one least well designed for a lifetime of service, one can at least take comfort from the thought that this is but a recognition by natural selection of its vital redundancy.

F. J. Ebling

Forest and Savanna

An Introduction to Tropical Plant Ecology with Special Reference to West Africa. By Brian Hopkins. Pp. xii+100+5 plates. (London: Heinemann Educational Books, Ltd., 1965. 18*s*. net.

Dr. Hopkins devotes the first few pages of *Forest and Savanna* to an explanation of what is meant by ecology and he then gives background information about West African population, geology, soil and climate. This information is clearly set out at an elementary level and it would serve beginners at college, as well as the interested layman or others unfamiliar with the West African scene. The real meat is to be found in Chapters 3 and 4, which deal with forest and savanna respectively from an ecological point of view. They provide sufficient detail to instruct without overloading the beginner. On the other hand, as the author points out in his preface, he has in some sections reached the limit of our knowledge simply because the study of tropical ecology is still relatively neglected. Things are changing in this respect,

however, partly as a result of Hopkins's own valuable researches, and it is to be hoped that this book may hasten the progress by interesting African nationals in the subject. Conservation of natural vegetation can only be achieved effectively by those who live in the country concerned having an intelligent appreciation of the need for it. *Forest and Savanna* should have a part to play in this all-important educational aspect. In particular the fifth chapter, which deals with the relationship between forest and savanna, brings out many points concerning land management that are vital to the inter-related aspects of agriculture, forestry and conservation. Two appendixes, dealing with field methods for vegetation analysis and suggested student projects, will be of special value to the instructor. References and an index conclude this small text-book which should rapidly find an ecological niche in the curricula of school sixth-forms and first-year university courses.

F. N. HEPPER

Mathematical Analysis

Differentiation and Integration. By I. G. Aramanovich, R. S. Guter, L. A. Lyusternik, I. L. Raukhvarger, M. I. Skanavi and A. R. Yanpol'skii. Translated by H. Moss. English edition edited by I. N. Sneddon. (International Series of Monographs in Pure and Applied Mathematics, Vol. 81.) Pp. xi+322. (London and New York: Pergamon Press, Ltd., 1965.) 63*s*. net.

THIS book contains a concise account of the properties of differentiation, differentials, Riemann integration in one and several dimensions, together with implicit function theory and the effect of transformations in differentiation and integration theory. The Stieltjes integral is briefly introduced.

There are no proofs, examples, or exercises, but there are several counter-examples to show where and why the theory will not extend. This renders the book useful for reference for the non-specialist, and it might be valuable to a lecturer planning a course, but not to a student.

The fact that different authors have written different parts is apparent in an inconsistent notation. Thus, for example, $y[n](x)$ and $y(n)(x)$ are used to denote the Schwartzian derivative, and elsewhere both $y(n)(x)$ and $y^n(x)$ denote the ordinary derivative. The book concludes with useful lists of integrals, etc., and a few tables of higher transcendental functions.

R. L. PERRY

Die Tierische Zelle in Zellkultur

Von R. Schindler. (Fortschritte der Krebsforschung. Recent Results in Cancer Research, Vol. 1.) Pp. vi+88. (Berlin: Springer-Verlag, 1965.) 16 D.M.

To assess the value of cell culture in cancer research, it is clearly necessary to consider many different aspects. In the series on "Recent Results in Cancer Research", published by Springer, the author, Dr. R. Schindler, has discussed the culture of animal cells rather generally. This book deals with various culture methods, basic medium and biochemical requirements of cells, pharmacological studies, cytogenetics, specific cell functions, the mitotic cycle, effects of ionizing radiation and changes brought about by viruses. The main description of cancer cells in culture is given in the last chapter. There is an extensive bibliography of more than 700 references. The book therefore provides good background reading and a good bibliography for people interested in taking up cell culture work on cancer problems. A great deal of work has been done on cancer-cell culture—both hanging-drop cultures and cell lines in monolayer culture, and more recently in organ culture. One could wish that the author had covered these subjects in more detail. For the study of human cancer, where it is impossible to carry out experimental work *in vivo*, with one or two exceptions involving transplantation of tissues into animals, the main future is likely to lie in the use of cultures for experimental work.

A. HADDOW

MEETINGS

GEOPHYSICS AND COMPUTERS

THE Department of Applied Mathematics and Theoretical Physics at Cambridge was host from June 27 to July 5 to the Third International Symposium on Geophysical Theory and Computers, an activity of the I.U.G.G. Upper Mantle Committee.

About eighty-five attended the symposium, and more than forty papers were given, each between half an hour and an hour in length. It would be impossible to mention every paper—invidious though it is to mention particular contributions, certain recurrent new themes emerged which are specially worthy of report.

The major problem, one might say the only problem, in geophysics is that of inversion. Given a set or sets of data, what can be deduced about continuum parameters of specified regions of the Earth? And is that information a sufficient guide to the composition and thermodynamics of the region? The question of uniqueness of interpretation has until recently been treated in a rather indefinite way in seismology. Whereas it is fairly easy to show that surface observations of gravity and magnetic fields are insufficient to give unique distributions of density and magnetization beneath the surface, the uniqueness or otherwise of seismic data (which seems likely to be the principal source of information about the deep interior of the Earth for some time) is much more difficult to establish.

Prof. V. I. Keilis-Borok and two colleagues from the U.S.S.R. gave summaries of the present situation with regard to body wave travel times, where uniqueness has been a pressing problem. It is demonstrable that in the presence of a 'low velocity layer', two different subsurface velocity distributions may yield the same travel time curve. However, the situation is in practice bedevilled by the difficulties of positively identifying body wave signals on actual seismograms. A lively debate between Miss I. Lehmann (Copenhagen) and Dr. E. A. Flinn (Alexandria, Virginia) on work which the latter had presented using array processing techniques epitomized this problem. However, as Flinn and others, notably Dr. D. H. Weichert (Ottawa), Dr. E. J. Kelly (Lexington, Massachusetts) and Dr. R. A. Phinney (Princeton) showed, array processing is becoming a valuable tool in mantle and core geophysics.

The uniqueness, or otherwise, of normal mode data (from free oscillations of the Earth, Rayleigh waves and Love waves) has been an equally thorny problem. A notable paper by Prof. G. E. Backus and Prof. F. Gilbert (La Jolla, California) showed, among other things, that more than one density distribution can satisfy the same data to any prescribed degree of accuracy. This paper, with the Russian contributions, clearly showed the necessity of developing further criteria for the acceptance of Earth models.

One such consideration is seismic amplitude data, and much more reliable information about amplitude as a function of range from source is being compiled by the U.K. Atomic Energy Authority group, and was presented by Dr. A. Douglas (Aldermaston).

Another consideration is the plausibility of an Earth model on solid-state criteria. Prof. D. L. Anderson (California Institute of Technology) indicated the questions which we would wish to ask of solid-state physics, and Prof. L. Knopoff (University of California, Los Angeles) indicated the possible uses of solid-state physics in combination with seismology in the determination of reasonable composition models.

A seismological parameter of increasing importance and whose significance is still not fully understood is dissipation. There is no doubt that this too will have to be taken into account in any unified view of the Earth's structure.

Constant, or nearly constant, Q, the dimensionless attenuation, is commonly observed in laboratory tests on many materials.

Papers by Dr. E. Strick (Houston, Texas) and Dr. M. Caputo (Trieste) examined consequences of these observations. In different ways they both come to the same conclusion—that Q is very nearly frequency independent. This approach from an experimental point of view was complemented by a paper from Dr. B. M. Naimark (Moscow) in which it was shown how the effect of specific mathematical models of anelasticity on stress distributions could be calculated.

Not all the conference was devoted to seismology, however, and there were other impressive contributions. Dr. A. H. Cook (National Physical Laboratory) gave an authoritative account of the present status of gravitational potential determinations by satellite observations. There were several papers on magnetic and gravity fields and the application of computers to their analysis. Dr. N. O. Weiss (Cambridge) and Dr. M. G. Wurtele (University of California, Los Angeles) both demonstrated the power of the computer to solve problems in magneto-hydrodynamics and meteorological fluid mechanics.

D. DAVIES

NON-ELASTIC MANTLE

A SYMPOSIUM on "Non-Elastic Processes in the Mantle" was held in the School of Physics of the University of Newcastle upon Tyne during February 21–25. The symposium, which was organized at the request of the Upper Mantle Committee, was one of several to have been arranged in conjunction with the 'Upper Mantle Project', an attempt to co-ordinate internationally research on the outer 1,000 km of the Earth.

It is a good indication of the present explosive growth of seismological research and interest in the deformation of the Earth on a geological time scale that an international conference with more than a hundred participants can now be convened on such a specialized subject. As organizer of this symposium, my chief aim was to bring together physicists and mechanical engineers whose special interest is the deformation of solids and those geophysicists whose observational or theoretical interests entail some knowledge of the rheology of the mantle of the Earth. It is becoming ever more apparent to geophysicists that elasticity is only a convenient conceptual subdivision of a description of the total rheological behaviour of a material, and that it should not be given special significance. This has been obvious to solid-state physicists and professional rheologists for many years, and this remark is an indication of the need for much closer intellectual contact between these disciplines.

After an introductory lecture by Sir Harold Jeffreys on "Rheological Problems in Geophysics", the first one and a half days of the symposium were devoted to experimental and theoretical work on deformation in mineral and rock systems. Prof. P. L. Pratt (Imperial College of Science and Technology) reviewed current theories relating the microstructure of ionic solids to their plastic flow, creep and fracture. In ionic as opposed to covalent solids there is a more rapid decline with decreasing temperature of the number of slip systems, and this, together with the inhibition of dislocation multiplication mechanisms, accounts for the marked increase in brittleness of these materials at low temperatures. As the temperature is increased, the relative importance of deformation mechanisms based on diffusion processes increases and, as a result, permanent deformation occurs at very low applied stresses. A process of continuous deformation, usually referred to as steady-state creep, is observable in which hardening by deformation and thermal recovery are in a state of balance. Prof. Pratt commented that, so far as the interpretation of laboratory investigations is concerned, the transition from low temperature deformation by dislocation glide mechanisms to the high temperature thermally activated processes occurs at a temperature in the neighbourhood of 0·5–0·7 of the absolute melting temperature. (This figure may be somewhat less for deformation under low stresses applied on a geological time scale.)

Dr. Paterson (Australian National University, Canberra) discussed the general effect of confining pressure on the non-hydrostatic stress–strain relationship. He described how the different susceptibilities to such a pressure of various mechanisms of flow and fracture in a general solid can be used to elucidate the most important deformation mechanisms in at least some materials. Prof. Griggs (University of California, Los Angeles) reviewed the present evidence of weakening in rocks and minerals at high pressures by water, and described in some detail his recent experiments with Blacic on the behaviour of synthetic quartz in such conditions. Above a critical temperature, which is itself dependent on the water content (10^{-3}–10^{-1} per cent in the experiments), dislocation glide movement within the crystals appears to be enhanced by hydroxyl ions. Electron micrographs have demonstrated the generation and propagation of dislocations in the weakened quartz similar to those in unweakened quartz at higher stresses. Prof. Griggs considered that the occurrence of this and other hydrolytic weakening processes in silicates at such low concentrations of water is of considerable geophysical significance. Prof. Gordon (Yale University) reviewed the evidence pertaining to diffusional creep and, using the result that in certain circumstances these processes can be represented by a Newtonian viscosity, he described the derivation of a relationship of viscosity with depth in the mantle.

In this connexion there was a recurring debate throughout the symposium about the concentration of sources and sinks of point defects in mantle material, a quantity which enters directly into calculations of diffusional creep rates. Grain boundaries are often identified with such sources and sinks, but, judging from the discordant estimates of grain size that were made at the symposium, there is certainly a need for experimental work on high temperature, low stress creep in likely mantle material. A considerable problem here will be the acquisition of representative mantle material.

Dr. Raleigh (Australian National University, Canberra) presented papers on an experimental study of glide in olivine and pyroxene minerals, and on a study of the strength and ductility of serpentinite in a range of conditions up to 700° C and a confining pressure of 5 kilobars. In addition to a considerable weakening at temperatures exceeding 500° C, there was an accompanying increase of brittleness. It is believed that both effects are associated with the dehydration reaction, the embrittlement being due to growth of pore pressure which is known to decrease the effectiveness of a confining pressure. These experiments are thought to be of considerable significance for theories of the tectonic emplacement of serpentinites, and possibly may also bear on theories of deep earthquakes if the concept of a serpentinized oceanic upper mantle can be further substantiated.

During the session on fracture phenomena, an interesting theoretical paper was presented by B. V. Kostrov and L. V. Nikitin (Institute of Physics of the Earth, Moscow) on the equilibrium of a crack under the application of a uniform longitudinal shear at infinity in an elasto-plastic medium; the yield was determined by the Von Mises–Hencky theory. A full solution was obtained for both the pre-limiting and limiting stages of crack equilibrium and the results were compared with brittle fracture theory. It would seem that in the elasto-plastic theory it is impossible to decide whether crack propagation is unstable at stresses higher than the limiting stress.

In planning the sessions of specific geophysical interest, it was decided to consider deformations of progressively

greater period. Papers were presented by Prof. Anderson (Seismological Laboratory, Pasadena), Prof. Kovach (Stanford University) and Prof. Slichter (University of California, Los Angeles) on the observation of damping of seismic body-waves and free oscillations and their application in computing the specific dissipation function Q as a function of depth in the mantle. Prof. Orowan (Massachusetts Institute of Technology) reviewed data on amplitude and frequency dependence of the damping of oscillatory motions in solids in the light of observations of Q for the mantle obtained by various methods. He emphasized the fact that distinct physical processes are thought to be involved in damping at seismic frequencies and in viscous creep, and it is difficult to derive from seismology information about the long-term response of the mantle to non-hydrostatic stress.

Two papers by Jobert (Paris) and Melchoir (Brussels) described attempts to deduce the anelastic response of the upper mantle to oceanic tidal loads. Although regional differences have been detected which indicate non-elastic response of the crust, no data suitable for use in a model of upper mantle anelasticity have yet been obtained.

Another set of papers concerned the process of isostatic adjustment. Prof. Bott (University of Durham) emphasized the role of non-Newtonian effects accompanying adjustment, and Dr. Artyushkov (Institute of Physics of the Earth, Moscow) the great decrease of viscosity with depth in the outermost layers of the Earth. The latter can now be understood without direct appeal to partial melting in the upper mantle. Prof. V. Magnitsky (Institute of the Earth Sciences, Moscow) spoke of the possibility of accounting for the viscosities derived from post-glacial uplift theory in terms of a diffusional creep process. Dr. Crittenden (U.S. Geological Survey) described further data on isostatic adjustment from Lake Bonneville and Glacier Bay, Alaska, and emphasized that the inhomogeneity of the Earth with respect to viscosity could well explain the apparent permanence of certain topographic features and the disappearance of others.

A session of papers on the theory of mantle convection was enlivened by a vigorously critical paper by Dr. Lyustikh (Institute of Physics of the Earth, Moscow) on the shortcomings of present theories of mantle convection, and the evidence for continental drift. In particular, the simple assumptions that are made connecting surface topography and mantle convection were criticized and the blind use of spherical harmonics as an analytical tool was commented on. Prof. Knopoff (University of California, Los Angeles) described an investigation which he had made of the gravity field specifically associated with convection patterns. He concluded that there is general agreement on the magnitude of the observed departures of the geoid from a hydrostatic shape and those expected using the convection hypothesis. Prof. Orowan (Massachusetts Institute of Technology) described a theory which attempts to explain the arcuate form of certain island chains in terms of a redistribution of a sub-crustal flow and its associated stress system in the crust after an initial crustal fracture. An interesting feature of the theory is the use of the observations of hydrolytic weakening in serpentinite by Raleigh and Paterson to predict underthrusting by material on the upstream side of the fracture. If the flow of oceanic material towards continents is accepted, observed island structures in the Pacific basin are in significant agreement with this theory. Dr. Tozer (University of Newcastle upon Tyne) reported some model experiments on plane layers with internal heat generation. These show cellular flows at high values of the Rayleigh number that are greatly elongated in the horizontal direction. A ratio of horizontal to vertical length scales greater than five has been observed at values of the Rayleigh number of interest to mantle convection theorists. It was suggested that this feature overcomes objections that have been made to upper mantle convection on the grounds that the horizontal length scale is insufficient to account for continental drift. Other convection papers were presented by Dr. Oxburgh (Oxford) and Prof. Bott (Durham), who has attempted to deduce the pattern of heat flow on the Earth's external surface by a convection theory. He believes that a low heat on the flanks of oceanic ridges is a manifestation of non-Newtonian flow.

D. C. TOZER

RADIOSENSITIVITY AND REPAIR

A MEETING to consider current ideas about the mechanisms of repair of radiation damage was convened at the Vienna headquarters of the International Atomic Energy Agency during April 18–22.

The first session was devoted to repair at the chromosome level. Dr. S. Wolff (United States) reviewed evidence for the existence of repair mechanisms for radiation-induced chromosomal damage. It has been clearly established that metabolic and enzymatic activity is required for breakage and reunion, and evidence that proteins play an important part in the maintenance of chromosome integrity is increasing. Dr. J. R. K. Savage (United Kingdom), using data from fractionated dose experiments with *Tradescantia*, presented evidence that the initial decrease in exchange yield is consistent with the repair of partially damaged chromosome exchange sites to pre-irradiation sensitivity. The non-linearity of the X-ray dose-response curve for true chromatid discontinuities, and its bearing on the exchange hypothesis, was discussed by Dr. S. H. Revell (United Kingdom). Prof. H. J. Evans presented new data from dose fractionation effects in human leucocyte cultures, and challenged the classic breakage/reunion interpretation for chromosome aberrations. As an alternative hypothesis, he suggested that the observed changes are the result of "mis-repair".

There is much evidence to indicate that some genetic mutations can also be repaired, and in the second session Prof. F. H. Sobels (The Netherlands) reported some contrasting processes of post-irradiation modifications of genetic damage in *Drosophila*. After irradiation under anoxic conditions, treatment with nitrogen favours repair in mature spermatozoa as compared with treatment with oxygen. Precisely the reverse situation is obtained in early spermatids, where repair is favoured by post-treatment with oxygen. In another paper on *Drosophila*, Dr. H. Traut (Federal Republic of Germany) concluded that differential radiosensitivity during gametogenesis can be explained by metabolic repair of pre-mutational damage. Dr. S. Igali (Hungary) reported an antimutagenic effect in the bacterium *E. coli* which occurred when homologous DNA extract was present in the medium during irradiation.

In the third session, the various changes at the molecular level known to result in detectable mutation were summarized by Prof. M. Errera (Belgium), and he discussed the processes of mutation reversion and suppression on the basis of what is known about amino-acid sequences in specific proteins. Because most of the detailed knowledge of repair mechanisms has been derived from work with phages and bacteria, a number of the papers were concerned with this field. Dr. R. Devoret (France) reported some investigations of the effect of ultra-violet damage repair on the multiplication of phage λ, and he showed that the 'capacity' of the cell to support phage growth was less affected by the ultra-violet damage of the phage-synthesizing bacterial structures than by bacterial repair processes, which modified indirectly the expression of the information content carried by the phage. The genetic and enzymatic control of radiation sensitivity in *E. coli* formed the basis of a paper by Dr. A. Rörsch (The Netherlands). Five different classes of radiation-sensitive mutants are known, and these are associated with several different linkage groups on the

bacterial chromosome. He also reported details of a cell-free system for the demonstration of repair of ultra-violet-irradiated DNA *in vitro*. Dr. P. C. Hanawalt (United States) dealt with known repair/replication mechanisms in the bacterial genome. It is possible that some form of non-conservative DNA replication mechanism has a necessary function in the normal replication and transcription process, and that it may also function in the repair of a variety of defects in DNA. Repair of damage may also be related to the normal processes involved in genetic recombination, and this problem was reviewed by Dr. B. M. Wilkins (United Kingdom).

Prof. D. Shugar (Poland) outlined the fundamental chemical changes known to be induced by ultra-violet light in pyrimidine analogues and in model oligo- and polynucleotides. The processes involved in the reversal of a number of these changes are now well understood, and attempts may be made to relate them to photochemical transformations in nucleic acids. Dr. S. Robev (Bulgaria) discussed X-ray damage to some informational micromolecules. Investigations of the formation, after irradiation, of a DNA/*m*RNA hybrid indicate a similar intrinsic radiosensitivity for both molecules, and it is possible to explain many apparent differences on the grounds of the number and rapid turnover of *m*RNA molecules.

The last session of the panel took the form of a general discussion of some of the major topics which arose from the papers presented, and an attempt was made to interrelate observations at the chromosomal, genetic and molecular levels. The first question to be considered was concerned with the nature of the basic lesions in nucleic acids brought about by ultra-violet light, ionizing radiation and chemical mutagens. Work using ultra-violet light forms the current basis for the interpretation of much of the radiation chemistry of nucleic acids, and the panel emphasized the importance of pursuing comparable investigations with ionizing radiations.

The relative contributions of the various types of damage to such end-points as cell lethality and mutations were considered, and while some answers could be given for phages and bacteria, no assessment could be made for more complex systems. The panel then discussed known repair processes and how they operate. On almost all occasions, repair is of an enzymatic nature, and several genetic loci seem to be involved in its control. The DNA synthesis required in repair will occur in the absence of normal DNA replication.

Much information has been obtained from investigations of the factors which influence repair mechanisms (for example, metabolic inhibitors). In some systems these factors act by preventing the formation of enzymes required for repair, although in most cases these enzymes are already present. There is also a possibility that some radioprotective agents may exert their effects by way of promoting repair, rather than by radical scavenging.

The panel next examined models recently proposed for genetic recombination, and their possible relationships with known repair systems for irradiation damage. All these models involve single DNA molecules, and one of the major obstacles in any attempt to extend them to events at meiosis in higher organisms is an almost complete lack of information as to the fine structure of large chromosomes, which contain not only DNA but at least two types of protein and some RNA. There is increasing cytological evidence that such chromosomes are multi-strand, despite the fact that genetically they behave like a single DNA molecule.

Finally, consideration was given to radiation-induced achromatic chromosomal lesions (gaps) which appear to be completely reparable. Further progress in understanding their nature requires biochemical investigation, and in particular, whether DNA loss is involved in their formation.

MORTON W. MILLER
JOHN R. K. SAVAGE

OBITUARIES

Dirk Brouwer

WITH the unexpected death of Dirk Brouwer on January 31, 1966, the subject of celestial mechanics suffered an irreparable loss. It is almost entirely due to Brouwer, directly or through his former students, that this mainly nineteenth-century discipline has been able to meet the quite incredible demands made upon it by recent space research. In addition to his many contributions to what may be termed the classical branch of the subject, he pioneered and developed the methods of numerical integration which must still be the mainstay of current orbital calculations for artificial satellites; and he gave a completely general solution, of great practical as well as theoretical interest, of the effect of the oblateness of the Earth on the motions of satellites. Not content with his unique personal contributions, he created in 1959 an annual series of summer institutes in dynamical astronomy, supported by the National Science Foundation, from which have already come over 600 workers in this field, mainly in the space sciences.

Brouwer was born on September 1, 1902, in Rotterdam, and in due course studied mathematics and astronomy at Leiden, where he was greatly influenced by Willem de Sitter. After taking his doctorate (in celestial mechanics) he went to the United States in September 1927 with a post-doctoral fellowship for study at the University of California at Berkeley, and later at Yale. He there became research assistant to E. W. Brown, and, remaining at Yale, became in turn professor, director of the University Observatory (in 1941), chairman of the Department of Astronomy, and Hunson Professor (in 1944). He was to carry forward brilliantly the work of both his famous mentors and, moreover, to prove a worthy successor of Frank Schlesinger as director of the Observatory. Yale's traditional observational activity has been in the field of astrometry, particularly in the construction of photographic star catalogues and the derivation of proper motions. Brouwer pursued this activity with characteristic thoroughness and vigour, both scientifically and administratively. He himself developed new techniques of observation and measurement, as well as pioneering the reference system of the minor planets.

With his unique experience, Brouwer was in constant demand as chairman of or adviser to commissions and, more recently, to various ambitious projects. He served as President of Commissions 7 (Celestial Mechanics) and 20 (Minor Planets) of the International Astronomical Union; and on many special committees, such as those on astronomical constants. He was editor of the *Astronomical Journal* from 194_ and its rapid growth owes much to his influence. But, far from being overwhelmed by such administrative demands, he seemed to thrive on the additional work and responsibility.

Probably the most significant of Brouwer's many contributions to celestial mechanics are his work on planetary theory, using rectangular co-ordinates (1944); his discussion of the secular variations in the solar system (1950); his share of the numerical integration of the orbits of the five outer planets (1951); and the explanation of the "asteroid gaps" in the distribution of the minor planets (1963). But his work on astronomical constants, stretching from his completion of de Sitter's work in 1938 through the introduction of Ephemeris Time (1950) to the IAU System of Astronomical Constants in 1964 must not be overlooked.

Brouwer was a friendly and approachable man, willing at all times to discuss problems with his research associates and students, and capable of inspiring leadership; it is to be hoped that his monumental work at Yale can be continued, and even expanded, to meet still further challenges from space research, for this is surely what he would have most wished.

D. H. SADLER

ORIGIN OF ANTIBODY VARIATION

By DR. S. BRENNER and DR. C. MILSTEIN
Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

VARIATION of the structure of both κ (refs. 1–3) and λ (ref. 4) light chains of antibody molecules appears to be confined to the N-terminal halves of the proteins while the C-terminal sequences are invariant. All theories of the origin of the variation of antibody proteins must account for this remarkable structural feature of the molecules. Lederberg[5] proposed that the variety of antibodies is a consequence of a high rate of mutation confined to a few genes in the somatic line of antibody producing cells. It is generally believed that hypermutation theories are unlikely to be correct because of the difficulty of defining a mechanism which operates only on part of a gene[6]. The emphasis has therefore been placed on hypotheses which realize the observed restriction of sequence changes by postulating genetic incorporation or polypeptide fusion. Smithies[7] has proposed that the information specifying the variable region is carried by a virus which integrates into a gene determining the invariable region. In an analogous theory, Dreyer and Bennett[8] suggest that the constant region is specified by a virus or episome which is incorporated into many different genetic sites. Another suggestion is that the two halves of the polypeptide chains may be independently synthesized and then joined together by a peptide bond, perhaps by a specific enzyme[9,10]. One may generalize these and other theories by saying that two fragments of (*a*) DNA, (*b*) RNA or (*c*) protein are joined together to provide information for, or to make, the complete polypeptide chains. In addition, most of the mechanisms imply that many different genes will ultimately control the variable part of the antibody molecule.

In this article we resurrect the hypermutation theory by suggesting a mechanism which allows the mutational acts to be restricted to specific regions of a few genes. In general terms, we propose that part of the nucleotide sequence of the gene specifying the invariable region acts as a recognition site for an enzyme which cuts the DNA. During repair of this local region errors are introduced at random at a high rate to generate a large number of different sequences. There are many variants of this general hypothesis, but it is useful to examine one in detail. This is shown in Fig. 1 where we consider a gene specifying one of the light chains. The messenger RNA carrying this information will be copied from one of the chains of DNA and will therefore have the same sequence as the complementary chain. The absolute polarity is given by the direction of translation of the messenger, that is, the 5′ end corresponds to the N-terminal end of the polypeptide chain[11–13]. We assume that a cleaving enzyme recognizes the nucleotide sequence on the DNA corresponding to part of the invariable sequence of the light chain near the variable region, and cuts one of the strands of the DNA, exposing a free 3′ end. An exonuclease then degrades the DNA, exposing a stretch of the complementary strand. The gap is then repaired by a polymerase and, during this repair, errors are introduced. These could be base pairing mistakes or additions or deletions. In this particular scheme, the trimming and repair are carried out by enzymes with the same mechanism of action as exonuclease III and DNA polymerase isolated from bacteria[14–16]. Enzymes with opposite polarity, trimming and repairing from the 5′ end, have not yet been found. In the proposed mechanism the right-hand end of the variable region is definitively fixed by the point of cleavage. We do not need to postulate a specific location for the left-hand end. For example, the polymerase may displace the exonuclease when enough single stranded DNA has been generated for it to bind sufficiently strongly to initiate repair. It is therefore possible that, on the average, the repaired length may only rarely include the extreme left-hand region, and this would be reflected in the clustering of errors towards the centre of the molecule.

It is obvious that repeated repair of the region cannot in general lead to the accumulation of errors. Furthermore, while the region of the gene subject to repair corresponds to the N-terminal half of the protein, the DNA strand repaired is not the one which is copied into messenger RNA. Therefore, in order to express and stabilize the changes the cell must divide and the DNA must be replicated in the normal manner. One of the cells produced is like the original type, the other contains a mutant sequence. Repetition of the process could therefore generate a very large number of different sequences, but it is interesting to note that every sequence produced, including the primordial one, is also conserved. Exactly how many division cycles are necessary to generate the deviations in sequence would depend on the mutagenic rate of the repair polymerase.

The mutation process depends in the first instance on the presence of the cleaving enzyme, and both it and the polymerase may only be expressed at specific stages of the differentiation of antibody precursor cells. Further steps of differentiation could stop the sequence of events by destroying or inhibiting the cleaving and/or repair

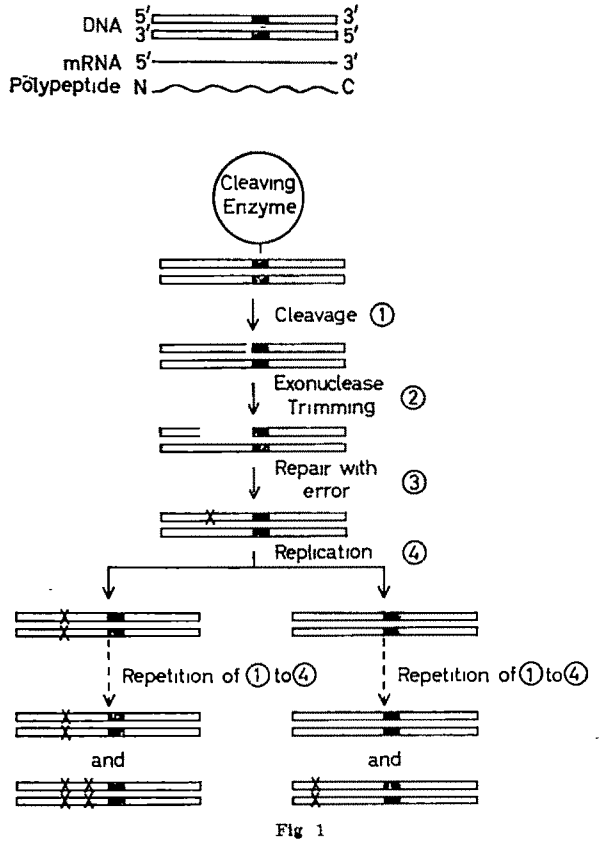

Fig. 1

enzymes. The subsequent clone produced from such a cell could therefore be genetically uniform and stable. As suggested by Lederberg[5], the immune response could involve selection of such clones by antigens.

The mechanism proposed has precedents in other biological systems. Excision and subsequent repair of DNA occurs after radiation damage in micro-organisms[17–19]. Specific recognition of DNA sequences for cleavage and chemical modification is the basis of host restriction and modification of bacterial and bacteriophage genomes[20]. Mutant DNA polymerases in bacteriophage *T4* produce high frequencies of errors[21] and an altered DNA polymerase may be responsible for the elevated mutation rate of one strain of *E. coli*[22].

We cannot propose a definitive test of this theory apart from the direct demonstration of a cleaving enzyme and a mutagenic polymerase in precursor cells, which may not be easy to do. One prediction is that the heavy chains of antibody molecules will have the same features as the L chains and, in particular, the junctional region should contain the same recognition site. We note, however, that this site must only have the same nucleotide sequence, and the amino-acid sequences of this region in H chains may not be the same as that in L chains but may be related to it by a phase shift. Unfortunately, this result, though striking, would only show that recognition occurs at the level of nucleic acid and would still be consistent with genetic incorporation models. Our main purpose in proposing this theory is to show that a mutational origin of antibody variation is consistent with the known facts and that we are not compelled to postulate more elaborate models.

Low molecular weight proteins immunologically related to the light chains of gamma globulin have been detected in normal human serum[1,2] and urine[1–7]. In contrast to plasma cell tumours of mice and man which have been shown to produce excess L chains[7], it is not certain whether the free L chains[2] found in normal individuals result from *de novo* synthesis[6] or the degradation of whole gamma globulin[3,4]. This paper reports the synthesis and release of excess L chains by cells from the lymph nodes of hyperimmunized rabbits.

Popliteal lymph nodes were removed from rabbits 6–8 days after secondary stimulation with T_2 phage. Cells were teased from the nodes as previously described[8] in Eagle's medium[9] containing 1/50 the normal amounts of amino-acids (in order to deplete the cellular pool). After pre-incubation at 37° C for 15 min, the cells were exposed to carbon-14-labelled amino-acids (amino-acid-^{14}C, u.l. mixture (New England Nuclear)) for either 30 or 60 min. Incorporation was terminated by chilling. The centrifuged cells were disrupted by five cycles of freezing and thawing in 0·01 M *tris*-hydrochloric acid buffer (*p*H 8·1), and cellular debris was removed by centrifugation at 1,500 r.p.m. for 15 min. The cell lysates were treated at 37° C with 10 per cent acetic acid, 1 per cent sodium dodecyl sulphate (SDS), and 0·5 M urea[10]. Half of each sample was reduced with 1 per cent 2-mercaptoethanol (ME). Samples were dialysed overnight at room temperature against 0·1 per cent SDS and 0·5 M urea in 0·01 M phosphate buffer *p*H 7·1, and 0·1 per cent mercaptoethanol was added to the dialysis fluid of the previously reduced samples[10]. Electrophoresis of 0·3 ml. samples was carried out on 5 per cent acrylamide gels for 150 min at 4 V/cm. The gels were then extruded[10] on to planchets which were dried and counted in a low background gas flow counter (Nuclear Chicago model 1050).

The electrophoretic mobility of whole 7*S* gamma globulin, and of the component H and L chains, was determined by staining electropherograms of purified proteins treated in the same way as the cell lysates. Preliminary experiments confirmed that acetic acid, SDS, and urea did not dissociate purified 7*S* gamma globulin whereas the addition of mercaptoethanol resulted in the complete dissociation into H and L chains[11,12]. Purified H and L chains were prepared by 'Sephadex' chromatography of gamma globulin reduced with ME in the presence of SDS and urea.

An electropherogram of the intracellular proteins synthesized by rabbit lymph node cells during the first 30 min of exposure to carbon-14-labelled amino-acids is shown in Fig. 1. When the cell lysate was treated at low *p*H with SDS and urea but not mercaptoethanol (lower panel of Fig. 1), there was a large peak representing whole 7*S* gamma globulin and a smaller peak the migration of which was identical with that of L chains prepared by 'Sephadex' chromatography. No H chains are detectable above the background radioactivity due to cellular proteins. In the presence of mercaptoethanol (upper panel, Fig. 1) the peak representing whole gamma globulin disappeared, the amount of material in the L chain area increased approximately two-fold, and a new peak of intermediate migration appeared in the area where H chains were found on stained gels of 'Sephadex' purified

reduced gamma globulin. Judged by the areas under the various peaks (above the background of cellular proteins), mercaptoethanol releases about twice as much radioactivity into the H chain area as into the L chain area. This result is consistent with the fact that H chains are

about twice as large as L chains. Further, preferential labelling of either chain was unlikely since a mixture of carbon-14-labelled amino-acids was used as precursor.

While, as shown by others[13], virtually no radioactivity was released from the cells into the medium in 30 min, after 60 min of incubation with carbon-14-labelled amino-acids both the whole gamma globulin and free L chains were found in the medium (Fig. 2).

The rapidly migrating material found in the cells at 30 min, and released into the medium by 60 min, had the electrophoretic mobility of L chains. In order to confirm the identity of this material, aliquots of the cell lysate were treated with either sheep anti-rabbit gamma globulin and unlabelled rabbit gamma globulin to coprecipitate newly synthesized gamma globulin, or with egg albumen and sheep anti-egg albumen as a control for non-specific coprecipitation[14]. The immune precipitates were treated with acetic acid, SDS, and urea, and analysed electrophoretically for radioactive material. As shown in Fig. 3, both whole gamma globulin, and the material which migrates as free L chains, were specifically precipitated.

The present experiments show that cells taken from lymph nodes of hyperimmunized rabbits 6–8 days after secondary stimulation synthesize and secrete excess free L chains. The absence of detectable amounts of H chains not associated with whole gamma globulin in solubilized whole cells suggests that the free L chains are synthesized *de novo* and are not the result of degradation of whole gamma globulin. Furthermore, under the immunization conditions of these experiments, the number of 7*S* gamma globulin molecules would seem to be limited by the number of H chains produced. Similar results have been obtained with cells from a limited number of animals 90 days after immunization. Preliminary experiments on cells from animals 3 days after secondary stimulation show a more complicated electropherogram perhaps related to the formation of 19*S* gamma globulin.

At a cellular level, the production of excess L chains could be due to either the synthesis of only L chains by some cells while others make equimolar amounts of both polypeptide chains or to the synthesis of more L than H chains by all cells. The latter possibility seems more

likely, since Bernier and Cebra have presented immunofluorescent evidence that in humans all gamma globulin producing cells contain both types of polypeptide chains[15].

It is not known whether the synthesis of excess L chains is determined at the level of the DNA, the synthesis of messenger RNA (transcription), or the reading of the messenger (translation). However, the observed synthesis of approximately twice as many of the smaller L chains as H chains would occur if there were equal numbers of H and L chain cistrons which were transcribed and translated at the same rate. In such circumstances, the synthesis of excess L chains might be more economical for the cell than the differential modulation of either the rate of synthesis or reading of the messenger RNAs for the two polypeptide chains.

AN ESTIMATE OF THE NUMBER OF ADENOSINE DIPHOSPHATE BINDING SITES ON HUMAN PLATELETS

By DR. J. R. HAMPTON and DR. J. R. A. MITCHELL
Department of the Regius Professor of Medicine, Radcliffe Infirmary, Oxford

THE surface charge on human platelets can be estimated from their electrophoretic mobility, and we have found that this mobility can be changed in two different ways. First, the electrophoretic mobility of platelets handled in siliconized containers is greater than it is after contact with a glass surface, and this change is probably due to the removal of adenosine diphosphate (ADP) from the platelet surface[1]. Secondly, charge can be changed by substances known to cause platelet aggregation, which in low concentrations increase mobility, and in higher concentrations cause a decrease in mobility[2]. We have suggested that the increase in mobility is due to the adsorption of ADP molecules by the platelet surface: because ADP is negatively charged like the platelet, the overall negative charge is increased. There are some differences between the actions of ADP and noradrenaline[3] and we have suggested that noradrenaline acts by causing the release of ADP from within the platelet on to its surface. We have also shown that in acute illnesses the sensitivity of the platelets to ADP and noradrenaline, as measured by the concentrations required to induce the maximum increase in mobility, is increased up to a hundred-fold[4]. In acute illnesses the sensitivity to ADP and noradrenaline changes in parallel, while in some patients with arterial disease, and in patients with hypercholesterolaemia there is a dissociation in sensitivity to these agents (unpublished observations).

In each of these situations there would seem to be a maximum platelet mobility: in the presence of higher concentrations of aggregating agents than induce this maximum there is a decrease in mobility. If the difference in platelet mobility between the basal post-contact state and the state of maximum mobility is due to the adsorption of ADP on to the platelet surface, then the difference in charge between the two states represents the charge carried by the adsorbed ADP molecules. An estimate of the number of molecules of ADP which each platelet can adsorb can therefore be made.

It is first necessary to show that there is a finite maximum platelet mobility:

(1) *The relationship between the glass-contact effect and the increase in mobility induced by aggregating agents.* The platelet mobility in thirteen subjects was measured before and after contact with a non-siliconized glass surface, and then the response to 0·005, 0·05 and 0·[illegible] of ADP was measured. The mean was 1·19 μ/sec/V/cm and the mean post-contact mobility was 1·08 μ/sec/V/cm. After 10 min incubation with 0·05 μg/ml. of ADP, which was the concentration inducing the maximum increase in mobility in each patient, the mean mobility was the same as in the pre-contact state (1·19 μ/sec/V/cm).

In twelve other subjects the pre- and post-contact mobilities were measured, and then the effect of three concentrations of noradrenaline was determined: in each patient the maximum increase in mobility was shown to be induced by 0·05 μg/ml. of noradrenaline. The mean pre-contact mobility was 1·15 and the mean post-contact mobility 1·05 μ/sec/V/cm. After incubation with noradrenaline 0·05 μg/ml., the mobility was the same as in the pre-contact state, 1·15 μ/sec/V/cm.

It would seem, therefore, that the pre-contact mobility is the same as the maximum mobility which can be induced by ADP or noradrenaline.

(2) *The maximum increase in mobility induced by ADP and noradrenaline:*

(*a*) *The normal response.* The response of platelet mobility to 0·05 μg/ml. of both ADP and noradrenaline was measured in seventeen normal subjects. The mean post-contact mobility was 1·07 μ/sec/V/cm; after incubation with 0·05 μg/ml. ADP or of noradrenaline the mean mobility was 1·15 μ/sec/V/cm with each agent. In normal subjects the maximum increase in mobility is therefore the same whether it is induced by ADP or by noradrenaline.

(*b*) *The abnormal response in acute illnesses.* Five patients admitted for elective surgery were investigated before operation and at intervals afterwards. Before the operation the platelet sensitivity was the same as that of the normal group of subjects, the maximum increase in mobility being induced by 0·05 μg/ml. of ADP or noradrenaline. In each patient the sensitivity to ADP and noradrenaline increased in parallel after the operation, and on the second day the maximum increase was induced by 0·005 μg/ml. of ADP or noradrenaline. Before operation the mean post-contact mobility was 1·05 μ/sec/V/cm; after incubation with either ADP or with noradrenaline the mean mobility was 1·14 μ/sec/V/cm. On the second post-operative day the mean post-contact mobility was [illegible]/sec/V/cm; the mean maximum mobility induced by [illegible] was 1·17 and the mean maximum induced by [illegible] was 1·16 μ/sec/V/cm. Thus, whatever [illegible] ADP or noradrenaline induces the

maximum increase in mobility, this final mobility is the same with both ADP and noradrenaline.

Four patients with acute myocardial infarctions were investigated serially: in each case, 24 h after the infarction the maximum increase in mobility was induced by 0·0005 μg/ml. of ADP. After a variable time each returned to normal sensitivity, the maximum increase being induced by 0·05 μg/ml. The post-contact mobilities in the abnormal and normal states of sensitivity were identical (1·05 μ/sec/V/cm) and the maximum mobility induced by ADP was 1·16 μ/sec/V/cm at the time of abnormal sensitivity, and 1·15 μ/sec/V/cm at the time of normal sensitivity. Whatever the sensitivity of the platelets the maximum mobility is not significantly changed.

(3) *Differential sensitivity to ADP and noradrenaline.* Twelve patients with either hypercholesterolaemia or obliterative arterial disease were found to have a dissociation of their dose-response curves to ADP and noradrenaline: the maximum increase in mobility was induced by 0·005 μg/ml. of ADP and 0·05 μg/ml. of noradrenaline. The mean post-contact mobility of these patients was 1·09 μ/sec/V/cm; with 0·005 μg/ml. of ADP the mobility was 1·17 μ/sec/V/cm, and with 0·05 μg/ml. of noradrenaline the mobility was also 1·17 μ/sec/V/cm. Here again, there is evidence that for a given group of patients, irrespective of the concentration of agents which induce the maximum mobility, this maximum mobility is the same.

Maximum increase in mobility. From these results we conclude that the state of maximum mobility is an entity: it can be produced in a variety of ways in different subjects and yet it has the same magnitude in any given group of subjects, however it is induced.

The platelets of twenty normal subjects were therefore tested with three concentrations of ADP and the maximum increase in mobility was shown to be induced by 0·05 μg/ml. The mean post-contact mobility was 1·06 μ/sec/V/cm and the mean maximum mobility was 1·16 μ/sec/V/cm, giving a difference of 0·10 μ/sec/V/cm. If this change in mobility were due to the adsorption of ADP molecules, it would represent a calculable change in surface charge, and could therefore give a quantitative estimate of the ADP binding.

Calculation of platelet surface charge. The surface charge density, σ, on the platelet can be calculated from its electrophoretic mobility using the Gouy-Chapman equation[5]:

$$\sigma = \left[1+(1-\alpha)^{\frac{1}{2}}\right] 2.\left[\frac{NDKT}{2000}\right]^{\frac{1}{2}}. I^{\frac{1}{2}} \sin h \left[\frac{eZ}{2KT}\right]$$

where α represents the fraction of space on the platelet surface not available for counter ions[6]. When $\alpha = 1$ the Gouy-Chapman equation is obeyed; when $\alpha = 0$ the actual surface charge density will be twice that calculated from the Gouy-Chapman equation. The value of α for platelets is not known, but because this correction should apply equally to the platelet in its post-contact state and in the state of maximum charge, it has been omitted. The remainder of the factors in the Gouy-Chapman equation are known or measurable constants: N is Avogadro's number; D is the dielectric constant of the medium; K is Boltzman's entropy constant; T is the absolute temperature; e is the electronic charge; I is the ionic strength of the medium and Z is the zeta potential of the platelet calculated by the Smoluchowski equation:

$$Z = \frac{4\pi\eta}{D} u$$

where η is the bulk phase viscosity, D the dielectric constant of the medium, and u the electrophoretic mobility of the platelet. As with Haydon's modification, any invalid assumption used in the estimation of any of these factors should apply equally to the platelet in both mobility states, and should not materially affect the calculation of the difference in charge density in the two states.

The surface charge density of the post-contact platelet as calculated from this formula is 4,620 E.S.U./cm² and of the maximally charged platelet 5,050 E.S.U./cm²: the difference in charge between the two states is thus 430 E.S.U./cm². If the mean platelet surface area is taken to be 28·3 μ² (ref. 7), then the mean charge per platelet can be determined; from this the number of "free electrons" per platelet is calculated by dividing by $4{\cdot}8 \times 10^{-10}$ (the charge per electron in E.S.U.).

If ADP molecules are attached to the platelet by their adenine rings[8] and if three negative charges of each molecule are available to influence the net negative charge on the platelet, then the number of ADP molecules attached is equal to the change in the number of free electrons on the platelet surface divided by 3. Using the results we have obtained, the number of ADP molecules which would change the mobility of a single platelet from the post-contact state to the maximally charged state is $0{\cdot}85 \times 10^5$; as no further increase in mobility can be produced this probably represents the maximum number of sites at which ADP molecules can be bound.

In these calculations we have made no correction for the electrical double layer and we have, of course, assumed that the change in mobility is entirely due to a change in surface charge. Although aggregating agents can change platelet shape[9] we are unable to account for the pattern of mobility changes which we have observed in terms of platelet shape or size, nor are the biphasic changes due to the aggregation process itself. Moreover, despite all the assumptions we have had to make, our estimate of $0{\cdot}85 \times 10^5$ ADP binding sites per platelet is in remarkable agreement with the value of 2×10^5 sites per platelet obtained by Born[10] using an entirely different approach.

PRODUCTION OF HAPTEN-SPECIFIC DELAYED SENSITIVITY WITH LOW MOLECULAR WEIGHT CONJUGATES

By DR. SIDNEY LESKOWITZ and SOLOMON J. ZAK*

Massachusetts General Hospital and Department of Bacteriology and Immunology, Harvard Medical School, Boston, Massachusetts

Two necessary conditions are required for the demonstration of hapten-specific delayed hypersensitivity: a carrier which will direct the ensuing response [illegible] hapten and a hapten which can by itself provide [illegible] sary interactive force with the delayed sensitivity moiety. Several properties of effective carriers have been investigated[1], and in general it has been found that they are [illegible] or antigens with respect to antibody production. The [illegible] characteristics of a hapten capable of inducing [illegible] delayed sensitivity have been under

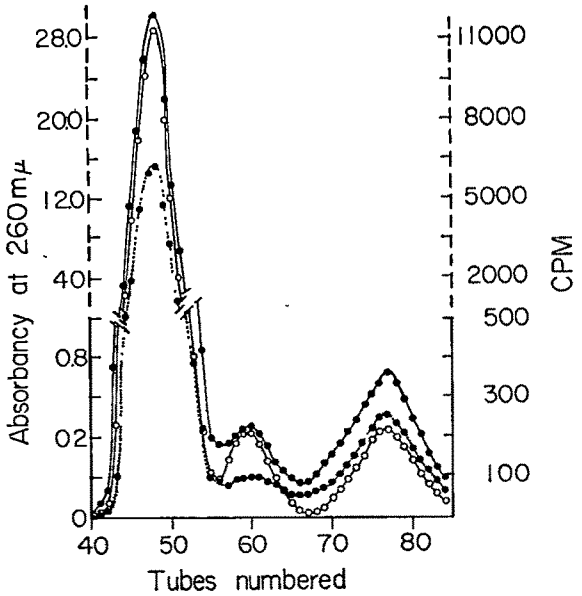

Fig. 2. Elution profile of microsomal mouse liver RNA after pulse labelling with carbon-14 labelled orotic acid. Open circles represent absorbancy, closed circles and dotted line the radioactivity after the 1-h pulse, closed circles and solid line after the 2-h pulse

To determine the quantity of 5*S* RNA on the ribosomes, ribosomal and microsomal rat liver RNA were fractionated on 'Sephadex *G*-100' and the total absorbancies of the three peaks at 260 mμ calculated. Two different concentrations of magnesium ions (0·001 M and 0·015 M magnesium chloride) were used in the sucrose media for isolation of ribosomes to ascertain whether the binding of 5*S* RNA to the ribosomes is dependent on magnesium ions. It was found that the 5*S* peak contained 1 per cent as much RNA as the high-molecular-weight RNA peak and that this relationship did not change with different concentrations of magnesium ions. Also, the relative amounts of 5*S* and ribosomal RNA were the same when RNA was extracted from ribosomes, microsomes, or whole cytoplasm. The amount of 4*S* RNA changed at different concentrations of magnesium ion from 1 per cent for ribosomes isolated in 0·001 M magnesium chloride to 2 per cent for ribosomes isolated in 0·015 M magnesium chloride, and was 3–4 per cent in the microsomal RNA. These results show that 5*S* RNA is a more stable component of the ribosomes than 4*S* RNA, and that 5*S* RNA is not contained in the membranes of the endoplasmic reticulum.

If we assume that the molecular weight of the RNA in one ribosome is $2·3–2·6 \times 10^6$ (ref. 12) and the molecular weights of 5*S* and 4*S* RNA are 35,000 and 28,000 respectively, then we find that each ribosome contains 1·1 (± 0·1) molecule of 5*S* RNA and from one to three molecules of 4*S* RNA depending on the experimental conditions. This is in agreement with the data of Rosset *et al.*[5] and supports the idea that 5*S* RNA may be a structural component of the ribosomes.

5*S* RNA is not produced by the degradation of RNA of higher molecular weight during extraction for the following reasons: (1) The amount of 5*S* RNA is independent of the experimental conditions of extraction or fractionation of RNA. (2) When ribosomes were dialysed against 0·01 M EDTA and then applied to a 'Sephadex *G*-100' column, some 5*S* RNA eluted separately from the ribosome peak; in this case no phenol extraction procedure was used.

To determine the rate of metabolism of 5*S* RNA, the labelling pattern of microsomal RNA 1 h, 2 h, and 4 h after injection of orotic acid labelled with carbon-14 in (6) position (30 mc./mmole) was investigated. Each mouse was injected intraperitoneally with 50 μc. for the 1-h pulse, and 30 μc. for the 2- and 4-h pulses. The extracted RNA was purified on 'Sephadex *G*-25', and fractionated on a 'Sephadex *G*-100' column. The specific activity of 5*S* RNA was similar to that of the high-molecular-weight RNA whereas the specific activity of 4*S* RNA was about twice as high at 1 and 2 h (Fig. 2). The same pattern of specific activity was found even at 4 h. This result rules out the possibility that 5*S* RNA is a precursor of 4*S* RNA, but suggests that 5*S* RNA is synthesized at the same rate as the two structural RNA components of the ribosomes.

The ability of 4*S* and 5*S* RNA to accept amino-acids was compared *in vitro* and *in vivo*. The procedure for *in vitro* acylation of Wettstein and Noll[13] was followed using carbon-14-labelled protein hydrolysate from *Chlorella*. Under conditions in which 4*S* RNA actively incorporated labelled amino-acids *in vitro*, 5*S* RNA accepted no label. 2 h after intraperitoneal injection of labelled amino-acids into mice, detectable radioactivity appeared in 4*S* RNA, but not in 5*S* RNA.

The nucleotide composition of RNA fractions from rat liver was determined after alkaline hydrolysis by the method of Katz and Comb[14]. The mole percentages uridine, guanine, cytosine and adenine in 5*S* RNA were 21·6, 33·2, 27·1, and 18·1 respectively, and in transfer RNA, 21·0, 30·8, 28 7, and 19·5. The quantity of methylated bases and pseudouridylic acid in 4 and 5*S* RNA was examined according to the method of Cantoni *et al.*[15]. 4*S* RNA contained about 3 per cent methylated nucleotides and 4 per cent pseudouridylic acid as reported by Cantoni *et al.*[15]. Only traces of methylcytidylic acid were found in 5*S* RNA and the pseudouridylic acid content was 0·3 per cent.

To confirm these findings 50 μc. of carbon-14-methyl methionine (29·5 mc./mmole) were injected intraperitoneally into each mouse and microsomal RNA from the livers was extracted 24 h later. As can be seen from Fig. 3, practically no incorporation of methyl groups was found in 5*S* RNA, whereas 4*S* RNA was labelled. To prove that the counts represented methylation of the nucleotides, carbon-14-methyl methionine-labelled high-molecular-weight RNA and 4*S* RNA were subjected to alkaline hydrolysis after the addition of carrier RNA, and the hydrolysates were examined for methylated nucleotides. The label in 4*S* RNA was recovered in the elution regions for methylated nucleotides whereas the label in high

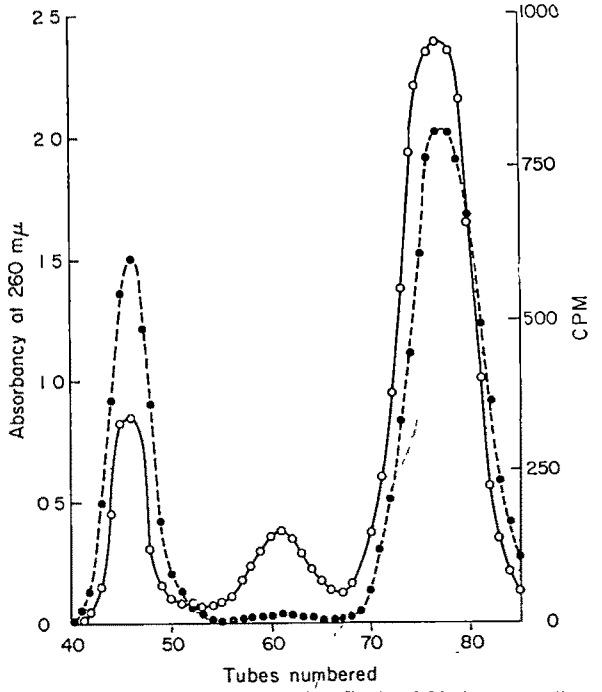

Fig. 3. Elution profile of mouse liver RNA soluble in 1 M sodium chloride after a 24-h pulse of carbon-14-methyl methionine. Open circles represent absorbancy and closed circles the c.p.m.

molecular-weight RNA did not represent methylation of nucleotides and was attributed to the poor deproteinization of this RNA.

Thus, although the base composition of 5*S* RNA was closely similar to that of 4*S* RNA, significant differences between the two RNAs were found so that 5*S* RNA cannot be a product of aggregation of 4*S* RNA.

The melting curve of 5*S* RNA was compared with that of 4*S* and high-molecular-weight ribosomal RNA (Fig. 4). In 0·15 M sodium chloride and 0·015 M sodium citrate buffer, *p*H 7·4, the total hyperchromicity of 4*S* and 5*S* RNA is similar. This suggests that they possess the same degree of ordered secondary structure. However, the T_m of 4*S* RNA is 49° C, compared with 55° C for 5*S* RNA, and at 37° C the 4*S* RNA has melted significantly more than the 5*S* RNA. These differences could result from the presence of fewer minor bases in 5*S* RNA and from variation in sequence of bases.

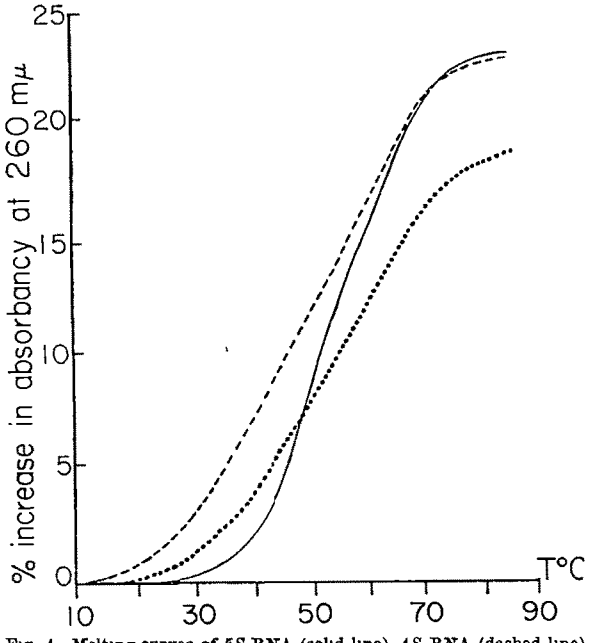

Fig. 4. Melting curves of 5*S* RNA (solid line), 4*S* RNA (dashed line), and high-molecular-weight ribosomal RNA (dotted line) in 0·15 M sodium chloride plus 0·015 M sodium citrate buffer, *p*H 7·4

The mammalian 5*S* RNA described here resembles the fraction found by Galibert *et al.*[7] in its presence on the ribosomes, its lack of acceptance of amino-acids, its gel-filtration properties on 'Sephadex *G*-100' and its chromatographic properties on MAK columns. Our data on its behaviour during agar electrophoresis, its *S* value, T_m, more stable binding to the ribosomes, and rate of synthesis, further distinguish 5*S* from 4*S* RNA. We suggest that 5*S* RNA may be a structural component of the ribosomes. Further experiments are in progress to elucidate the biological significance of 5*S* RNA.

We thank Dr. A. Morosko for performing the analytical ultracentrifugation and E. Horoshutina for her excellent assistance.

INFECTION OF THYMIDINE KINASE-DEFICIENT *BHK* CELLS WITH POLYOMA VIRUS

By DR. JOHN W. LITTLEFIELD* and DR. CLAUDIO BASILICO
International Laboratory of Genetics and Biophysics, Naples

BIOCHEMICAL variants occur in heteroploid mammalian cell cultures, but have not been described in cultures of diploid human fibroblasts. They do occur in the *BHK* 21/13 line of hamster cells[1], which is also primarily diploid[2]. A *BHK* 21/13 variant deficient in thymidine kinase would be useful for various genetic studies, as have been kinase-deficient *L* cell variants[3,4]. In particular we wondered if infection of such cells with polyoma virus would cause: (1) a generalized transient increase in kinase activity—as occurs in mouse kidney[5,6] and mouse embryo[7] cultures; (2) occasionally the permanent acquisition of the enzyme in a transformed cell through integration of the viral genome; (3) derepression or reverse mutation in the host cell genome; (4) transduction.

Thymidine kinase-deficient cells are unable to phosphorylate 5-bromodeoxyuridine, and therefore are protected against the lethal effect of the incorporation of this analogue into DNA. The kinase-deficient *L* cell sub-lines were selected by virtue of their resistance to 5-bromodeoxyuridine; however, it was not possible to isolate resistant cells directly as clones and the selection took a considerable time[8,9]. For the present experiments *BHK* 21/13 cells, kindly supplied by Prof. M. Stoker, were grown in Eagle's medium containing four times the usual concentration of amino-acids and vitamins and supplemented with either 10 per cent calf serum for routine maintenance or 20 per cent foetal calf serum for cloning experiments. To determine the sensitivity of this line to 5-bromodeoxyuridine, 200 cells were plated in Petri dishes containing medium with various concentrations of the analogue. Compared with untreated cells, the survival was 97 per cent at 0·04 μg/ml., 43 per cent at 0·12 μg/ml., 9 per cent at 0·37 μg/ml., and 0 at 1·1 μg/ml. Then 100-mm dishes containing only 5×10^5 cells were exposed to concentrations of 5-bromodeoxyuridine somewhat greater than 1·1 μg/ml., as it was expected that a larger number of sensitive cells would inhibit the growth of any partially resistant variants[8]. After 10 days there were about twenty colonies in each dish containing 3·3 μg/ml. Cells from these colonies were exposed to 30 μg of 5-bromodeoxyuridine/ml., in order to select highly resistant variants. A similar number of colonies appeared, two of which were isolated and enlarged into sub-lines designated *B*1 and *B*2.

These sub-lines have remained highly resistant to 5-bromodeoxyuridine. For example, the plating efficiency (without feeder cells) of *B*1 cells was 32 per cent in the absence or presence of 30 μg of 5-bromodeoxyuridine/ml., and 29 per cent with somewhat smaller colonies in 300

* Present address: Massachusetts General Hospital, Boston, Massachusetts.

μg/ml. Cells of both sub-lines align themselves in parallel fashion when confluent like *BHK* 21/13 cells. They grow more slowly than *BHK* 21/13 (generation time about 15 h for *B*1). Preliminary studies suggest that each sub-line has lost two or three chromosomes, and detailed karyotype analyses are in progress. As expected, extracts of *B*1 and *B*2 cells contained very little thymidine kinase activity (Table 1). For these determinations it was important to use 2-day-old cultures containing not more than $1{\cdot}5 \times 10^6$ cells in each 100-mm Petri dish, as kinase activity decreases markedly in crowded cultures.

Table 1. THYMIDINE KINASE ACTIVITIES OF *BHK* SUB-LINES

Sub-line	μμmoles/10⁶ cells/10 min	Per cent
BHK 21/13	796	100
*B*1	24 0	3·0
*B*2	13·0	1·6
T × 1	11·3	1 4
T × 5	14·3	1 8
*B*1*R*1	491	62
*B*1*R*2	499	63

The values represent the μμmoles of thymidine-2-^{14}C phosphorylated in 10 min at 37° C by the extract of 10^6 cells, assayed in duplicate and corrected for a blank reaction mixture from which ATP was omitted, as previously described (ref. 9). *B*1 and *B*2 are the 5-bromodeoxyuridine-resistant sub-lines; *T* × 1 and *T* × 5 are polyoma virus-transformed sub-lines of *B*1; and *B*1*R*1 and *B*1*R*2 are aminopterin-resistant revertants isolated from the *B*1 sub-line.

The deficiency of kinase is reflected in the low rate of incorporation of thymidine-2-^{14}C into the DNA of growing *B*1 and *B*2 cells (Table 2). If the incorporation were increased during the hours following infection with polyoma virus, this would suggest an increase in kinase. *B*1 cells were infected with a small plaque type of polyoma virus (2×10^3 P.F.U./cell), and at the end of the virus adsorption period (1 h) medium containing thymidine-2-^{14}C was added. Twenty-four hours later the incorporation of thymidine-2-^{14}C into DNA was determined as previously described[10], and compared with that into uninfected control cultures. Likewise, *B*2 cells were infected with a large plaque virus (2×10^3 P.F.U./cell), and then exposed to thymidine-2-^{14}C for 48 h. In neither of these experiments was the incorporation of thymidine-2-^{14}C into DNA increased after infection (Table 2). The same preparation of small plaque virus (grown in mouse kidney cells) had been shown to induce a twelve-fold increase in kinase in confluent mouse kidney cultures 24 h after infection.

Table 2. THYMIDINE-2-^{14}C INCORPORATION INTO DNA OF *BHK* SUB-LINES

Sub-line	mμmoles/10⁶ cells/24 h	Per cent
BHK 21/13	14 8	100
*B*1	0·74	5·0
*B*2	1·0	6 8
*B*1 after infection	0 60	4·1
*B*2 after infection	0 82	5 5
T × 1	0 89	6 0
T × 2	0·85	5 7
T × 3	0·81	5 5
T × 5	0 65	4·4

Actively growing cultures containing not more than 3×10^5 cells/35 mm Petri dish were exposed for 24 or 48 h to medium containing thymidine-2-^{14}C (4×10^{-8} M, 2 5 μc /μmole), and then analysed as described previously (ref 10). The values represent the mμmoles of thymidine-2-^{14}C incorporated into DNA in 24 h by 10^6 cells, corrected for the incorporation into control cultures held at 4° C Certain cultures were infected with polyoma virus before the addition of thymidine-2-^{14}C, as described in the text *T* × 1, *T* × 2, *T* × 3, and *T* × 5 are polyoma virus-transformed sub-lines of *B*1.

It was important to know if the kinase-deficient cells could be transformed with polyoma virus-like *BHK* 21/13 cells. The ability of cells to grow in Eagle's medium containing 10 per cent calf serum, 2 per cent tryptose phosphate broth, and 0·34 per cent agar was used as the criterion of transformation[11]. None of $3{\cdot}3 \times 10^4$ *B*1 cells and 0·05 per cent of *B*2 cells was able to grow in this medium (Table 3). Under standard techniques of infection[12,13], *B*1 cells seemed normally susceptible to transformation, while *B*2 cells were less so. Thus in one experiment 4·4 per cent of *B*1 cells were transformed after infection, and in another experiment only 0·25 per cent of *B*2 cells were transformed (Table 3).

Four transformed *B*1 colonies (*T* × 1, *T* × 2, *T* × 3 and *T* × 5) were isolated during Experiment 1 of Table 3. These cells showed the random orientation in culture described for transformed cells[2]. They incorporated thymidine-2-^{14}C at the same low rate as untreated *B*1 cells (Table 2), and extracts of two of these transformed sub-lines contained no more kinase activity than extracts of *B*1 cells (Table 1). These experiments indicated that transformation was not regularly accompanied by permanent acquisition of the enzyme.

To determine if polyoma virus caused the acquisition of the kinase in an occasional cell, it was possible to take advantage of the fact that kinase-deficient cells, such as *B*1 and *B*2, cannot survive in medium containing 10^{-5} M aminopterin, 4×10^{-5} M thymidine, 10^{-4} M hypoxanthine, and 10^{-5} M glycine[9]. The endogenous synthesis of thymidylic acid is blocked by aminopterin, and thymidine in the medium can be utilized only by cells containing thymidine kinase. Normal or transformed *BHK* 21/13 cells show the usual plating efficiency in this medium (30–40 per cent), alone or in the presence of many killed *B*1 or *B*2 cells. Similarly transformed *BHK* 21/13 cells plate with the same efficiency in 0·34 per cent agar medium or in 0·34 per cent agar medium containing aminopterin, thymidine, hypoxanthine, and glycine. However, when *B*1 or *B*2 cells were infected with polyoma virus and 24 h later plated into this medium, no colonies appeared (Table 3). Thus none of the cells transformed had acquired the enzyme. It is likely that regain of one-half (see below), or perhaps less[9], of the usual thymidine kinase activity/cell would have permitted survival in this medium.

In other experiments (last 2 columns of Table 3) monolayer cultures containing even larger numbers of *B*1 or *B*2 cells were infected with polyoma virus, and aminopterin, thymidine, hypoxanthine, and glycine added to the medium after 24 h (Experiments 1, 2 and 4) or 48 h (Experiment 3). The cultures were re-fed with the selective medium once or twice, and colonies scored about 10 days after infection. In these experiments colonies occurred at about the same low frequency in both infected and control cultures (Table 3), indicating that infection had not led to the acquisition of the enzyme in even a rare cell.

None of these aminopterin-resistant colonies appeared morphologically to be transformed. Presumably they

Table 3. FREQUENCIES OF TRANSFORMATION AND REVERSION IN *BHK* SUB-LINES INFECTED WITH POLYOMA VIRUS

Expt.	Sub-line	Multiplicity of infection (P.F.U /cell)	Normal agar medium		Aminopterin agar medium		Aminopterin fluid medium	
			No. of cells	No. of colonies	No. of cells	No. of colonies	No. of cells	No of colonies

	T × 5	—	—	—	—	—	10^7	2

See text for details For the experiments with agar medium, the number of cells indicated was plated into agar in several dishes 24 h after infection. For the experiments with fluid medium, monolayer cultures containing up to 10^6 cells/100-mm Petri dish were made 24 h before infection, and the number of cells given is an estimate of those present when aminopterin was added. Small plaque polyoma virus was used in experiments 1 and 2, and large plaque virus in experiments 3 and 4. The cells were infected in suspension in experiment 1, and otherwise in monolayer. In all cases virus adsorption was carried out for 1 h at 37° C.

represent revertant cells in the *B*1 and *B*2 sub-lines, such as occur in kinase-deficient *L* cells[9]. Extracts of cells grown from two of these colonies were found to contain 62 per cent and 63 per cent of the kinase activity of *BHK* 21/13 cells (Table 1).

The overall frequency of revertants in *B*1 cultures was 8×10^{-8}, and that in *B*2 cultures and two transformed *B*1 sub-lines was much the same (Table 3). To remove revertants, the cells used in Experiments 2 and 3 of Table 3 had been treated with 30 μg of 5-bromodeoxyuridine/ml. up to 5 and 15 days, respectively, before exposure to aminopterin during the experiments. From the reversion frequencies in these and two other experiments and the generation time of *B*1 cells it is possible to estimate[14] that the reversion rate is about 10^{-7}/cell/generation (range $0{\cdot}1–2{\cdot}0 \times 10^{-7}$).

The findings of these investigations indicate that variant cells markedly deficient in thymidine kinase activity can be isolated from the *BHK* 21/13 line of hamster fibroblasts. They were obtained by a stepwise procedure in which clones partially resistant to 5-bromodeoxyuridine were selected from the *BHK* 21/13 culture, and then markedly resistant clones selected from the partially resistant cultures. Infection of kinase-deficient cells with polyoma virus does not seem to cause an initial increase in kinase, as occurs during the lytic cycle in mouse embryo and mouse kidney cultures. The enzyme-deficient cells can be transformed with polyoma virus. Kinase is not permanently acquired by even a rare (10^{-7}) infected or transformed cell.

MECHANISM OF ACTION OF BOVINE PANCREATIC RIBONUCLEASE

By DR. A. DEAVIN, DR. A. P. MATHIAS and DR. B. R. RABIN
Department of Biochemistry, University College, London

RIBONUCLEASE has been shown to catalyse the hydrolysis of substrates of the type (I) in a two-step reaction involving the intermediate formation of a cyclic phosphate (II) (Fig. 1).

For substrates of low molecular weight and RNA, but apparently not for some homopolynucleotides, *B* must be a pyrimidine[1]. From an investigation of the kinetics of step 2 in a variety of solvents it was concluded that two histidine residues, one as an acid and the other as a base, form part of the active site of the enzyme[2,3]. Iodoacetate, but not iodoacetamide, inhibits the monomeric enzyme at *p*H 5·5 by reaction with either, but never both, of histidine residues 12 and 119[4]. The elegant hybridization experiments of Crestfield, Fruchter, Moore and Stein provide further evidence for the postulate that two histidine residues are involved at the catalytic site of the enzyme[5,6]. We have proposed that step 1 requires the interaction of one of the histidine residues (*a*), in the base form, with the 2′-hydroxyl, and the other (*b*), in the acid form, with the oxygen atom bridging *R* and *P* (ref. 3). In step 2, residue (*a*) in the acid form reacts with the 2′-oxygen and the base form of residue (*b*) binds the attacking water molecule. It was postulated that the proper positioning of the substrate with respect to the catalytic groups of the enzyme was achieved by specific interactions between the protein and the pyrimidine base, *B*. Spectrophotometric investigations in this laboratory and elsewhere lend support to this proposal[7]. Obviously there would be a tendency for interaction to occur between the negatively charged phosphate oxygen of (I) and the histidine cation (*b*) to give an abortive complex. Clearly this tendency would be counteracted by an interaction between a site on the protein and the group *R* restricting the rotational freedom about the P—OC_3 bond. The data of Witzel and Barnard (Table 1)[8] can be interpreted in these terms on the assumption that the strengths of the *R*-protein interactions are in the order adenine > guanine > cytidine > uridine. Interaction between the *R* group and the protein would be expected to affect the parameter k_{+2} to a much greater extent than K_m. This suggests that ribonuclease possesses two sites, one of which is specific for pyrimidines and the other of which prefers purines.

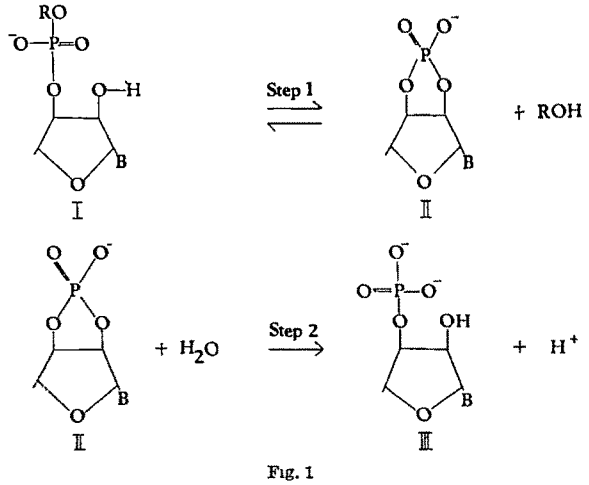

Fig. 1

Table 1. KINETIC CONSTANTS (ref. 8) AT *p*H 7·0 (IMIDAZOLE BUFFER), 26° C

Substrate	k^+_2 (sec^{-1})	K_m (mM)
CpA	3000	1·0
CpG	500	3·0
CpC	240	4·0
CpU	27	3·7

We have attempted to gain further information on the nature of these sites and the chemistry of their interactions with substrates by spectrophotometric and spectropolarimetric investigations of the binding of nucleotides, coupled with kinetic and protection experiments.

In this work, ribonuclease *A* was either prepared by the method of Taborsky[9], or was a commercial sample which had been rechromatographed to eliminate the appreciable

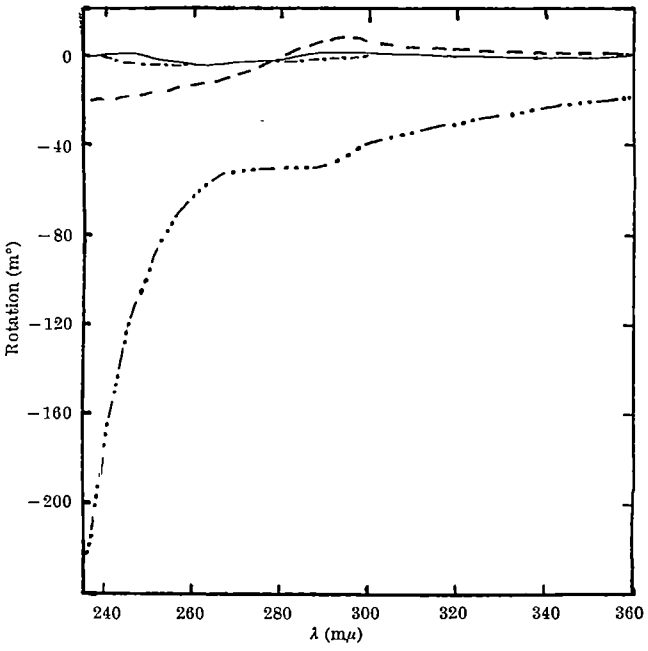

Fig. 2. Optical rotatory dispersion spectra of nucleotides ($1{\cdot}0 \times 10^{-4}$ M) and ribonuclease ($0{\cdot}5 \times 10^{-4}$ M) in a 1-cm cell. 0·02 M sodium acetate buffer *p*H 5·2, 25° C – – –, C3′P; ———, ATP; – · – ·, deoxythymidine 3′-phosphate benzyl ester, ·· –···–, RNase and CM–RNase

amounts of impurities which we have found more often than not in these preparations. Optical rotatory dispersion spectra were determined with a Bellingham and Stanley 'Polarmatic 62' spectropolarimeter fitted with a cell compartment maintained at a constant temperature of 25° C and equipped with an *X*–*Y* plotter. The instrument was flushed with nitrogen and the base-line determined in the same cell at the beginning and end of each run. Optical rotatory dispersion spectra of some nucleotides, ribonuclease and 119-carboxymethylated ribonuclease are shown in Fig. 2. Carboxymethyl RNase and native RNase have identical rotatory dispersion spectra within the limits of experimental error, making it unlikely that the loss of catalytic activity on carboxymethylation is a result of a conformational change in the protein. These spectra were determined at *p*H 5·2 and low ionic strength (0·02). Fig. 3 shows the difference in the optical rotatory dispersion spectra of enzyme–ligand mixtures and the computed sum of the separate components. Of particular note are the large differences, especially at low wave-lengths, observed with cytidine 3′-phosphate. We have recorded similar effects with a large number of other pyrimidine nucleotides, for example C2′P, C5′P, U2′ and 5′P, provided these possess a 2′-oxygen atom, with 2′-deoxynucleotides or their esters as illustrated for 2′-deoxythymidine 3′-phosphate benzyl ester in Fig. 3, no optical rotatory dispersion difference spectra are seen. For purine nucleotides including the 2′, 3′ and 5′ mononucleotides and the 5′ di- and tri-phosphates, only very small changes (if any) are detected. Similarly, no changes are found for pyrophosphate. It should be emphasized that all these compounds are powerful competitive inhibitors of the enzyme. Obviously they must bind to the protein and, indeed, with the exception of pyrophosphate, spectral changes can be observed on interaction with the ligand as illustrated in Fig. 4. These difference spectra were determined in split compartment cells type *T*/*E*8/1/5/41 manufactured by Thermal Syndicate Ltd., in a Cary 'model 14' spectrophotometer with a thermostatted cell compartment, on the 0–0·1 slide wire. We have found that split compartment cells manufactured to narrow tolerances have decisive advantages over tandem cell arrangements in that they yield much more reproducible results. They also enable artefacts to be eliminated because it is possible to recheck the base-line after mixing the component solutions in the reference compartment. The absence of any difference spectrum for pyrophosphate suggests that the difference spectra found with the nucleotides result from interactions involving the nucleoside. Spectrophotometric and spectropolarimetric titrations of the protein with nucleotides have been carried out for some

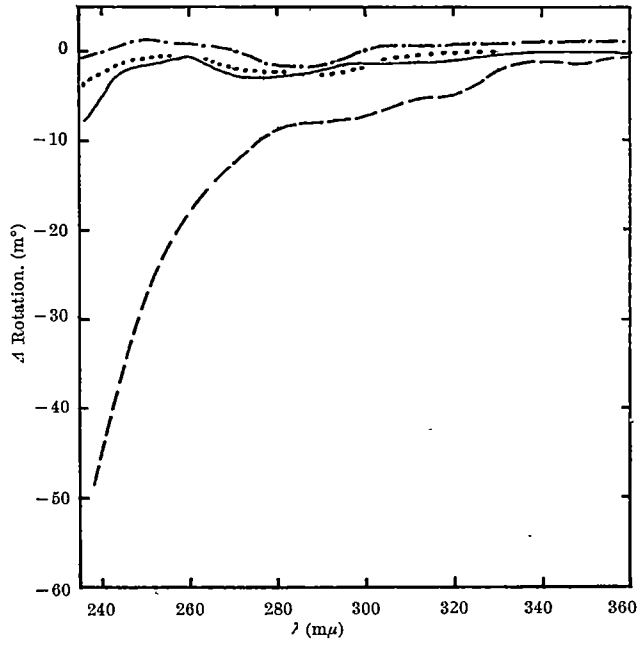

Fig. 3. Optical rotatory difference spectra of mixtures of ribonuclease and ligands measured under same conditions as in Fig. 2. – – –, C3′P, ———, ATP; –·–·–, deoxythymidine 3′-phosphate benzyl ester, ·····, pyrophosphate

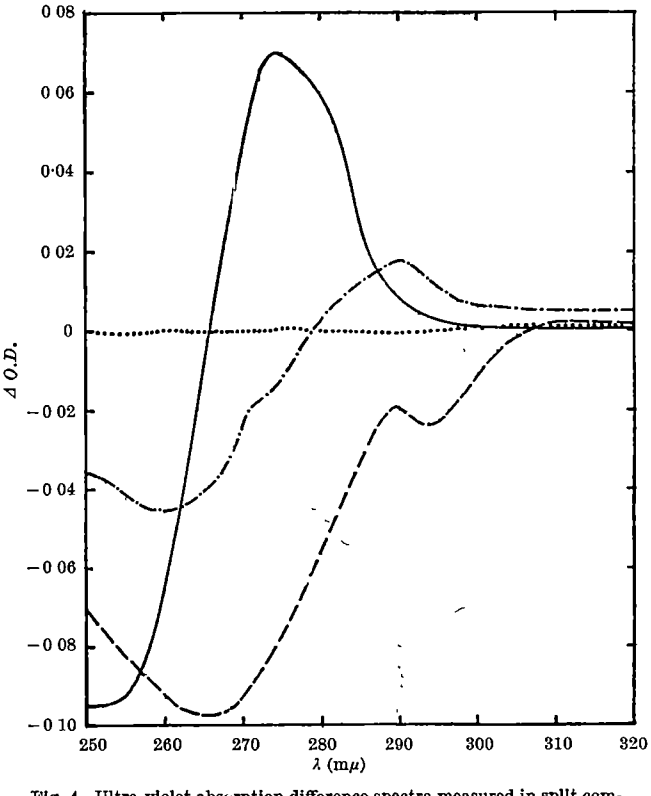

Fig. 4. Ultra-violet absorption difference spectra measured in split compartment cells (total path length 1 cm), in 0·02 M sodium acetate buffer *p*H 5·2, 25° C. All concentrations $0{\cdot}5 \times 10^{-4}$ M. – – –, C3′P; ———, ATP; ·–·–·, deoxythymidine 3′-phosphate benzyl ester; ·····, pyrophosphate

of the compounds and have demonstrated the formation of 1 : 1 complexes for ATP and C3′P. For C2′P the stepwise addition of two molecules of nucleotide has been observed by spectropolarimetry. No interactions were detected by either method between C2′P and 1-carboxymethyl histidine-119 RNase, 3-carboxymethyl histidine-12 RNase or 2 : 4-dinitrophenyl lysine-41 RNase. All these proteins had essentially the same optical rotatory dispersion spectra.

Dissociation constants of the enzyme ligand complexes have been calculated by measurements of their ability to protect the enzyme against alkylation by iodoacetate, and by determination of inhibition constants from the steady-state kinetics of hydrolysis of cytidine 2′ : 3′ phosphate. Some of the results are shown in Table 2. Spectrophotometric determinations of the binding constants of a commercial sample of ribonuclease with C3′P as a function of *p*H have been reported[10]. A maximum was observed at *p*H 5·5. We have found a similar maximum in our optical rotatory dispersion studies. At this *p*H there is also a minimum in the Michaelis constant for C2′ : 3′P. Unfortunately interpretations of mechanism from these data are impossible, in the absence of additional information, because the measured constants reflect the *pK* values of the free enzyme, free ligand and enzyme–ligand complexes. The decrease in binding which occurs on the acid side of *p*H 5·5 could well be associated with protonation of the cytosine ring, and in no way contravenes the mechanism that we have previously outlined[3].

Table 2 DISSOCIATION CONSTANTS OF ENZYME–INHIBITOR COMPLEXES. SODIUM ACETATE BUFFER *p*H 5·2, I = 0·02, TEMPERATURE 25° C

	$K_I \times 10^6$ (Ml.$^{-1}$)	
	Hydrolysis of cytidine 2′ : 3′ phosphate	Alkylation reaction
Cytidine 3′ phosphate	16	4·8
ATP	0·3	—
2′-Deoxythymidine-3′-phosphate benzyl ester	1·0	6·0
Pyrophosphate	7·6	4·9

Table 3. DISSOCIATION CONSTANTS (ref. 11) OF GROUPS AT THE ACTIVE SITE OF RIBONUCLEASE 25° C, I = 0·20

Free enzyme		Enzyme–substrate complex	
pK$_b$	5·22 ± 0·20	*pK*$_b$′	6·30 ± 0·09
pK$_a$	6·78 ± 0·20	*pK*$_a$′	8·10 ± 0·09

We wish to propose an extension of this model of the enzyme–substrate complex which encompasses the data presented in this article. The *pK* values for the functional groups at the active site are shown in Table 3. On interaction with the substrate C2′ : 3′P both *pK* values increase. It is to be expected that the group required in the acid form will have its *pK* raised if it interacts directly with the substrate. Similarly, the group required in the base form should have its *pK* lowered if it binds directly with the substrate. In fact, its *pK* is also shifted to higher values. It was suggested that this group functions by forming a hydrogen bond with the attacking water (or alcohol) molecule as shown in Fig. 5.

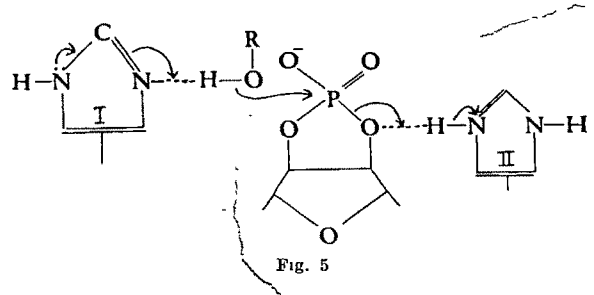

Fig. 5

This mechanism readily accounts for the raised *pK* of group (II) on formation of the enzyme substrate complex. In order to explain a similar shift in the *pK* of (I), it is necessary to postulate an acid-stabilizing inter-

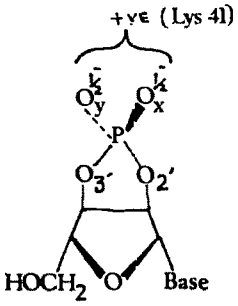

Fig. 6

action between this group and the substrate. If this interaction involves the pyrimidine ring it would give rise to shifts in the absorption spectrum of the type observed. To understand this problem in detail it is necessary to know the direction of approach of the attacking nucleophile to the phosphorus atom. The geometry around the phosphorus atom is shown in Fig. 6. Here the negative charges on the oxygen atoms *x* and *y* are shown as interacting with a positive charge in the protein, and this may well be the amino side chain of lysine 41. There are four possible directions along which a water molecule could approach. These may be defined by the trio of oxygen atoms surrounding the surface region of the phosphorus atom which makes contact with the attacking nucleophile. These four regions are defined by the following oxygen trios:

(1) O_2', O_3', O_x
(2) O_3', O_x, O_y
(3) O_2', O_x, O_y
(4) O_2', O_3', O_y

Classical nucleophilic displacement would involve (2). However, there is a considerable density of negative charge impeding attack in this region. If interaction occurs with lysine 41, access along this direction would be hampered by steric hindrance. The same objections apply to region 3. The approach to region 4 is prevented by the hydrogen atoms on $C_{2'}$ and $C_{3'}$. Therefore we suggest that the attacking water molecule approaches region 1. If a model is constructed from Cortauld space-filling atoms an interesting feature becomes obvious. The pyrimidine ring can be so positioned that its oxygen interacts, through a water bridge, with the hydrogen atom attached to imidazole (I), as illustrated in Fig. 7.

The geometry is difficult to illustrate in two dimensions, but the model shows that, in the active configuration, the imidazole and pyrimidine rings are co-planar and approximately at right angles to the plane of the sugar. The

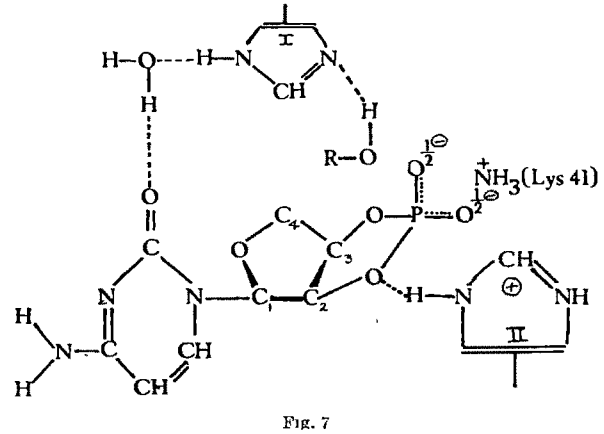

Fig. 7

hydrogen atom on C_2 of imidazole (I) is in Van der Waals contact with the hydrogen atom on $C_{1'}$ of the ribose. An analogous structure is not possible for the cyclic phosphate derivatives of purine nucleotides and this may account for the specificity of the enzyme. The interaction between the pyrimidine oxygen and the imidazole by way of the water bridge would stabilize this group in its acid form and hence raise its *pK*. Thus it would be expected that interaction of the enzyme with a cyclic phosphate substrate would result in the elevation of both *pK*s at the active site, as has been found experimentally. A further consequence of the interaction would be a perturbation of the pyrimidine spectrum similar to that found for enzyme–inhibitor complexes.

Alkylation of imidazole (I) in Fig. 7 should cause complete loss of activity. This suggests that this group is histidine 119. We propose that histidine 12, in the acid form, interacts with the 2′ oxygen of the substrate. Alkylation of this histidine would not necessarily cause complete loss of activity since the alkylated imidazole could still function as an acid catalyst[12]. The optical rotatory dispersion studies reported in this article indicate that conformational changes on binding require the presence of an oxygen atom on $C_{2'}$ of the sugar. It is possible that these conformational changes arise during the formation of a hydrogen bond between $O_{2'}$ and histidine 12.

We thank the Science Research Council for a grant for the purchase of the spectropolarimeter and a personal grant to one of us (A. D.). We also thank the Wellcome Trust for a grant for the purchase of a Cary model 14 spectrophotometer and Miss Angela Hardy for skilled technical assistance. We are grateful to Prof. Lord Todd for samples of deoxyribonucleotides.

SWARMING OF *Proteus* — A SOLUTION TO AN OLD PROBLEM?

By DR. R. B. MORRISON and DR. ANN SCOTT
Department of Bacteriology, University of Glasgow

THE swarming of *Proteus* has intrigued bacteriologists ever since Hauser first isolated and described this organism in 1885 (ref. 1). Anyone who has attempted to isolate pathogens from faeces must have known the irritation of finding a thin veil of *Proteus* covering the whole surface of his plate culture including the colonies of possible pathogens which he had hoped to isolate and identify.

This phenomenon of swarming raises a host of questions to which a clear answer has not yet been given. Why do many other highly motile bacteria fail to swarm over the surface of plate cultures? Why does a period of stationary growth (in which transference to liquid media indicates the presence of motile cells) always precede the phase of swarming[2–4]? Why do many chemically unrelated compounds inhibit swarming[5]? Why does the absence of sodium chloride and certain sugars from the medium prevent swarming[5]? Why does the production of a negative chemostatic substance[4] make certain zones of a plate culture "forbidden zones" to the swarming cells? Why is swarming associated with the production of giant cells up to twenty times longer than the non-swarming, but still motile, *Proteus* cells[2,3,6,7]?

The work described here has a limited purpose, namely, to see whether the behaviour of the individual cells during swarming could be related to the fact that *Proteus* cells can swarm, whereas other equally motile and similarly peritrichously flagellate cells do not normally do so. The technique used was simple if tedious.

Meat extract agar plates were inoculated at the centre of the plate with a strain of *Proteus mirabilis* and incubated at 37° C or at room temperature. After 3–4 h, in the case of plates incubated at 37° C, and a longer period for plates kept at the lower temperature, the cultures were placed on a microscope stage and the surface growth observed with the 4-mm objective and a 10 × eyepiece using bright field illumination. Sometimes continuous observation was made for several hours with the plate resting on a heated stage at 37° C. Sometimes the surface growth was examined at regular intervals with the plate returned to the 37° C incubator between observations. With plates incubated at a higher temperature, microscopic observation was frequently continued until swarming had covered the whole surface of the plate. With plates incubated at lower temperatures the need for an interval for sleep prevented continuous observation.

Over a period of time a more or less clear understanding of the sequence of events from the first multiplication of the cells of the inoculum to the arrival of swarming cells at the edge of the plate was established. The conclusions of a series of observations can be summarized as follows:

(1) When the cells of the inoculum begin to multiply without swarming the development of a normal type of colony occurs and the cells produced are motile and a few microns in length

(2) Somewhere between 3 and 4 h after inoculation and subsequent incubation at 37° C, cell division diminishes and longer cells become visible.

(3) Motion of these long cells without emergence from the edge of the colony becomes apparent and they extend in length.

(4) Eventually, cells of between 20μ and 80μ in length protrude from the edge of the colony and move towards the edge of the plate, losing contact with the main mass of short bacteria. Cells often move outwards in the form of large rafts.

(5) The process intensifies and within 30 min cells can be seen journeying outwards, with some (but only a minority) circling in their tracks and returning towards the central mass of growth.

(6) This outward motion of long cells occurs in groups of cells and not by single-cell movement.

(7) The group may appear to move as one unit or may obviously consist of rapid movement of one or more cells along other cells forming part of the group.

(8) Sometimes a cell is left behind by the group; when it has parted company with the other cells in the group, movement only continues for a short space of time.

(9) Sometimes a moving group comes into contact with an immobilized cell and moves alongside the single cell, which is then reactivated into movement.

(10) Eventually, large groups of cells showing outward movement tend to break down into smaller groups, each

showing intermittent movement until finally two cells part company and each component cell ceases to move.

(11) In the early stages the main movement is outward until an annulus of thin growth of about 2-cm diameter is formed which surrounds the central and initially stationary, colonial, type of growth. Towards the end of the first swarming stage the moving cells tend to curve back towards their starting point and form eventually a continuous entanglement of long cells with no further swarming movement at the periphery.

(12) The long cells break up into normal-sized *Proteus* cells 2–4μ in length, which undergo multiplication, giving a mass of stationary growth consisting of short cells in which some long cells which have failed to sub-divide remain entangled.

(13) After 0·5–1 h, the whole sequence of events repeats itself until at the end of 8–10 h incubation at 37° C we find ourselves with a plate culture covered with cells arranged in concentric rings of thin and thick growth.

It would be tedious and space-consuming to illustrate photographically the whole of the foregoing series of events and, in any case, only part of the description is relevant to the problem of why *Proteus* cells swarm and other motile bacteria do not. Fig. 1 contains a sequence of photographs taken at about 4-sec intervals. In these can be seen a number of the foregoing features, namely, the movement of a raft of cells in which the position of the component cells relative to each other differs from one photograph to the next; the reversal of the direction of movement of a group of cells, the movement of cells along the surface of other cells, and the cessation of movement when cells become isolated.

Bright-field illumination was chosen as a matter of convenience though phase-contrast observation was also used. The use of bright-field illumination with the condenser adjusted to a suitable distance from the stage and with the brightness adjusted to give the maximum of contrast between cells and medium with the minimum of eye-strain, and with the medium interposed between the light and the camera, made the achievement of aesthetically satisfying photographs difficult. Fig. 1 does, however, show the manner in which the cells move even if the

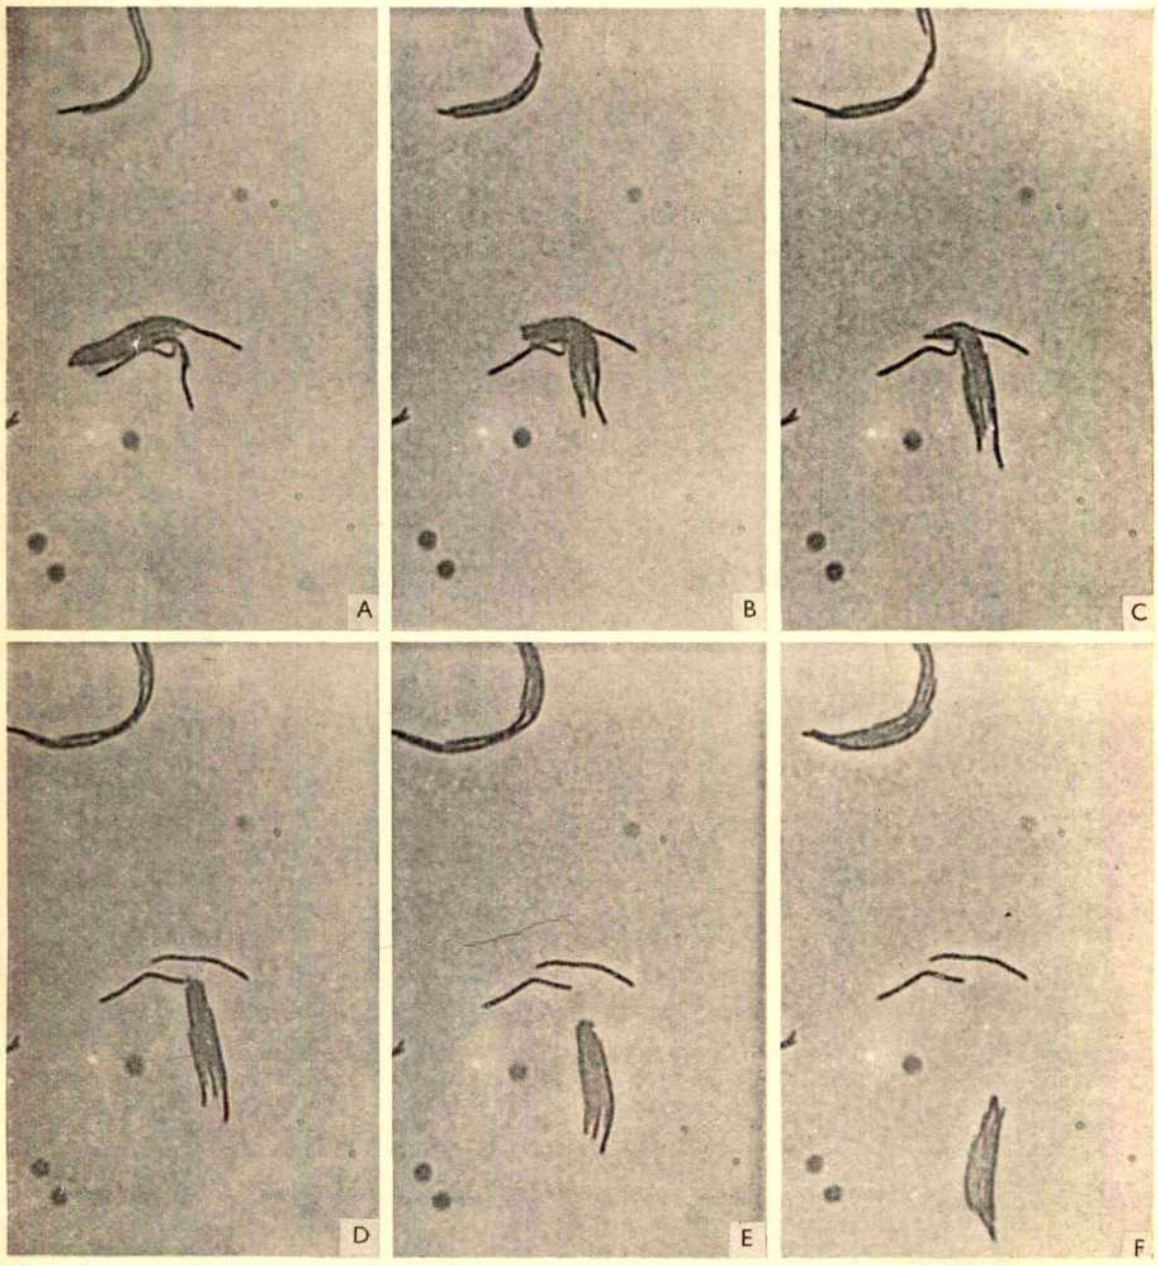

Fig. 1. A sequence of photomicrographs, lettered *A-F*, of swarming cells of *Proteus mirabilis* taken at intervals of about 4 sec. (× *c.* 350)

background is full of blemishes from the photographer's point of view.

To summarize the conclusions drawn from the observations, it might be stated that the swarming of *Proteus* is a consequence of the movement of long cells and that this movement is only continuous when one cell is in contact with another. The long, swarmer, cells of *Proteus* move (and sometimes with startling rapidity) by climbing or sliding along each other. When contact between cells is broken, movement soon stops. When contact is re-established, a motionless cell may once more begin to move. The cells appear to slide along each other and usually the group movement is towards the periphery of the plate, but sometimes retrogression of the group towards the stationary growth occurs. Often when a raft of cells appears to move as a whole, careful study shows that the movement is a kind of shuffling or shuttling of the individual cells upon each other.

One might frame the hypothesis that the flagella of these very long, heavily flagellate, cells are able to obtain a thrust on neighbouring cells which gives them sufficient impetus to propel themselves over the surface of a solid medium. To use an analogy, when the cell is isolated it is like a beached galley with the oars beating uselessly on air. When it is in contact with other cells it can be likened to a galley with scores of oars and oarsmen which, even on dry land, can move forward by leverage on an adjacent galley if the friction between galley and ground should differ in each case. The small, less heavily flagellate cells[7] are like boats with a few oarsmen who have not the force at their disposal to overcome the resistance to movement.

One must not, of course, mistake an analogy for an explanation and much remains to be explained. What is the role of negative chemotactic substance[4], what is the role of electrolytes and sugars[5], and why do all sorts of chemically unrelated compounds inhibit swarming[5]? Why do the cells not climb on top of each other? How is the movement of the large number of flagella on a swarm cell co-ordinated? What is the signal which sometimes leads to a cell reversing direction like a shuttle which has reached the limit of its travel? This long-observed phenomenon still presents many questions intriguing to the curious mind. The work described here makes no attempt to answer them and is, in fact, a description of the behaviour of swarming cells which must have been observed many times in the past even if it has not been described in these terms. It is interesting to note in this connexion that the excellent photographs of swarming cells presented by Hoeniger[6] show a number, of features illustrated in Fig. 1; she did not, however interpret them in the foregoing way.

It is perhaps of some consolation to the older bacteriologist that the application of simple, classical, techniques with the long-used tools of the bacteriologist's trade can still give rewarding information about a very old and intriguing problem.

INTERACTION OF BUBBLES AND BACTERIA IN THE FORMATION OF ORGANIC AGGREGATES IN SEA-WATER

By RICHARD T. BARBER

Hopkins Marine Station of Stanford University, Pacific Grove, California

MEASUREMENTS of particulate organic matter in the ocean have shown that below the top 200 m the amount of particulate material does not consistently decrease with increasing depth[1–5]. This conflicts with the observation that organic particles sink and are consumed by organisms as they do so[4]. The contradiction may be resolved by supposing that much of the particulate material in sea-water is formed by the aggregation of dissolved organic carbon[6–8] in a physical process by which organic molecules come out of solution to form an organic skin around a rising bubble. At the surface of the sea the bubble is ejected into the air, leaving behind its organic skin as a collapsed monomolecular film which then may sink through the water column, providing a seed on to which additional dissolved material may aggregate.

This physical process, promoting exchange between the dissolved and particulate organic pools of carbon in the ocean, has been used by ecologists to explain the common gap in the amount of food required by filter feeders and the amount of particulate food available to them in the form of phytoplankton cells and debris[9–13]. From this ecological point of view, it is important to be sure that the aggregation of dissolved material is a simple physical process and not the result of a complex interaction involving bacteria. The experiments described in this report were therefore designed to determine whether organic molecules will aggregate into discrete particles under conditions of complete sterility.

Carbon-14 incorporated into organic molecules was used to follow the distribution of the organic material. The labelled molecules were prepared by growing the diatom *Nitzschia closterium* in the presence of carbon-14 sodium bicarbonate. The labelled diatoms were concentrated and washed to remove inorganic carbon-14 and then ruptured by sonication. The particulate debris was spun down and discarded, and the supernatant containing the soluble cell material was passed through a 'Bio-Gel *P*-100' polyacrylamide gel column. This molecular gel, which retards molecules with a molecular weight usually less than 100,000, was hydrated and eluted with fresh '*HA* Millipore'-filtered sea-water. The retarded fraction was collected and added to fresh '*HA* Millipore'-filtered sea-water to make several litres of solution with about 120 c.p.m./ml. carbon-14 activity after correction for background and self-absorption. The sea-water used in these experiments was bucket-dipped as needed from Monterey Bay (California) at the site of the Hopkins Marine Station sea-water intake.

The foam tower was a modification of that described by Baylor and Sutcliffe[8]. Air bubbled through the solution was thoroughly heated to ensure combustion of any organic contaminants and was then cooled. Sterile barriers made it possible to draw the solution through a 'Millipore' filter into a 2-l. 'Plexiglas' foam tower, to bubble the solution, and to draw the solution out of the foam tower through a 'Millipore' filter without introducing contamination. All the components of this system were autoclaved before use and assembled aseptically. During the experiments, sterility was assayed by adding 1 ml. inocula from the foam tower to 'Difco *AC*' medium rehydrated with autoclaved sea-water.

The experimental assay is based on the assumption that if the labelled organic material in the bubbled sea-water forms aggregates, they will be retained on a 'Millipore'

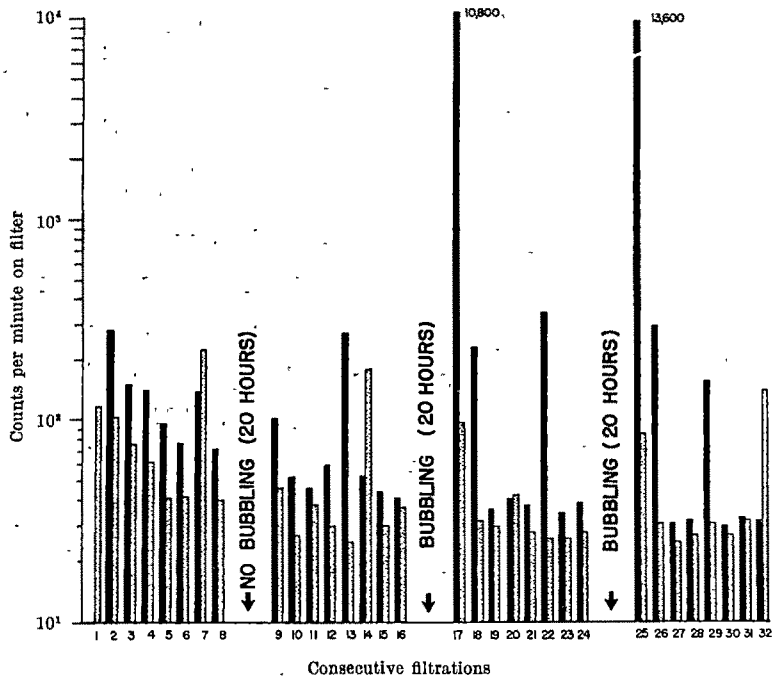

Fig. 1. The effect of bubbling a sea-water solution containing labelled organic molecules of molecular weight less than 100,000. Each bar represents the c.p.m. on a particular 'Millipore' filter through which the entire 1 l of solution has been passed. The solid bars show the results of experiment *A*, using '*HA* Millipore' (0·45-μ) filters; the stippled bars show the results of an identical experiment, experiment *B*, done with '*GS* Millipore' (0·22-μ) filters

filter when the solution is filtered. The amount of carbon-14 activity on the filter is assumed to reflect the amount of material aggregated. The 'Millipore' filters were mounted on planchets and counted by a Nuclear Chicago gas-flow counter, model *D*-47. Preliminary experiments showed that when a solution of labelled organic molecules is repeatedly filtered, the amount of organic material retained on the filters occasionally varies rather markedly. To establish the average amount of material retained on the filter, the solution was filtered eight times before and after all experimental and control treatments.

The data from two experiments using this procedure are shown in Fig. 1. The abscissa shows the sequence in which the solution was filtered and bubbled; the ordinate is a three-cycle log scale of counts per min (c.p.m.) on the filter. Each bar represents the c.p.m. on a particular 'Millipore' filter through which the entire solution passed. The solid bars show the results of experiment *A*, using '*HA* Millipore' (0·45-μ) filters; the stippled bars show the results of experiment *B*, identical with *A*, except that it was carried out with '*GS* Millipore' (0·22-μ) filters.

In experiment *A*, c.p.m. on the filter increased greatly following bubbling. After both the 20-h bubbling periods c.p.m. increased more than 200-fold, indicating that a significant amount of organic material came out of solution in the form of particles large enough to be retained on the filter. These data are shown in Fig. 1 by the solid bars of filtrations Nos. 17 and 25. However, the sterility assay showed that bacteria were present throughout. Anderson and Heffernan's[14] isolation of several marine microbes that readily pass through 0·45-μ filters suggested that it would be necessary to use a 0·22-μ filter to remove all the micro-organisms from the sea-water.

In experiment *B*, 0·22-μ rather than 0·45-μ filters were used for all thirty-two filtrations; the 20-h bubbling periods did not cause a significant increase in c.p.m., and the sterility assay showed that the sea-water solution was free from bacteria throughout the experiment. After the control treatment in experiment *A* there was no increase in c.p.m., indicating that when the filterable bacterium is present but not bubbled there is no increase in the amount of organic material retained on the filter. When an inoculum of the microbe isolated from experiment *A* was added to a sterile solution, a solution that had produced no aggregates, the c.p.m. on the filter increased after bubbling. These data suggest that neither bacteria alone nor bubbling alone will cause a significant increase in the amount of particulate material produced in this system.

When the 'Millipore' filters were cleared with immersion oil and examined under a phase microscope, the filters with increased c.p.m., that is, those from the filtrations following bubbling, were found to contain large amounts of detrital material. Much of the material on these filters appears to be identical to the organic aggregates described by Riley[9] and Wangersky[13]. Some are plate-like with definite, markedly refringent edges; others have very fuzzy edges and many small refringent inclusions. The relatively amorphous appearance of the aggregates on the filter and their similarity to the detrital material found in the sea indicate that the increased amount of organic material on the filters after bubbling does not represent merely an increase in the bacterial biomass.

Sieburth[16] found that without bubbling, natural bacterial populations formed aggregates when proteinaceous substrates were decomposed producing ammonia. He suggested that the microzonal alkalinization that must occur during ammonia liberation could initiate the precipitation of inorganic nuclei around which organic aggregates could form. Such a mechanism could be operating in the experiments described here.

Carlucci and Williams[15] showed that bubbling concentrates the bacteria in sea-water in the surface film and froth. In our experiments, such partitioning of the bacterial flora would not have been detected because the entire solution, water and foam, was filtered in all thirty-two filtrations. The increased amount of labelled organic material retained on the filter after bubbling represents a net increase in particulate matter in the complete system.

While more work is needed to clarify the interaction of bubbles and bacteria in the formation of aggregates from dissolved organic matter, it can be concluded from the experiments reported here that bubbling will not aggregate organic molecules of molecular weight less than 100,000 into discrete particles under sterile conditions.

This work was supported by a grant from the U.S. Public Health Service from the National Institute of General Medical Sciences.

ORGANOCHLORINE PESTICIDES IN THE ATMOSPHERE

By DR. D. C. ABBOTT, R. B. HARRISON, J. O'G. TATTON and DR. J. THOMSON

Laboratory of the Government Chemist, Cornwall House, Stamford Street, London, S.E.1

THE problems introduced by the pollution of our atmospheric environment have been concerned largely with those pollutants the effects and presence of which are readily demonstrated, for example, smog, sulphur dioxide, sooty materials and dusts. More recently, attention has been directed to the polynuclear hydrocarbons[1–3], although their presence in air is by no means solely of modern origin.

Recent publications have given evidence for the presence of some organochlorine pesticides in rainwater[4,5]. It has been suggested[5] that the minute traces found arose from the 'scrubbing' action of the falling rain on the air through which it passed, in a manner analogous to the collection of the inorganic constituents of rainwater[6]. The present work describes the experiments which have been carried out to ascertain the extent to which these organochlorine compounds are present in the atmosphere.

Pesticidal compounds may enter the atmospheric environment in several ways and in various physical states. Direct drift from spraying operations will contribute particulate or globular matter at concentrations which are likely to vary inversely as the distance from the site of application, such effects being mainly local but possibly appreciable in extent. It has been shown[7,8] that several organochlorine insecticides volatilize from treated soils, thus adding a slow, long-term contribution. Effluents and vapours from industrial processes, such as pesticide manufacture or moth-proofing of garments, may also contribute, while further quantities may accrue from the use of domestic aerosol insecticides and thermal vaporizers, and the dust from treated clothing and carpets.

Wheatley and Hardman[4] examined rainwater for traces of pesticides in order to try to account for residues found in soil from untreated plots of land. The amounts which they found were insufficient to account for more than a very small proportion of the pesticides present in such soil. Although the concentration of these compounds in air is lower by a factor in the range of 10–100 than that in rainwater, the vastly greater volumes of air may render this contribution of greater significance. As well as the normal, constantly changing contact between air and soil, the mass of air in surface soil may alter by up to 5 per cent owing to diurnal variations in temperature. Pesticides may thus be absorbed by the soil acting as a gas-solid chromatographic 'column' as well as by direct surface adsorption mechanisms. Assuming a tendency to equilibrium, treated soils will lose pesticides while untreated plots will gain them.

Preliminary experiments to illustrate the presence of pesticides in air were carried out by using a small portable constant-rate air-sampler which was used to suck air through a hexane trap. Although this method gave a total sample of only about 180 l. of air per power-canister, gas-liquid chromatography showed the presence of traces of BHC, DDT, DDE, TDE and dieldrin in samples taken in central London and its suburbs. Dieldrin alone was observed in a sample taken in Norfolk, while Aberystwyth air gave no detectable amounts of pesticide at this sample size. It was clear from these preliminary observations that an analytical problem existed and that larger samples would be required before reliable data could be obtained. Accordingly, an electrically operated vacuum pump capable of drawing 15 l. of air per min for long periods of time was brought into use. At this rate of flow hexane was too volatile, but dimethylformamide proved to be a suitable, non-volatile extractant. Examination of the separate contents of a sequential train of four solvent traps showed that nearly all the pesticide content was retained in the first vessel. Attempts have also been made to ascertain whether the pesticides present were in the vapour state or in association with the particulate matter of the air. Interposing bacteriological membrane filters (pore size 0·22 μ) between the air inlet and the solvent trap showed that variable proportions of the pesticides were retained on the filter. The amount retained, however, tended to reach an equilibrium value, indicating that the compounds were volatilizing again from the filter into the air stream. Similar effects have been observed with some polynuclear hydrocarbons[9]. Thus, although the use of membrane filters offers a simple qualitative test for pesticides in air, quantitative results can only be obtained by solvent scrubbing procedures.

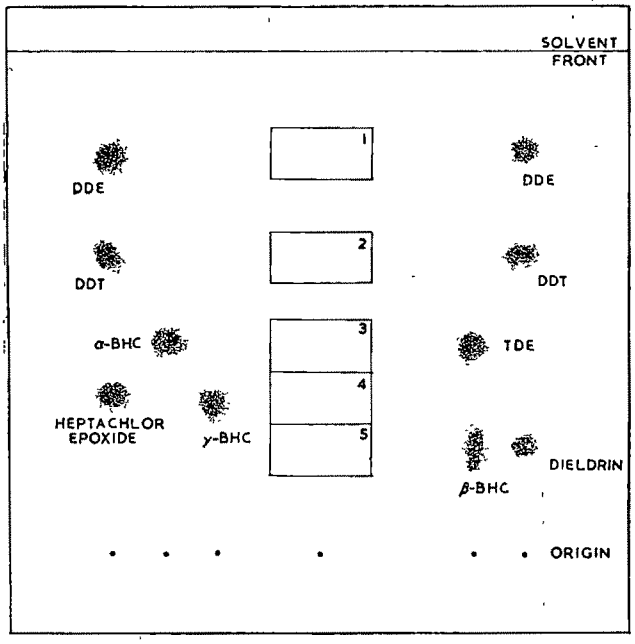

Fig. 1. Thin-layer chromatoplate

Metropolitan air was sampled by suction at about 15 l./min through 100 ml. of dimethylformamide contained in a Drechsel bottle fitted with a coarse sinter at the inlet to the solvent to ensure adequate diffusion. Dispersion of the solvent in 500 ml. of 5 per cent sodium sulphate solution followed by hexane extraction yielded a clean solution which, after evaporation to small bulk, was applied to a 250 μ silica-gel chromatoplate. This was developed with hexane : acetone, 99 + 1, for 35 min and appropriate fractions eluted with hexane[10] for examination by gas-liquid chromatography on both silicone and 'Apiezon' columns with electron-capture detection[11].

Fig. 1 shows the positions on the thin-layer plate of the more important organochlorine pesticides and indicates the areas containing the residues which were re-

moved for examination. Figs. 2–4 illustrate gas-chromatograph traces obtained from some of these areas; peaks corresponding to known pesticidal materials are marked—the other peaks have not been positively identified as yet. The appearance of a peak at the appropriate retention time on two chromatographic columns of differing polarity on injecting the eluate from the chromatoplate area of correct R_F value for the compound concerned has been taken as evidence of the identity of the compounds. Table 1 lists the quantities of pesticides found on examination of 8,000 l. of air taken on the roof of Cornwall House in August, 1965. The presence of alpha-BHC, gamma-BHC, dieldrin (HEOD), *pp'*-DDE, *pp'*-TDE and *pp'*-DDT was confirmed as already described; substantial agreement between quantitative results on both columns confirmed the absence of any appreciable amount of interfering non-pesticidal material of similar retention time.

Table 1. ORGANOCHLORINE PESTICIDES FOUND IN LONDON AIR

Compound	R_F range of chromatoplate area	Concentration found (parts per 10^{12} w/w) by gas-liquid chromatography on (a) Silicone *E*.301	(b) 'Apiezon *L*'
Alpha-BHC	0·37–0·48	1	1
Gamma-BHC	0 27–0·36	5	11
Dieldrin (HEOD)	0 17–0 26	18	21
pp'-DDE	0·75–0 84	4	7
pp'-DDT	0·54–0 64	3	3
pp'-TDE	0·37–0 48	3	8

Silica-gel chromatoplate developed with hexane : acetone, 99 + 1.
Silicone column: 1·2 per cent silicone *E*.301 plus 0·12 per cent 'Epikote 1001' on 'Silanized Chromosorb *G*' (70–80 mesh) at 158° C; nitrogen carrier gas, 100 ml./min.
'Apiezon' column: 3 per cent 'Apiezon *L*' plus 0·3 per cent 'Epikote 1001' on 'Celite 545' (100–120 mesh) at 186° C; nitrogen carrier gas, 100 ml./min.

Great care must be taken in the interpretation of the gas-liquid chromatograms obtained from air samples. Even after the thin-layer separation process used, each fraction from the plate contained several peaks of unidentified materials showing electron-capturing properties. Some of the short-retention time peaks (Fig. 3) corresponding to section 2 of the chromatoplate (R_F 0·54–0·66) have been tentatively identified as the polynuclear hydrocarbons acenaphthylene (R_F 0·57), anthracene (0·67), fluoranthene (0·57) and fluorene (0·70). Retention times on both columns confirmed these identities; these substances are known to be among the polynuclear hydrocarbon ingredients of atmospheric dusts[2,12].

The three peaks of longest retention times obtained from section 1 of the chromatoplate (Fig. 2) would seem to result from compounds the behaviour of which on the plate and on each column is identical with that shown by the compounds giving the first three of a series of unidentified peaks often found in chromatograms of extracts from

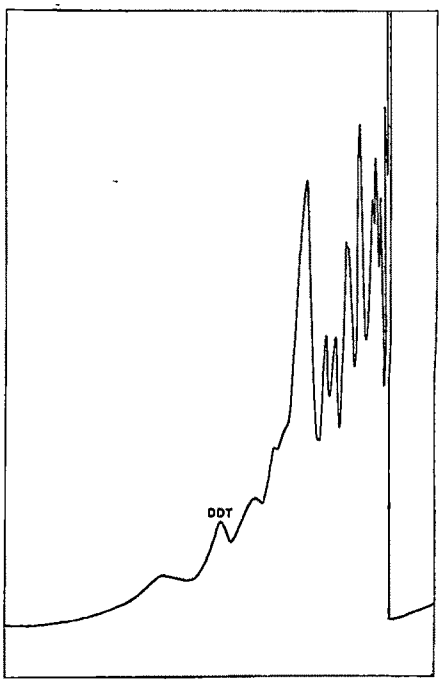

Fig. 3. Gas-liquid chromatogram from section 2 of the thin-layer chromatoplate

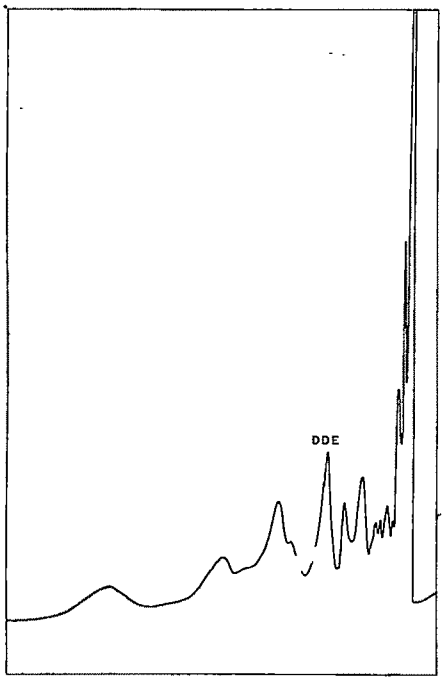

Fig. 2. Gas-liquid chromatogram from section 1 of the thin-layer chromatoplate

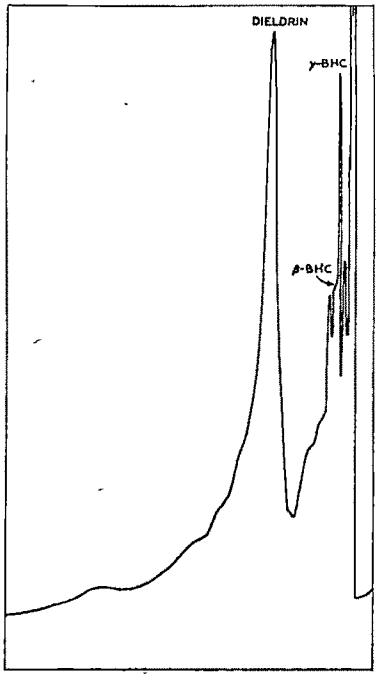

Fig. 4. Gas-liquid chromatogram from section 5 of the thin-layer chromatoplate

the tissue and eggs of some predatory birds. Their concentrations relative to each other in these two sample sources are also closely similar. Total chlorine determinations on avian tissue samples have indicated that these compounds contain chlorine, and because they are only found in samples containing appreciable residues they are probably breakdown products of organochlorine pesticides.

The evidence presented here and from rainwater examination[4,5] indicates the general occurrence in the atmosphere of minute traces of some of the persistent organochlorine pesticides. Such compounds have also been found in samples of air taken during the spraying season in American peach-orchard districts[13]. The concentrations of these residues are so low that it is necessary to work almost at the limit of sensitivity of the detection systems at present in use. For this reason, scrupulous care is necessary in order to avoid contamination at each manipulative stage, from the initial apparatus preparation to the final injection on to the gas chromatograph. Blank experiments must be performed at each stage and on all materials used. Particular care is required to exclude laboratory dust, for it is found that it is frequently a carrier of interfering electron-capturing materials.

Although the levels concerned are extremely low, these indications of the presence in air of organochlorine pesticides call for further and more detailed investigation. Confirmation of the identity of these residues by other methods such as infra-red spectroscopy or mass spectrometry would also be desirable, although far larger samples would be required in order to obtain sufficient material in a suitably pure state. It would also be of interest to compare the levels found in London with those found in other parts of the country; seasonal variation and correlation with other indices of atmospheric pollution would also be worth investigation. In these ways it may be possible to obtain some indication as to whether the pesticides derive from within the shores of the British Isles or from further afield.

HORMONES OF THE VERTEBRATE HOST CONTROLLING OVARIAN REGRESSION AND COPULATION OF THE RABBIT FLEA

By the Hon. MIRIAM ROTHSCHILD and BOB FORD
Ashton, Peterborough

In Nature, the rabbit flea (*Spilopsyllus cuniculi* Dale) only undergoes maturation on the healthy host during the last 10 days of the doe's pregnancy, or on nestlings 1–7 days old. Soon after the young rabbits are born, the fleas transfer to the nestlings, on which they feed avidly and pair: egg-laying on the body of the young and in the nest follows[1,2]. Between 8 and 22 (average 11) days later, the fleas abandon the young rabbits and return to the lactating doe. Any gravid fleas which remain on the doe after parturition, or are still gravid when they return to the lactating doe, regress rapidly and the developing oocytes are resorbed[1]. If, at a later date, the doe has a second pregnancy, these fleas are capable of undergoing maturation for a second time[3].

It was shown previously[3] that one of the principal groups of hormones governing maturation was the corticosteroids under the control of adrenocorticotrophic hormone (ACTH), while the oestrogens (and, to a lesser degree, thyroxine) played an important contributory part in development and egg-laying. It is probable that prolactin is a subsidiary factor in maintaining and promoting maturation on the nestling rabbits. The experiments described here indicate that luteinizing hormone (LH) and the progestins are two of the principal factors governing ovarian regression and that somatotropin (growth hormone), also secreted by the anterior lobe of the pituitary gland, constitutes one of the major "copulation factors".

Earlier, it was claimed[3–5] that not only fleas feeding on buck rabbits injected with cortisone, corticosterone or hydrocortisone, but also fleas sprayed externally with these hormones, matured their eggs and displayed the various characteristics associated with maturation. It was thus shown that the hormones acted directly on the flea and not indirectly by way of the host. During the early stages of the investigation, it was thought that the rise and fall of the corticosteroid-levels in the blood of the host, and, to a lesser degree, in the levels of oestrogens and thyroxine during pregnancy, were sufficient to account for both maturation and regression. Thus the increased defaecation rate, which indicated an increased flow of blood through the body of the flea in response to the rise in hormone-level, automatically ensured that larger amounts of both hormone and food were available to the parasite. Conversely, a fall in the hormone levels cut down the defaecation rate (Table 2) and the amount of blood passing through the body of the flea, thus further reducing the amount of available hormones and nutrient material. Reduction in food intake alone does not account for the rapid regression of the ovaries of fleas feeding on the postpartum or oestrous doe; gravid fleas removed from the host and completely starved do not

Table 1. Movement of Fleas between Doe and Nestlings

Total No. of litters observed	66
Successful litters in which at least some young survived 10 days or longer	51
Unsuccessful litters: (*a*) all dead	15
(*b*) some dead (16 of these litters born during winter months)	18
No. of litters in which some or all fleas transferred from postpartum doe to nest or nestlings (9 litters in which fleas were removed by hand are not included)	38
No. of litters in which no fleas transferred (14 were winter litters)	19
No. of litters in which all fleas transferred to nestlings or nest	
Mean No. of days in nest before returning to doe (range 8–22)	11
Average time (approx) for transfer from doe to young after parturition (range 10 min–26 h)	7–8 h
Day on which fleas of F^1 generation first emerged from pupa: Range 21–56 days Mean 30 days	

regress nearly as rapidly as they do when feeding on the non-pregnant host, and no resorption or degeneration is observed for 7 days after they have ceased feeding altogether[1].

Experiments were performed (Table 3) to test the possibility that other hormones, among them luteinizing hormone and progestins, are involved in the phenomenon of ovarian regression. Buck rabbits (New Zealand Whites), infested with fleas (bred in an artificial warren or collected from wild rabbits on the myxomatosis-free island of Herm, Channel Islands), were injected with 0·32–0·75 mg of hydrocortisone ('Hydrocortisyl', Roussel, London, *B.*6572/9G8T) until maturation of the female fleas was clearly visible externally and the defaecation

Table 2. DEFAECATION RATE OF FLEAS ON NORMAL AND INJECTED RABBITS

	Fleas feeding on oestrous does		Fleas feeding on pregnant does 3 days prepartum	Fleas feeding on pregnant does one day prepartum		Fleas maturing on does injected with cortisol	Fleas regressing after the does were injected with cortisol and progestin

Third period: prolactin (ovine) 5·0	Nil	8	Full maturation of some fleas only with chorionated eggs	1 · 10–14

rate had risen (from one pellet passed every 15–30 min) and stabilized at about one pellet passed every 6–8 min. This defaecation rate is characteristic of female fleas at about 3 days before parturition of the host (see Table 2) and before egg-laying commences. Following stabilization of the defaecation rate, 20 mg progesterone ('Progestin', B.D.H., London, 33326/13/2501, 40437/15/2506 and 24717/13/2408) was injected daily into the rabbits for a further period in addition to 0·32–0·50 mg of hydrocortisone. By the seventh day defaecation rates of the fleas had fallen to 1 : 20–40 min, resorption of the largest oocytes was occurring and empty follicles were present in the pedicels of the ovarioles. Little if any yolk could be seen in the developing oocytes. At the end of a further 6 days, resorption of developing oocytes was complete, yolk had been totally resorbed and the ovaries had regressed to a resting stage; the internal organs generally resembled those of spent fleas. The process of regression was then reversed by continuing daily injections of 0·32 mg of hydrocortisone only (without progesterone), for a further 14 days until maturation was again clearly visible externally; yolk was present in the developing oocytes and chorionated eggs were present in the oviducts of a proportion of the fleas sectioned. Regression and resorption could also be obtained not only by injecting the host, but also by spraying matured gravid fleas externally with progesterone or 20α-hydroxy-pregn-4-en-3-one (Roussel metered spray; 100 mg of progesterone dissolved in 30 ml. of fluid carrier; 20 mg of 20α-hydroxy-pregn-4-en-3-one dissolved in 12 ml. of fluid carrier) and then replacing them on doe or buck rabbits receiving 0·32 mg of hydrocortisone daily.

Rabbit fleas mature their ovaries if they are transferred on to castrated buck rabbits which have previously received 0·40 mg of hydrocortisone sprayed (externally) on to the tip of the ear with the Roussel spray[3]. It was possible to induce reduction of defaecation rate and ovarian regression of gravid fleas by feeding them on a female rabbit which had been sprayed externally with (i) 0·20 mg 20α-hydroxy-pregn-4-en-3-one (20α-OH) on the ear, and (ii) 2 mg chlormadinone (6-chloro 6-dehydro 17-acetoxy progesterone) on the flanks for 10 alternative successive days, although daily injections of 0·30–0·75 mg of hydrocortisone were continued throughout the experiments.

Luteinizing hormone was available for four experiments only. In the first experiment 2 mg of LH (*NIH/LH/S/7* ovine) were injected into an ovariectomized New Zealand White doe in three daily doses for a period of 6 days. No changes were observed in the fleas feeding on this rabbit. In the second experiment, fleas were matured on 0·30–0·50 mg of hydrocortisone injected into a buck New Zealand White rabbit, daily, for 20 days. On the tenth day, 2 mg of LH (*NIH/LH/S/6*, ovine, lot 1334) was also injected into the rabbit, in three daily doses, and continued for 10 days. The defaecation rate of the fleas began to fall on the fourth day and regression and resorption were complete by the ninth day. Three days only after the LH injections were stopped the fleas had fully matured and once again had chorionated eggs in their ovaries.

This experiment suggested that LH itself was probably exerting a direct effect on the fleas and not merely stimulating a high secretion of progestins and testosterone in the rabbit. Fleas which have regressed completely, owing to high blood levels (or prolonged effects of smaller levels) of these steroids, require a period of 9–14 days, or longer, in which to return to the chorionated egg stage of maturation.

In the third and fourth experiments a castrated buck and an ovariectomized doe were chosen as hosts, as it is unlikely that injections of LH stimulate the release of steroid hormones in these rabbits. The fleas were matured on daily injections of 0·75–1 mg of hydrocortisone (into the rabbit) for 15–18 days, a higher dosage being generally required to mature the parasites on the castrated host. Afterwards, for 10 days, 2 mg of LH (*NIH/LH/B/3* bovine) was injected in three daily doses in addition to hydrocortisone. The defaecation rate of the fleas fell by the fourth day and regression appeared complete by the eighth day. The fleas on the ovariectomized doe redeveloped on the seventh day after injections of LH had ceased; probably owing to the prolonged high dosage of cortisol required on the castrated host (see Table 3) redevelopment was slower than in the previous experiment.

No regression or resorption of the yolk or of the chorionated eggs was found in gravid matured fleas transferred to buck and doe rabbits which were later injected with 0·25–0·75 mg of hydrocortisone for periods ranging from 4 to 24 days, or injected with 0·32 mg of hydrocortisone together with (i) 5 mg of prolactin (National Institutes of Health, Bethesda, ovine prolactin 23116) for 5 days; (ii) oxytocin (10 units 'Pitocin', Parke Davis, Ltd., London, 3/160/12/16) for 5 days; and (iii) 2 mg oestradiol ('Oestroform', B.D.H., 33753/124/2501) for 9 days. No regression was observed if matured fleas were sprayed with the Roussel spray excipient only. Among the control samples there were a few exceptions in which fleas after 7 days (or longer) feeding on rabbits injected with 0·75 mg of hydrocortisone had either failed to respond or had responded and then afterwards regressed. It must be remembered that many of the fleas had previously been used in other experiments involving maturation and it has been noted that such fleas can fail to respond to further hormone stimulation. On the other hand, it is possible that with large pharmacological doses of either corticosteroids or oestrogens the fleas become exhausted and regression occurs spontaneously without the influence of either luteinizing hormone or progestins. It is therefore important, when LH or progesterone regression experiments are involved, to ascertain that, after the cessation of the experiment with the regression factor, the fleas can be brought back immediately to egg-laying when stimulated with corticosteroids.

Our experiments suggest that luteinizing hormone, progestins (and to a certain limited extent, testosterone) can play an active part in regression and resorption in the rabbit flea and, moreover, that these particular hormones exert a direct effect on the flea and do not act only indirectly by way of the host. In Nature, maturation followed by bouts of egg-laying in the nest may predispose the female flea to rapid regression on the postpartum host.

Insufficient 20α-OH was available to compare its activity with that of progesterone on the fleas' ovaries, as we were able to do in the case of corticosterone and hydrocortisone. In the rabbit[6], 20α-OH is two thirds less active weight for weight than progesterone and when direct applications were made to fleas a correspondingly low activity was anticipated. However, results suggested that 20α-OH is the more active of the two hormones in fleas when sprayed on externally—a somewhat surprising conclusion because the Roussel spray used contained about half as much 20α-OH per measured dose as the progesterone spray. Furthermore, the defaecation rate of fleas sprayed with the latter hormone returned to the pre-spraying rate (1 : 6–8) after about 9 days on a rabbit treated with hydrocortisyl, whereas those sprayed with 20α-OH remained below the pre-spraying rate for 21 days.

It is evident that the reduced intake of blood (estimated by the reduced defaecation rate), which is characteristic of fleas feeding on rabbits with a high blood-level of LH or progestins, plays an important part in regression. Apart from any other consideration, such as the reduction of nutrient material ingested, it follows that the intake of corticosteroids is thus drastically curtailed. It was noted earlier[3] that on thyroidectomized pregnant does maturation occurred without accelerated defaecation rates suggesting that maturation and yolk formation, although linked to faster feeding rates in Nature, were not dependent on it. Similarly, by raising the corticosteroid-levels of the blood very slightly (0·1 mg of hydrocortisone into the 10 lb. rabbit) yolk formation could be engendered in the fleas without raising their defaecation rate. A similar effect could be produced by injecting somewhat larger doses of corticosterone simultaneously with progesterone. Conversely, relatively large doses of progesterone injected into the rabbit, in conjunction with smaller doses of hydrocortisone, could produce the reverse effect, namely regression of the ovaries without a reduction in the feeding rate.

It would seem, therefore, that maturation, egg production, ovarian regression and the resting stages of the rabbit flea (feeding on both the doe and buck rabbit) depend on the relative blood-levels of various groups of hormones under the control of the anterior lobe of the pituitary gland. Maturation is probably delayed by the high levels of luteinizing hormone and progestins present during the early stages of the rabbits' pregnancy, even if the corticosteroid blood-levels have already begun to rise before the twentieth day, when maturation of the flea first becomes evident. Regression of fleas on the postpartum doe seems to indicate a higher level of progestin (particularly 20α-OH) circulating in the peripheral blood than has hitherto been suspected[7], because the corticosteroid levels are still somewhat elevated in the lactating doe[8]. It is of interest that regression of the fleas on the postpartum doe is more rapid if the rabbit is re-mated immediately following parturition when, in consequence, the level of luteinizing hormone and progestins in the blood is raised[9]. Nevertheless, at this stage of the life-cycle other factors may influence regression. It has been noted, for example, that fleas

which have been matured by spraying with oestradiol show, after 12 days, features reminiscent of the spent flea, which are rarely seen in fleas sprayed with corticosteroids, even after such fleas have been maintained for periods of several weeks in the matured condition. In particular, the secretions in the oviducts of oestradiol-sprayed fleas coalesce to form thin sheets of tissue[10]. If these fleas thus sprayed with oestradiol, are replaced on rabbits with high corticosteroid blood-levels, the characteristics of the spent flea become grossly exaggerated. It would appear, therefore, that oestrogen blood-levels may speed up egg-laying and the process of maturation and play some preparatory part in the regression of fleas which invariably occurs on the postpartum doe, in which the corticosteroid levels are still elevated.

In Nature, fleas do not mature on the healthy buck rabbit over the age of 10 days, although they may do so feeding on diseased rabbits[4]. The results of the experiments with testosterone were somewhat perplexing and, although the general picture suggests that this hormone acts as a long-term inhibitory factor, further experiments are required. If fleas are sprayed externally with testosterone and placed on a normal oestrus doe, no maturation occurs and no change in the defaecation rate and the state of the ovaries can be observed. If, on the other hand, fleas are first matured on a doe receiving daily injections of 0·75 mg of hydrocortisone, then sprayed with testosterone and replaced on the doe, the fleas temporarily increase their defaecation rate and lay eggs by the sixth day, and then regress, despite the continued injections into the host of 0·75 mg of cortisol daily, and are fully regressed by the fifteenth day, the defaecation rate dropping from 1 : 2–7 to 1 : 21–30. If fleas are fed on either oestrus does or ovariectomized does injected with 50 mg of testosterone every fourth day for 20 days, a somewhat similar picture is presented. There is uneven maturation of the fleas during the first week, but here without increase in the defaecation rate, although yolk is present in the oocytes, followed later by regression.

It was pointed out earlier[3] that the relationship between the hormone-levels, maturation and feeding behaviour of the fleas required further investigation, and this still remains true. There are indications that certain factors in the blood, apart from the various hormones mentioned above, play an important part in both initiating and maintaining maturation. This is clearly the case in other species of fleas because we have obtained maturation, pairing and egg-laying of *Xenopsylla cheopis* Roths. feeding for 5 days on the hypophysectomized male white rat, and maturation of *Nosopsyllus fasciatus* Bosc. and *Ceratophyllus gallinae* Schrank feeding for 5 and 12 days, respectively, on the castrated adrenalectomized male white rat. Furthermore, the rabbit flea does not undergo maturation on the pregnant cat—one of the few animals on which this host-specific flea will feed steadily. Certain cultures of the rabbit flea collected on Herm Island are relatively very resistant to cortisol and oestrogens injected into the host[11]. Furthermore, it is not at all clear how many of the various changes seen during maturation and regression arise directly from the larger or reduced intake of blood engendered by the influence of the hormone in question.

Copulation of the rabbit flea does not occur in Nature on the adult host but only on the new-born young from one to seven days of age[1,3]. The copulation factors (like the maturation factors) are most active in nestlings during the first day of life and thereafter wane fairly rapidly until at the seventh day few, if any, fleas are stimulated to copulate. The copulation factors were assumed to be present in the prepartum doe at low levels because, after feeding on certain individual pregnant does, mature fleas occasionally copulate if removed from the rabbit and placed in test-tubes. It was also noticed that sometimes males were stimulated to attempt copulation in the test-tubes but that they were not accepted by the females. Just as there is variation in the speed and degree of maturation of fleas feeding on individual does, so there is variation in the 'ripeness' for copulation of fleas feeding on individual prepartum female rabbits, and also in the time interval between parturition and their transfer to the nestlings from the postpartum doe (see Table 1).

If individual new-born young rabbits were placed in observation boxes and matured female fleas off a prepartum doe were removed from the doe's ears and introduced on to them, pairing first occurred after 40–50 min, whether the males present had fed and matured previously on the pregnant doe, or merely fed on a non-pregnant doe or buck. If, on the other hand, unmatured female fleas with ovaries at the resting stage were introduced, even together with males matured for 30 days on the prepartum doe, pairing did not occur until after these female fleas had fed for a minimum of 10 h on the day-old young. Copulation, and in some cases fertilization, then occurred, although the ovaries of these fleas had not yet matured and no yolk was as yet present in the oocytes. Again, if female fleas matured on the prepartum doe were transferred to the day-old young and allowed to feed on them for 3·5 h and male fleas then introduced, pairing occurred within 10–12 min, sometimes before the males had fed.

These observations indicate that it is the female which responds to the copulation factors—the male copulating directly she is ripe for pairing. Furthermore, copulation can precede maturation providing sufficient of the required factors are present in the blood of the host.

The act of leaving the doe for the young and possibly the change of temperature in the nest (which is lower than the ear (skin) temperature of the doe) may predispose the gravid female flea to copulate.

Preliminary trials with beef growth hormone (supplied by the Department of Biochemistry, Cambridge) in which 3-week-old nestlings were injected with 1·80 mg and a few pairs of gravid and matured fleas observed, afterwards, pairing on them, suggested that this hormone might provide one of the necessary factors for copulation. No rabbit growth hormone is available for experiments and therefore three trials were later carried out using human growth hormone (somatotropin, also supplied by the Department of Biochemistry, Cambridge). Two age-groups of rabbits were selected for these experiments: (*a*) 10-day-old rabbits, on which age-group we have not previously seen fleas pairing and from whose nest the fleas returned to the doe the same day on which the experiment was performed (indicating that these particular nestlings had ceased to be attractive to fleas). (*b*) Eight-week-old rabbits, an age-group which is still comparatively unattractive to fleas and on which copulation of fleas has not hitherto been observed.

Two 10-day-old nestlings from the same litter were placed in observation boxes and forty matured fleas from a doe, immediately prepartum, were introduced on to each of them. One of the nestlings was injected with 1·80 mg of human growth hormone dissolved in normal saline at 12.30 p.m. Two hours later, five pairs of fleas were copulating on this 10-day-old nestling, nine pairs at 3.15 p.m. and a further eight pairs at 3.45 p.m. No copulation had occurred up to this time on the control rabbit. Therefore at 4 p.m., 3·5 h after the commencement of the experiment, the control was in turn injected with 1·80 mg of human growth hormone. At 6 p.m. two pairs of fleas were seen in copulation on this rabbit, three further pairs at 7 p.m., and two pairs at 9 p.m. No further pairing was seen on either 10-day-old rabbit after 10 p.m. This experiment was repeated with two 10-day-old rabbits from another litter except that in this case the experimental rabbit was injected with 1·67 mg of human growth hormone dissolved in normal saline (at 3.40 p.m.) and the control rabbit received at the same time an injection of normal saline only. One hundred matured fleas were introduced on to each rabbit from a prepartum doe. One pair of fleas was seen in copulation before they were introduced to either

nestling. Pairing was first seen on the rabbit injected with growth hormone at 4.2 p.m., 22 min after transfer from the doe, when four pairs were seen to be copulating. A total of thirty pairs were counted up to 11.5 p.m. One pair of fleas was noted copulating on the control 35 min after their transfer from the doe, but no further pairing occurred on the control for the following 4 h. Therefore at 7 p.m. it was injected with 1·67 mg of growth hormone. One hour later three pairs were seen in copulation, and, in all, twenty-five pairs were counted on the control rabbit following the injection. Pairing was not observed on the experimental nestling after 11.5 p.m. but continued on the injected control until 2 a.m. when three pairs were still in copulation.

Gravid fleas do not behave in the same manner on the 10-day-old nestling as on the day-old nestling. Possibly the relatively high level of corticosteroids in the blood of the day-old rabbit[8] accounts for the fact that the fleas tend to scatter over the body without fixing to any specific area, feeding chiefly on the sacral regions and the flanks; the naked skin of the new-born rabbit may also play a part in determining their behaviour. The defaecation rate of fleas on the day-old nestling is at a maximum of 1 : 1–4 but drops steadily until on the 10-day-old it is about 1 : 30. Unmatured fleas, fed for 26 h on the 9–10-day-old rabbits and later sectioned, are found to show no trace of development, whereas those fed for similar periods on 1–2-day-old nestlings invariably display signs of maturation. On the 10-day-old rabbit the fleas, possibly in response to the longer hair and relative lack of certain hormones, tend to congregate on the head and fix in this position.

The experiment on the 8-week-old rabbit was far less satisfactory. One of these was injected with 4·50 mg of human growth hormone and forty fleas matured on a prepartum doe were introduced on to it. Observations were difficult in the longer hair of this age-group and were not considered altogether satisfactory. Three pairs of fleas were seen in copulation 4·5 h after the injection and none were observed on the control. All fleas on the injected rabbit were later sectioned, but only one specimen (despite the three observed pairing) had been successfully fertilized.

Although it seems clear that growth hormone is a powerful copulation factor if injected into young rabbits about the time when the fleas normally abandon them for the doe, yet it is insufficient to stimulate much pairing on the 8-week-old rabbit. Some other factors are probably required or else some inhibitory elements are present in the 8-week-old rabbit which counteract the effect of the growth hormone.

Fleas matured and feeding on adult rabbits were not stimulated to copulate by intramuscular and subcutaneous injections into the host of ACTH, hydrocortisone, corticosterone, cortisone, prolactin, oxytocin, adrenaline, oestradiol, luteinizing hormone, progesterone, 5-hydroxytryptamine, and fructose (intravenous injections) and 'Metopirone' (Ciba Laboratories, Ltd., Horsham, Sussex), nor by cholesterol administered orally to the host, or farnesol sprayed on to the fleas externally. No matured fleas were observed to pair on 10- or 12-day-old nestlings injected with hydrocortisone or normal saline, but two pairs were seen in copulation 14 h after an injection of 2·5 mg of prolactin (*NIH/P/S/6*, ovine), and one pair 40 min after an injection of 10 mg of testosterone.

There is considerable variation in the behaviour of copulating fleas. Bird fleas of the genus *Ceratophyllus* will pair immediately on emerging from their pupae without a blood meal[12], but the female (not the male) of *Xenopsylla* and *Echidnophaga* requires a blood meal before she will pair[13]. The specialized behaviour of the rabbit flea, in which the insect's copulation appears to be partly under the control of a protein hormone secreted by the anterior lobe of the pituitary gland of the host, seems to be unique.

The various changes associated with maturation can all be observed, with minor variations, during the maturation of *Xenopsylla*, *Echidnophaga*, *Nosopsyllus* and *Ceratophyllus*. Owing to the fact that maturation, pairing and egg-laying in the rabbit flea are compressed into a very short breeding period (10 days on the prepartum doe and 10 days in the nest), these changes appear with dramatic suddenness but, apart from the time element and certain specializations, such as the simultaneous maturation of large batches of eggs, and sperm bundles (which can also be observed in *Echidnophaga gallinacea*), the process of maturation is fundamentally similar in the four genera which have been observed and sectioned during their development from the unfed imago to fertilization and egg-laying. It is not, of course, known how the hormones of the rabbit act on the flea, but it is unlikely that they each exert a direct effect on the reproductive or other organs of the insect; it would seem more probable that they influence the release of the fleas' own hormones. It is possible to envisage a progressive increase in the release of the juvenile hormone, and a specific response in the various target organs in the flea to these different levels of juvenile hormone. The gradual increase in defaecation rate seen in both sexes of the flea during the last 10 days of the host's pregnancy could, for example, reflect a rise in the level of juvenile hormones released in response to the rise in blood levels of certain hormones in the host. It is also possible that a hormone resembling that recorded[14–16] from the corpus cardiacum of *Periplanata americana*[14,15] is concerned with the accelerated defaecation rate. This hormone, which is released by feeding, stimulates an increase in the rate and amplitude of the muscles of the heart, gut and Malpighian tubes. It is also claimed[16] that a factor (P_2), which is more or less specific for the hind gut, can be separated from extracts of the corpus cardiacum. On the other hand, it is also possible that a much lower level of juvenile hormone is sufficient to stimulate maturation without affecting the defaecation rate. Nevertheless, these observations suggest that the rabbit flea may have a specific hormone (distinct from the juvenile hormone controlling maturation[18,19]) which is concerned with the regulation of ovarian regression and resorption.

We thank Dr. D. Exley, Dr. R. J. Gellert, Prof. G. M. Harris, Dr. A. Stockell Hartree, Dr. K. Highram, Prof. H. Hinton, Prof. W. Klyne, Mr. K. McWhirter, Dr. J. Parsons, Dr. R. V. Short and also the Department of Biochemistry, University of Cambridge, the Department of Human Anatomy, University of Oxford, the National Institutes of Health, Bethesda, and the Upjohn Co., Michigan, for advice and gifts of hormone preparations. We also thank Mr. R. Lawrence and Dr. V. Wilson (Roussel Laboratories, London) for the preparation of the hormone sprays, Major A. J. Woods for assisting us in collecting the fleas from Herm, and Mr. W. G. Westley for cutting serial sections of fleas.

A FAST-NEUTRON SOURCE FOR RADIOTHERAPY

By DR. ROGER J. BERRY
Radiobiology Laboratory, Department of Radiotherapy, Churchill Hospital, Oxford
AND
DR. ROY E. ELLIS
Department of Physics, Medical College of St. Bartholomew's Hospital, London

As part of a comprehensive study of the effects of radiations of differing linear energy transfer (LET), dose-response curves for the survival of reproductive capacity of murine *P*-388 leukaemia cells were obtained *in vivo* after irradiation with fission-spectrum and 14-MeV monoenergetic fast neutrons[1] and after irradiation with cyclotron-produced fast neutrons with an average energy of 6 MeV (ref. 2). Comparison between the slopes of the dose-response curves indicated that there was a rather large difference in the radiosensitivity of these cells over a narrow range of difference in LET between the monoenergetic 14-MeV neutrons and those produced in the Medical Research Council's cyclotron at Hammersmith Hospital. On the basis of this difference, it was suggested that there might be similar gross differences in the sensitivity of anoxic tumour cells *in situ* over this narrow range of LET, and this would have important implications and limitations in the application of fast neutrons of these energies to clinical radiotherapy[3–5].

The present experiments were designed to repeat and extend Berry and Andrews's original observations[1] using 14-MeV monoenergetic neutrons, and to compare the response of tumour cells irradiated in a mouse in air with that of tumour cells in a mouse confined at 10 cm depth within a tissue-equivalent phantom to simulate the response of a deep-seated human tumour.

The *P*-388 lymphocytic leukaemia of the *DBA/2JN* mouse and the assay of the reproductive capacity of its cells by serial dilution techniques have been described previously[6]; the tumour does not provoke any detectable immune response from the brother–sister mated recipient animals of the $DBA/2JN_{oxf.}$ sub-line[2,6]. The statistical handling of the data has also been described[7]; the 'surviving fraction' (the fraction of cells retaining reproductive capacity after irradiation) was determined by the expression:

$$S.F. = \frac{E \text{ (irradiated)}}{E \text{ (control)}}$$

where E is a fraction analogous to the 'plating efficiency' of cells grown in clonal culture *in vitro*, and represents the percentage of morphologically intact tumour cells injected into recipient mice which are capable of producing tumours in those mice.

Tumour-bearing donor animals were irradiated 7 days after the intraperitoneal injection of 10^6 cells; at the time of irradiation their ascites fluid volume was 5–7 ml. and the majority of tumour cells were anoxic when the mouse itself was breathing air[6], so that the radiation survival curves obtained were those for anoxic tumour cells. The 14-MeV neutrons were produced in a *SAMES* neutron generator. Deuterons were accelerated by an electrostatic generator operating at 150 kV. At a beam current of 400–500 μamp, the deuterons were used to bombard a thin tritiated (titanium) target (5·5–9·5 c., initial activity) supplied by the Radiochemical Centre, Amersham. The radiation exposure was measured with a tissue-equivalent type '*B*' Rossi chamber[8], which had been calibrated against radium. This chamber was placed in the positions occupied by the tumour-bearing donor mice, and simultaneous readings were obtained with a remotely placed tissue-equivalent protection chamber which was connected to a vibrating reed electrometer. Instantaneous measurements of dose-rate were obtained on the remotely placed chamber at regular (5 min) intervals throughout the irradiation period. These were then integrated to give an estimate of the final total dose received by each individual mouse. Because of the rapid depletion of the tritium target at these high beam currents, the dose-rate varied during the exposure. At the position in which the tumour-bearing donor mice were irradiated, the maximum dose-rate was 11 rads/min and the minimum was 2·2 rads/min.

The polythene containers used to confine the mice during irradiation were identical with those used by Berry, Bewley and Parnell[2], as was the tank of tissue-equivalent solution used for irradiation of one tumour-bearing donor animal at a depth of 10 cm. The containers were placed 5 cm from the cooling water jacket around the tritium target and were rotated during the exposure to produce the most uniform distribution of radiation dose within the ascites fluid in the abdomen.

The results obtained in two separate experiments are shown in Table 1, and plotted graphically in Fig. 1. In addition, the earlier data obtained by Berry and Andrews[1] have been subjected to the improved statistical analysis[7] used in the present experiments, and are shown in Table 2 and plotted against the current results in Fig. 1. For purposes of comparison, the dose-response of anoxic *P*-388 leukaemia cells to X-rays, cyclotron-produced fast neutrons[2] and fission-spectrum fast neutrons[1] is also shown.

The present results extend the survival curve for 14-MeV neutrons below one cell in a thousand, and form a quite homogeneous set of observations. The response of tumour cells in the donor animal irradiated at a depth of 10 cm in tissue-equivalent material to simulate a deep-seated human tumour did not differ from the optimal regression line drawn through the data for survival of tumour cells irradiated in donor animals in air. This indicates that there is no significant change in the relative biological efficiency of these 14-MeV neutrons due to degradation of energy caused by passing through tissue to a depth of 10 cm.

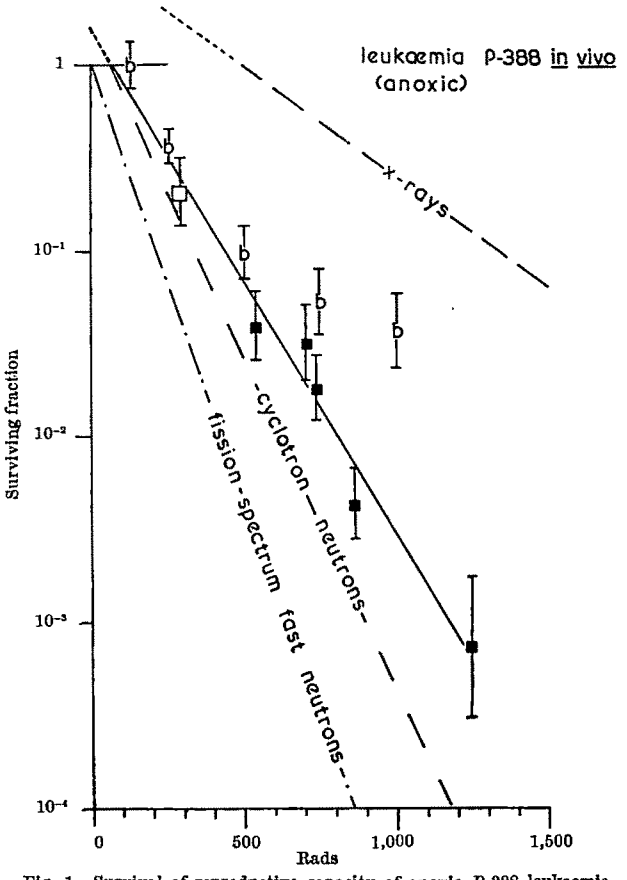

Fig. 1. Survival of reproductive capacity of anoxic *P*-388 leukaemia cells *in vivo*. ■, Present series of experiments, irradiation with 14-MeV monoenergetic neutrons, donor mouse irradiated in air; □, present experiment, irradiation with 14-MeV monoenergetic neutrons, donor mouse confined 10 cm deep in tissue-equivalent phantom; *b*, data re-calculated from Berry and Andrews[1], Irradiation with 14-MeV monoenergetic neutrons at Brookhaven National Laboratory. "X-rays, Cyclotron, Neutrons", data from Berry, Bewley and Parnell (ref. 2). "Fission-spectrum fast neutrons", data re-calculated from Berry and Andrews (ref. 1). The vertical bars indicate the standard error of each determination of fraction of surviving cells

The present results, however, differ somewhat from those obtained by Berry and Andrews in the earlier experiments[1] in which *P*-388 leukaemia cells were irradiated with 14-MeV neutrons produced in the Van de Graaf generator at the Brookhaven National Laboratory. The physical parameters of the radiation exposure, however, differed in that at Brookhaven a low, but relatively constant, dose-rate was achieved. It has been shown that *P*-388 cells are capable of recovery between fractionated acute X-ray doses spaced over 4 h apart[6,9], and that recovery occurs in these cells during protracted γ-irradiation at low dose-rates[10]. Recovery has also been shown to occur between fractionated acute doses of 14-MeV fast neutrons[1]. The initial agreement between the two sets of results at low radiation doses, followed by divergence between them at doses where the Brookhaven exposure times were excessively long (more than 8 h) owing to interruptions caused by temporary machine failures, etc., suggests that intra-cellular recovery during the radiation exposure may be an explanation of the differences observed; in the present series of experiments, none of the exposures exceeded 6 h in overall duration and the high initial dose-rate meant that a majority of the dose was delivered even more rapidly (presumably before recovery could occur).

The present results indicate that there is relatively little difference in the biological response of mammalian tumour cells to 14-MeV monoenergetic neutrons, and to the fast neutrons of quite similar average LET produced in the Medical Research Council's cyclotron. If the generators of 14-MeV neutrons can produce sufficiently high outputs[11], and the problems of collimation of a beam of these neutrons can be overcome[12] (as now seems practicable[13]), there now seems little doubt that irradiation with 14-MeV neutrons in clinical radiotherapy could produce a useful decrease in the protection normally afforded to tumour cells by anoxia[14] when they are irradiated with low-LET X- or gamma-radiation.

This work was supported by a grant from the Medical Research Council. We thank Prof. J. E. Roberts and Prof. J. Rotblat for permission to use the Middlesex Hospital neutron generator (at present installed at the Medical College of St. Bartholomew's Hospital). We also thank Prof. H. H. Rossi for donating the tissue equivalent liners for the type *B* chamber (the chamber was constructed by T. Cornell and J. Musgrove). We also thank Mr. J. Lewis and Mrs. Jeanne Crane for technical assistance.

INFRA-RED DETERMINATION OF THE PERCENTAGE OF CRYSTALLINITY IN APATITIC CALCIUM PHOSPHATES

By JOHN D. TERMINE and DR. AARON S. POSNER
The Hospital for Special Surgery, Cornell University Graduate School of Medical Sciences, New York

MANY solid systems contain an amorphous phase admixed with a crystalline phase. Because the exact proportion of the mixture contributes to the chemical and physical properties of the system, the measurement of the percentage of crystallinity (that is, the percentage by weight of the material found in the crystalline form) is of fundamental importance. Various methods such as X-ray diffraction, infra-red spectroscopy, specific volume and density measurements have been used to determine the ratio of the crystalline phase to the amorphous phase in polymers[1]. This report presents an infra-red spectrophotometric technique designed to measure the percentage of crystallinity on a series of apatitic calcium phosphates.

The first solid formed during the precipitation of hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, from a carbonate-free alkaline medium is a non-crystalline, or amorphous, calcium phosphate with a calcium to phosphorus molar ratio (Ca/P) of 1·50 (ref. 2). Afterwards, this solid in contact with the precipitating solution converts slowly to crystalline apatite (calcium : phosphorus = 1·67) by an autocatalytic mechanism[2]. By sampling the reaction at intermediate stages it is possible to obtain a series of

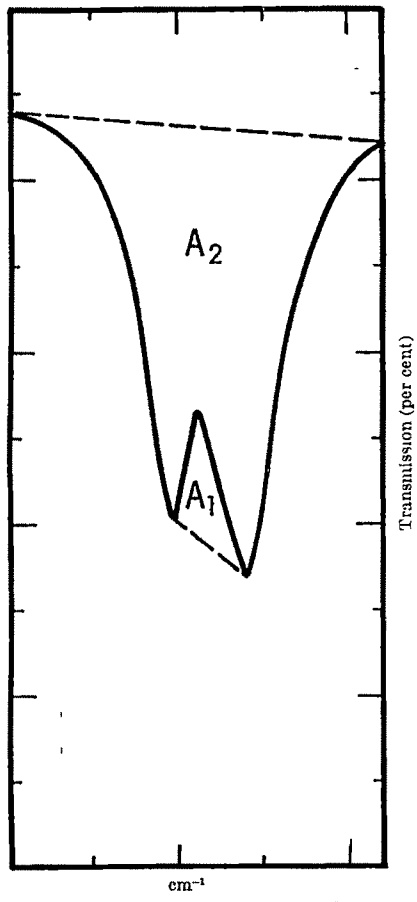

Fig. 1. Method of obtaining splitting function

calcium phosphates with varying amorphous to crystalline compositions with the crystalline content remaining at a constant crystallite size[2]. Infra-red spectra of the solids formed in the conversion of amorphous calcium phosphate to crystalline hydroxyapatite show a gradual splitting of the 600 cm^{-1} phosphate ion antisymmetric bending frequency (ν_4) from a broad singlet for amorphous calcium phosphate to a well-defined doublet for the fully crystalline solid[3]. Because the X-ray diffraction assay of the percentage of crystallinity has certain experimental limitations (for example, large sample size), we decided to use this infra-red splitting effect to develop a quantitative measure of the percentage of crystallinity of these mixtures of amorphous and crystalline calcium phosphates.

All infra-red absorption spectra were obtained on a Beckman *IR*-9 spectrophotometer by the potassium bromide pelleting technique; 700-mg disks of potassium bromide 22 mm in diameter, which contained 2·0 mg of sample (ground to 325 mesh) pressed at 52,000 lb./in.^{2} under vacuum, were used.

Standard samples of varying percentages of crystallinities were obtained by physically admixing, in a dental amalgamator, different proportions (by weight) of pure amorphous calcium phosphate and a pure crystalline hydroxyapatite prepared as described elsewhere[2]. Identification and purity of the phases used as standards were determined by X-ray diffraction. The Ca/P ratios for these standard mixtures were obtained by weight averaging the analyses obtained from the amorphous and crystalline phases in the proper proportion. These prepared mixtures, labelled as series 1, 2 and 3, ranged from 0 to 100 per cent crystalline. The methods of chemical and X-ray diffraction analyses used throughout provided a precision of ± 1 per cent for the Ca/P ratios and ± 10 per cent for the percentage of crystallinities.

A second specimen series, labelled VI, VII, VIII and XIII, was obtained by sampling the preparation of hydroxyapatite[2] at various times in the conversion of the precursor amorphous calcium phosphate to the final crystalline phase. The samples obtained in this manner ranged from 0 to 100 per cent in crystallinity as determined by X-ray diffraction.

X-ray diffraction line broadening showed the apatite crystals in both sample series examined by infra-red to have about the same crystal size. To ascertain the effect of crystal growth in the infra-red data, a preliminary examination was made of two synthetic hydroxyapatites (100 per cent crystalline) of differing crystal size ($\sim$ 125 Å and $\sim$450 Å in average *c*-axis crystal diameter).

The method of measuring the splitting of the phosphate ion antisymmetric bending mode at about 600 cm^{-1} is depicted in Fig. 1. As shown, a base line was drawn, by visual estimation, at the high transmission (top) end of the absorption band to mark the area limits, A_2, of the band. The two minimum points of transmission on the band were connected to form the splitting area, A_1. Both areas were measured by planimetry and the amount of splitting is given by the ratio of the two areas, A_1/A_2, and is defined as the splitting function (SF). For a completely amorphous calcium phosphate where a single broad peak exists, a value for the splitting function of zero is obtained as A_1 is equal to zero. The precision of the measurement of the splitting function was found to be ± 3 per cent.

A plot of splitting function values against X-ray diffraction-assayed percentage of crystallinity (per cent *C*) for both series of calcium phosphates is shown in Fig. 2. A statistical analysis of variance showed no significant differences in either splitting function or per cent *C* between standard mixture sample points (1, 2, 3) and experimentally obtained points (VI, VII, VIII, XIII). Using all the data, mixtures as well as experimental samples, a regression analysis yielded a line with a slope of 549·5 per cent *C*/SF units and an intercept on the abscissa of 6·4 per cent *C*. The correlation coefficient for this line is 0·799 and a statistical test for linearity was positive ($P < 0{\cdot}001$).

This plot shows that the infra-red splitting function measurement can serve as a quantitative measure of the percentage of crystallinity for the calcium phosphate system. Despite the low value of per cent *C* intercept on the abscissa, the practical lower limit of detection of the percentage of crystallinity by this infra-red method was found to be about 15 per cent. The precision of splitting function analysis above this lower limit is, as already stated, ± 3 per cent.

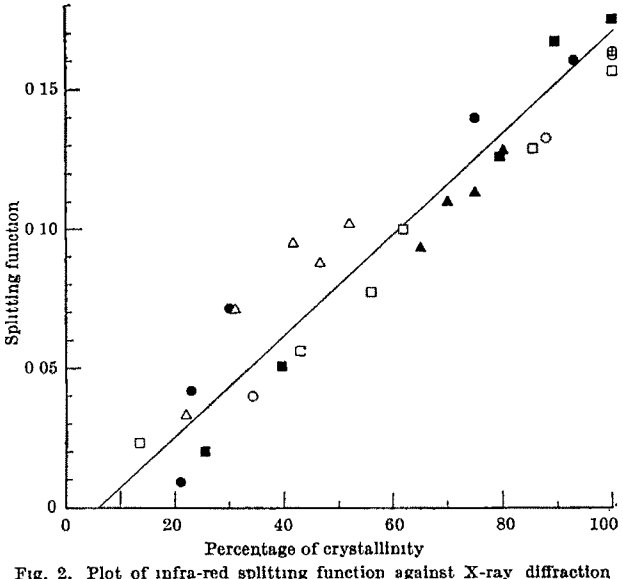

Fig. 2. Plot of infra-red splitting function against X-ray diffraction percentage of crystallinity of a series of calcium phosphate. ⊕, VI; ○, VII, ●, VIII, □, XIII, △, 1-, ■, 2-; ▲, 3-

Fig. 3 shows a plot of the splitting function against the Ca/P ratio for all the samples. Again, no significant differences could be observed between the standard mixtures and the samples obtained at various time intervals from the preparation of hydroxyapatite. Regression analysis yielded a line of slope 0·52 $\frac{\text{Ca/P}}{\text{SF}}$ units with an intercept on the abscissa of 1·51 Ca/P units. This line gave a correlation coefficient of 0·961 and a high level of linearity significance ($P < 0·001$). Thus, within the limits of the experiment, the splitting function values can be used as a means of obtaining the Ca/P ratio of a given calcium phosphate mixture of amorphous (Ca/P = 1·50) and crystalline hydroxyapatite (Ca/P = 1·67). Because the Ca/P and the per cent C of a given sample in both series are related, it is reasonable that both these values can be obtained from a measure of the splitting function.

The crystal size was shown to have an effect on the value of the splitting function of a fully crystalline hydroxyapatite. The values of the splitting function observed for the two extreme samples with sizes of about 125 Å and 450 Å were 0·155 and 0·250, respectively. This preliminary result points up the necessity for further investigation of the effect of crystal size on the infra-red splitting function factor. It should be emphasized, however, that all the samples examined in the foregoing study contained hydroxyapatite with the same crystal size.

This method of determining the percentage of crystallinity in a mixture of amorphous and apatitic calcium phosphates has a few simple advantages over the present X-ray diffraction method. The infra-red study uses only a few milligrams of sample, while the X-ray method requires at least twenty-five to fifty times as much. This could be particularly important in the analysis of such biological calcium phosphates as bone and tooth minerals, if organic matrix effects are taken into account. In addition, the time for the infra-red analysis is much

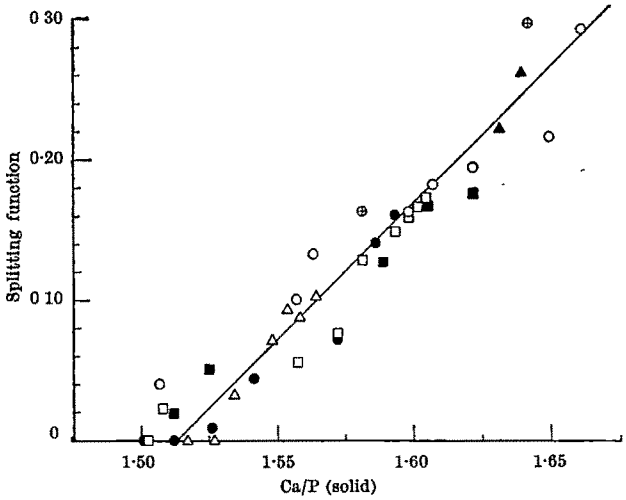

Fig. 3. Plot of infra-red splitting function against molar Ca/P of a calcium phosphate series. Symbols as in Fig 2

shorter than that required for X-ray diffraction analysis. The method should be immediately applicable to studies on bone and tooth minerals if the effect of crystal size is taken into account, where necessary. Application of the splitting function technique to other chemical systems is possible, but as this is an empirical method, experimental factors must be found suitable for the system under study.

The chemical analyses, X-ray diffraction studies, and certain calcium phosphate samples were provided by Drs. I. H. Gillessen and E. D. Eanes of this laboratory. This work was supported in part by a grant from the National Institute of Dental Research.

AGE OF ALLUVIAL CLAYS IN THE WESTERN GEZIRA, REPUBLIC OF THE SUDAN

By M. A. J. WILLIAMS
Research School of Pacific Studies, Australian National University, Canberra

THE Gezira plains occupy a triangle of about 5 million acres between the Blue Nile, the White Nile and the Kosti-Sennar railway-line. Khartoum forms the northern apex.

Tothill[1] noted that freshwater snail shells occur down to depths of 2 m in vertisolic clays in a belt of land up to 30 km wide on either side of the White Nile. He believed that the shells were laid down under swampy or lacustrine conditions. The climate would have resembled that now prevailing in the *toich*-lands north of Malakal (mean annual rainfall 820 mm; compare Kosti, 406 mm, Khartoum, 164 mm).

Sub-fossil shells of the land snail *Limicolaria flammata* (Cail.) are common in the upper few feet of Gezira clays in areas now too dry for it to survive[2]. *Limicolaria* is present in occupation sites near Khartoum dated by Arkell at between 5,000 B.C. and 3,000 B.C.[1,2]. The invasion of *Limicolaria* probably occurred when conditions became too dry for the aquatic mollusca, but still not as dry as now.

During the course of a recent reconnaissance soil survey along the White Nile, undertaken on behalf of the Sudan Ministry of Agriculture by Messrs. Hunting Technical Services, Ltd., I collected unbroken freshwater mollusc shells from soils of White Nile origin at distances up to 15 km from the present river.

One sample came from a pit 11 km east of Esh Shawal, in latitude 13° 34′ N., at a ground elevation of 381·5 m (3·75 m above local high river level). *Lanistes carinatus* (Oliv.) and *Cleopatra bulimoides* (Oliv.) occurred in a matrix of fine sandy loam at a depth of 145–170 cm, and were overlain by slightly calcareous clays. From carbon-14 measurements, it would seem that this shell layer was deposited 11,300 ± 400 years B.P. (Date by Isotopes, Inc., by courtesy of Prof. A. J. Whiteman, Department of Geology, University of Khartoum.)

Another sample came from a pit between Kawa and Hashaba, 2 km east of the river, in latitude 13° 56′ N., at a ground elevation of 381 m (*c.* 4 m above local high river level). Large shells of *Ampullaria wernei* (Phil.) were set in a silty calcareous matrix at a depth of 160–190 cm, and were overlain by a calcic horizon 10 cm thick. By carbon-14 dating it was found that these shells were laid down 8,370 ± 350 years B.P. (date by Isotopes Inc.). Above the carbonate pan, the calcareous clay contained a further shell band (depth 140–160 cm) for which no date is available, and this band is in turn overlain by dark grey cracking clay.

Tothill[3] regarded the 382 m strand-line at Hashaba, with its associated water-worn shells of *Cleopatra* and *Melanoides*, as the highest level attained by the White Nile lake at the time of its greatest development. Between 15 cm and 200 cm of clay overlie locally fossiliferous calcic layers in the Kawa-Hashaba-Esh Shawal area. In the first pit, more than 140 cm of clay were laid down some time after 10,900–11,700 B.P.; in the second pit more than 150 cm of clay were laid down after about 8,000–8,700 B.P. Deposition at the latter site was intermittent, with impeded drainage and calcium carbonate precipitation sufficient for the development of a calcrete pan, followed by a phase of perennially wet conditions during which aquatic mollusca flourished, and finally succeeded by a period characterized by seasonal swamps.

From dated shell-beds in silt terraces between the First and Third Cataracts[4], it would seem that aggradation on the Main Nile began between 30,000 and 15,000 years ago, and reached its peak about 10,000 years B.P. At Singa on the Blue Nile, Levallois-type implements were found in alluvial sands beneath snail-bearing alluvial clays which were in turn overlain by Neolithic artefacts[5]. These clays must therefore have been laid down at some stage after the formation of the lower Palaeolithic terrace and before about 6,000 B.P. The evidence from the Blue Nile and the Main Nile suggests that in Mesolithic times, deposition was roughly synchronous. At some time, after about 8,000–12,000 B.P., some 150 cm of clay were laid down over snail-bearing deposits of White Nile origin. It is still uncertain whether these later clays are of Blue Nile origin, as the abundance of gypsum and mica in them suggests, or whether they represent purely local aggradation in swamps bordering the receding White Nile.

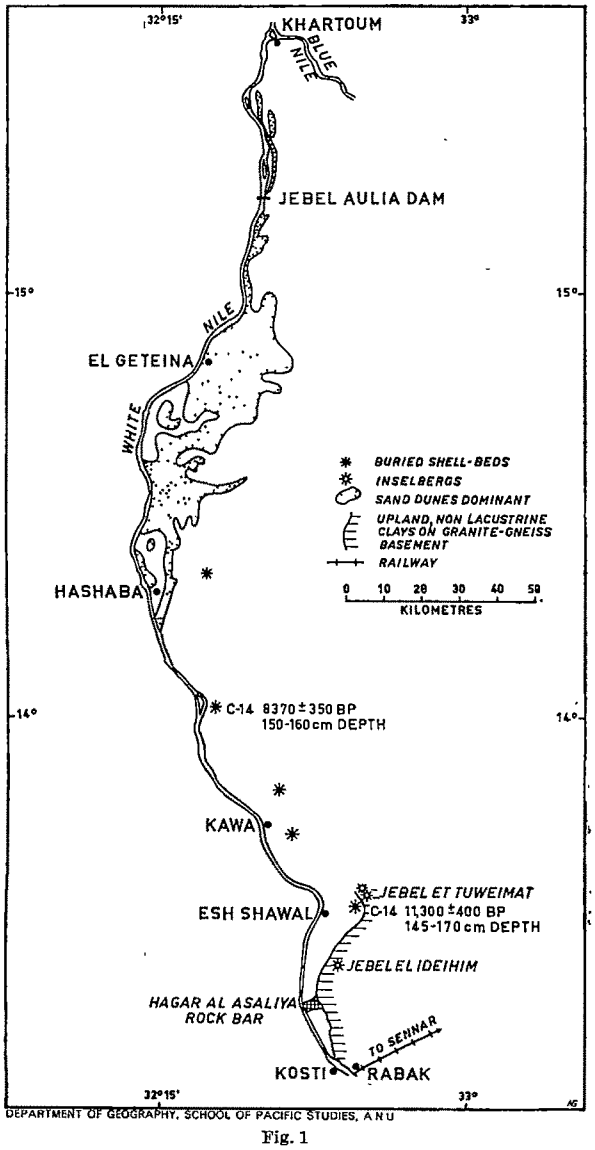

Fig. 1

To the north of Hashaba, winding sand dunes and former meander channels follow a sinuous course from south-south-east to north-north-west. They occupy perhaps 3–400,000 acres, and may be traced on air photo mosaics from near Sennar on the Blue Nile, through the scattered *qozes* of the Central Gezira, to the country around El Geteina, on the right bank of the White Nile, where they attain fullest development (Fig. 1). The dune sands overlie calcareous clays of unknown derivation, and Mesolithic and Neolithic artefacts are common on some of the dunes. It seems that as the White Nile dwindled to its present size, sandy distributaries of the proto-Blue Nile meandered across the alluvial clay plains left exposed by the receding White Nile lake and a series of sinuous channels with sandy bedloads came into being.

As discharge diminished, perhaps due to climatic desiccation, the channels were abandoned and their bedloads resorted by wind action. Inversion of relief occurred as channel deposits were raised into dunes by aeolian activity, levees were removed by deflation, and the formerly channelled localities became filled in and levelled off.

Conditions on the clay plains and inter-dune swales remained sufficiently unattractive (perhaps owing to swamps or to dense woodland) to discourage Mesolithic and Neolithic settlement other than on the dunes. Evidence[6] at Esh Shaheinab near Khartoum points to an annual rainfall of 800 mm in Mesolithic times, diminishing by Neolithic times (*c.* 4,000 B.C.). This accords with the inferred drainage chronology in the sand dune region around El Geteina.

The recent depositional history of the land bordering the right bank of the White Nile between Jebel Aulia and Rabak may be summarized as follows: Until about 8,000–12,000 years ago, the White Nile formed a lake up to 50 km wide which reached a height of 382 m. There is some evidence of a higher lake level at 386 m (ref. 7), and I found shell-beds in pits up to an elevation of 384 m. These lakes probably had similar surface gradients to the present river when the reservoir at Jebel Aulia is full (377·8 m elevation), at which time the gradient between the dam and Rabak is 0·1 cm/km.

Fine sands and silts were laid down in the 382 m lake as littoral deposits. They contain mica and gypsum, and are far too coarse in texture to be authigenic White Nile deposits. They are probably re-worked deposits of Blue Nile origin. As the lake shrank, up to 150 cm of clay were laid down under swampy conditions over the snail-bearing silts between Hashaba and Esh Shawal. North of Hashaba, the proto-Blue Nile transported medium to coarse sands in braided or meandering channels, and fine-textured sediments accumulated in back-plain situations. By about 6,000 B.P., annual rainfall had diminished to about 600 mm near Khartoum, the level of the White Nile had fallen to 0·5–1 m above its present mean high level, and the Blue Nile was either in the final stages of meandering across the clay plain north of El Geteina, or had already been diverted northwards to its present confluence with the White Nile at Khartoum.

ORIGIN OF TRITIUM IN HYDROTHERMAL SOLUTIONS

By STUART H. WILSON

Institute of Nuclear Sciences, Department of Scientific and Industrial Research, Private Bag, Lower Hutt, New Zealand

THE difficulty of deciding whether the tritium content of a natural water is a function only of the age of the water, or whether it arises from admixture of old water with new tritium, is particularly marked in the case of hydrothermal water. The results of forty-three determinations of the tritium content of the water tapped by drillholes at the Wairakei Geothermal Power Development have now been made available by Taylor *et al.*[1].

Wilson[2] recently discussed the tritium determinations in the light of the chloride contents of the bore waters and the enthalpies of the bore discharges, and concluded that even tritium concentrations of 0·1 T.U. could not be explained by dilution with surface water. (1 T.U. is a concentration of 1 tritium atom in 10^{18} hydrogen atoms.) The alternative explanation is that the tritium concentration indicates the lapse of time since pre-thermonuclear rainwater, of average tritium concentration 2 T.U., left the surface, was heated, and ascended again to be tapped by the bores. It is not only that the times indicated (the shortest is 40 years) do not seem long enough for the formation of a large body of heated water of volume at least 3 km^3, with fairly uniform chloride and heat content, but also that the variation in tritium concentrations from 0·05 to 2·3 T.U. for water from bores of good output does not seem likely if age is the explanation.

A possible cause of the occurrence of tritium seems to be the radioactivity of rock. Morrison and Pine[3], in giving evidence for the radiogenic origin of helium-3, estimate that a million alpha particles give a yield of two thermal neutrons, of which 5 per cent are captured by lithium-6 to produce tritium. Calculations, using estimates of the uranium, thorium and lithium contents and the water content of deep rock at Wairakei, show that the concentration of radiogenic tritium would be under 0·01 T.U.

My first new suggestion is that consideration must be given to the transport of radioactive elements by the deep geothermal water, and their deposition in more concentrated form. It is well known that uranium minerals may be deposited by low-temperature hydrothermal solutions, and the assumption is that the Wairakei underground water can also act as such an ore-forming fluid. Leonova[4] recently suggested that thorium can also be transported by low-temperature hydrothermal solutions. Further, the concentration of radium and radium-*D* can also be considered, along with the evidence at Wairakei[5] for the transportation and concentration of lithium.

If certain reasonable assumptions are made about the water content at great depth (4 per cent of the mass of the rock), and the flow of the water (0·5 cm/h), and it is assumed that uranium or radium is concentrated to 100 times the content normally present in rock, then a thickness of 100 m of such a deposit would give a concentration of 0·1 T.U. to the water.

There are enough consistent results on drillholes of high output and average enthalpy to give a good average result for the tritium concentration of the underground water in 1960. The value for seven samples was $0{\cdot}11 \pm 0{\cdot}01$ T.U. The possibility that this small concentration is due to radioactivity is of no great significance, but of fifty Wairakei samples collected from 1956 to 1963, twenty-eight were found to have tritium concentrations from 0·3 to 2·3 T.U.[1]. Many more determinations on rain and river waters have given values in agreement with reasonable hypotheses, and contamination or gross error in the above values is most unlikely. For most of the results, dilution can be excluded[2], and an age effect is unlikely so that it is particularly for these values that a more satisfactory explanation is required.

An additional hypothesis to explain these high values was suggested by a rough correlation with the enthalpy of the bore discharge. This suggested that high tritium concentrations were due to mixture near the bore intake of the underground water with steam held in pockets in rock with some concentration of radioactivity. If steam replaces water, and tritium production is the same, the T.U. values will be thirty times as great because of the lower density of steam. If the combined effect of increased radioactivity and lithium content of the rock is assumed to be fifty times that which is normal to the rock, it can be calculated that after 40 years (three times the half-life of tritium), the tritium concentration will be about 10 T.U. Of course the actual concentration will be less because some of the HTO will diffuse out of the steam and there may be some flow of steam (example below of reduction to 0·4 T.U.). In two cases given by Wilson[2], the enthalpy was known to be 340 cal/g instead of the normal 270, indicating a steam dilution of 20 per cent. The tritium concentration of the steam would have to be 2·6 T.U. to give the concentration found in the samples, 0·6 T.U.

The best evidence for a steam horizon in New Zealand is the blow-out at Hole 204, which is described by Bolton[6]. However, around the large fumarole, Karapiti Blowhole, there is a steaming area of 350,000 m^2 with a heat output of 100,000 kcal/sec. The average tritium concentration of four samples from the fumarole was $0{\cdot}8 \pm 0{\cdot}3$ T.U. This steam is coming from hot water about 600 m below and from this source it would bring 0·1 T.U. The ground water to cool the steam from 250° to 120° C could add only 0·15 T.U., a total of 0·25 T.U. The upward velocity of the steam is estimated as 8 cm/h, and allowance for this gives a calculated tritium concentration due to radioactivity of 0·4 T.U., giving a total in the steam of 0·7 T.U.

There is not yet much direct evidence in favour of this hypothesis. It is hard to prove the presence of excess steam in the discharges of high tritium bores, for the enthalpy is not measured at the time of sampling, and in many cases the excess steam will be steam flashed recently from underground water, and hence of low tritium concentration. If the steam is indeed from steam horizons in the country, then these should gradually be exhausted. From determinations on five bores at different times, it has been found that for an initial concentration of 1 T.U. the average decrease is 0·5 T.U./yr.

Well-logging equipment has been constructed by this Institute, but unfortunately it cannot be used above 180° C. Considerable differences in radioactivity were found by Ministry of Works engineers in three rather cold bores[7]. An eight-fold difference in gamma-ray counts was found at one bore at different levels in the same size casing, but this does not go far in supporting the assumptions made.

Investigations are required to check the different possibilities in the assumed production of tritium by alpha-rays. For instance, if lithium is absorbed on the surface of grains in porous rock, its local concentration may be so high that a much greater proportion than 5 per cent of the neutrons may be captured. The effect of radon in the steam would have to be considered, although in water it is ineffective in the production of tritium.

It may be objected that by juggling with assumptions one can make a case for the production of tritium by radioactivity. However, there is a good reason for not waiting for actual measurements before drawing attention to the

possibility of this origin for tritium. Soon, owing to the difficulty with high tritium levels in rain-water from bomb tests, there will be no interest in the use of tritium determinations on thermal waters for determining the age of the water. Dilution by surface water can be measured in other ways. It is difficult to apply any conclusions as to the age or the effect of radioactivity to thermal areas other than Wairakei. Only in this area has drilling made it possible to get enough data on the chloride and enthalpy of the underground water to exclude the possibility of dilution by surface water. However, in the case of steam from fumaroles or drillholes, in hot spring areas or volcanic craters, it may be possible from the temperature of the steam to set an upper limit to the dilution by surface water. However, this will be useful in the Southern Hemisphere only for samples collected before the autumn of 1962, and in the Northern Hemisphere before 1954, for after these dates tritium from bomb tests brought concentrations in rain to values over 10 T.U.

In New Zealand the only other samples of interest are from two drillholes at Kawerau (1·6 and 0·3 T.U.), and two from White Island crater[1] with tritium about 0·6 T.U. Results for other places are given in a list of the International Atomic Energy Agency[8]. Concentrations at hot springs in the United States are obviously due to surface water, except for one case of 0·6 T.U. at Lassen Park. The only values for steam are four samples from deep wells at Lardarello, Tuscany, and the tritium concentrations were 0·3–2·7 T.U. The impression has been given from the New Zealand results that the circulation time of geothermal water may be only 50 years[9], and the same deduction may have been made for Lardarello steam. It should be pointed out that a radioactive origin for most of the tritium would surmount the difficulty of accepting such a short age for geothermal waters.

The suggested origin of tritium will not apply to deep cold water, as this is unlikely to transport and concentrate uranium and radium. However, it would be of interest before it is too late to have determinations of tritium in water vapour saturating natural gas in underground reservoirs. Unless the outward diffusion of HTO was rapid, the concentration of tritium in this vapour due to natural radioactivity should be appreciable.

I thank Mr. C. B. Taylor of this Institute for drawing my attention to the article by Morrison and Pine, and for helpful discussions.

POLARITY OF THE EARTHQUAKE SOURCE

By Dr. F. F. EVISON
Geophysics Division, Department of Scientific and Industrial Research, Wellington, New Zealand

THE direction in which the ground first moves at the onset of an earthquake can give important information about the nature of the earthquake source. In a given earthquake, some seismograph stations record an initial compression (motion away from the source), and others an initial dilatation (motion towards the source). By projecting these observations back to the earthquake focus it is possible, in principle, to determine the pattern of first motions about the source. In practice only part of the pattern is ever well defined, the main reason being that all radiation from the upper half of the source reaches the surface within so small an area (of radius comparable with the focal depth) that few stations are in a position to observe this radiation.

Without any presuppositions about the mechanism of earthquakes it would be natural to analyse an observed pattern of first motion on the focal sphere into a series of components; for example, it might be possible to find a spherical component (either of compressions or of dilatations), a second component with compressions in one focal hemisphere and dilatations in the other, a third component with compressions and dilatations in alternate quadrants, and so on.

It is widely supposed, however, that earthquakes are generated by sudden fault movement, and that this movement produces an essentially quadrantal pattern of *P*-wave motion about the source—no other components being generated. In accord with this supposition, the analysis of recorded first motions has customarily taken the form of finding the orientation of that quadrantal pattern which best fits the observations, and thus arriving at a "fault-plane solution" for the earthquake. This does not mean that the observations definitely prescribe a quadrantal pattern; moreover, different authors have often given widely different quadrantal solutions for the same earthquake[1].

It is debatable whether or not fault movement really is the cause of earthquakes. It has been suggested[2] that sudden faulting may be but a gross kind of earthquake damage. Indeed, it is difficult to see how shear fracture, as usually understood, could occur at depths greater than a few kilometres, because the expected frictional forces become prohibitively large.

Thus there is scope for an investigation of first-motion patterns from points of view other than that of the fault hypothesis. A full analysis of the various components would require more accurate information about the amplitude of the initial wave than is at present available. If the simplest of these components—the spherical one—is important in the earthquake source, it will make the pattern of first motions for any given earthquake either dominantly compressional or dominantly dilatational; though in practice, because coverage of the focal sphere is limited, an observed dominance of one direction of first motion over the other is not conclusive evidence for a spherical component.

Polarity

Observations of first motions for a large number of earthquakes have been collected and tabulated by the Dominion Observatory, Ottawa, Canada. For sixty-five earthquakes in the period 1955–62 the number of observations per earthquake is a hundred or more. Data have been published[3–5] for the years 1955–58, and Dr. J. H. Hodgson has kindly provided me with data for 1959–62. The sixty-five earthquakes are well distributed over the major seismic regions of the world, and also in depth of focus; the magnitudes vary from 6·5 to 8·5.

The numbers of compressions (N_C) and dilatations (N_D) observed for these earthquakes are shown in Fig. 1, in which N_C is plotted against N_D for each earthquake. There is a clear tendency for one direction of first motion to be dominant over the other: in fifty-two earthquakes (80 per cent) the ratio exceeds 2 : 1; in thirty-eight earthquakes (58 per cent) the ratio exceeds 3:1. This is, in fact, what would be expected if the first motion at the

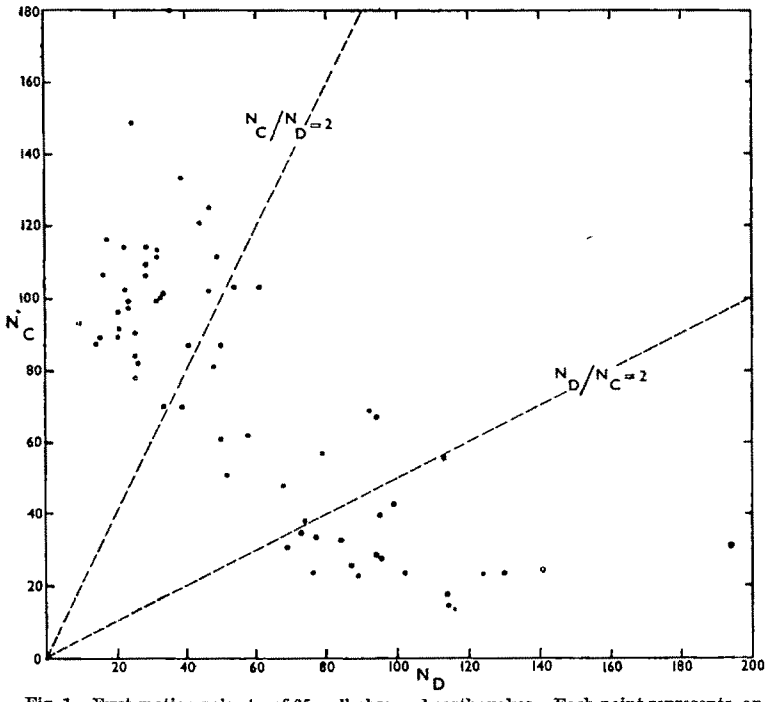

Fig. 1. First-motion polarity of 65 well-observed earthquakes. Each point represents an earthquake and shows the observed number of compressions (Nc) plotted against the observed number of dilatations (ND)

earthquake source had a strong spherical component; however, for reasons already mentioned, an apparent dominance could still arise from sources that were essentially hemispherical, or even of higher order.

Polarity and Environment

Of the sixty-five earthquakes investigated, forty gave a majority of compressional and twenty-five a majority of dilatational first motions. The polarity of an earthquake seems to be related to focal depth and geographical position. Adopting the earthquake parameters published by the U.S. Coast and Geodetic Survey, and bathymetry from the 1961 World Map published by the U.S. Navy Hydrographic Office, the following correlations are found. In most deep-focus earthquakes the first motions are dominantly dilatational: twelve out of fifteen earthquakes with a focal depth (h) of 200 km or more were dilatational. Most of the shallow-focus earthquakes which occur beneath deep ocean trenches are also dominantly dilatational: five out of six earthquakes with epicentres coinciding with a water depth (d) of 2,500 fathoms or more were dilatational. Most other earthquakes are dominantly compressional: thirty-six out of forty-four earthquakes with focal depths less than 200 km and epicentres on land or in water shallower than 2,500 fathoms were compressional. These statistics are summarized in Table 1.

The forty-four earthquakes in category (ii$b$) of Table 1 can be further classified according to geographical location, as in Table 2. Here it can be seen that compressions were dominant in twelve out of thirteen earthquakes located in island chains, in eighteen out of twenty-four on coasts (continental margins), and in six out of seven located in continental hinterlands.

Considering Table 1 as the formulation of a global rule about the occurrence of dominantly dilatational and dominantly compressional earthquakes, it is seen that the number of exceptions is 20 per cent or less in each of the three categories. This seems a remarkable degree of correlation, especially as some apparent exceptions to the proposed rule would result from uncertainties in the calculated epicentres and focal depths. For example, a strongly dilatational earthquake situated near the Chile–Argentina border was given a focal depth of 71 km by the U.S. Coast and Geodetic Survey, and appears as one of the exceptions in Tables 1 and 2; but the focal depth according to the U.S.S.R. Central Station, Moscow, was 250 km, which would make this earthquake conform to the rule. The possibility remains, though it seems remote, that the correlations are a fortuitous effect of such factors as the distribution of existing seismograph stations relative to the main seismic regions. Detailed work is in progress to examine such possibilities.

What physical significance can be ascribed to these apparent correlations between the polarity of the earthquake source and its geographical environment?

Geophysical Implications

Any interpretation of the observed polarity as arising from a strong spherical component in the earthquake source leads to a consideration of the source as (in part) a sudden volume change: an implosion for deep sources and for those shallow sources that are situated beneath deep ocean trenches; and an explosion for all other shallow sources.

Volume changes accompany many of the polymorphic transitions that occur in minerals within the range of pressure and temperature occurring in the upper mantle and crust. The idea that these solid–solid phase changes might be the immediate cause of earthquakes has been discussed by several authors[2,6–8], though it is not yet known whether such reactions could run sufficiently rapidly through the requisite quantity of material. Some support for this hypothesis of earthquake causation is implied by the unexpected similarity found between the seismic radiation from underground nuclear explosions and from natural earthquakes. The present study of radiation from a variety of well-observed earthquakes provides a more direct kind of evidence that earthquakes in general may be caused by sudden polymorphic transitions.

On this hypothesis, the opposite polarities of deep and shallow earthquakes are what one might expect. In those disturbed regions where most of the world's seismic, volcanic and diastrophic activity occurs one can envisage that the outer mantle is at present undergoing gravitative differentiation. As the heavier fractions sink they become concentrated under conditions of higher pressures; some minerals become unstable and implode to a denser polymorph, giving deep-focus earthquakes. At the same time the lighter fractions rise and become concentrated under conditions of lower pressure; some of these minerals become unstable and explode to a less dense polymorph, giving shallow-focus earthquakes.

Thus most earthquakes originating at shallow levels should be explosive in character, as in the present study. These earthquakes may be regarded as part of the process of diastrophic uplift, to which they contribute sporadic sudden increments. On the other hand, in certain limited

Table 1. NUMBERS OF EARTHQUAKES WITH DILATATIONS AND WITH COMPRESSIONS DOMINANT IN THE OBSERVED FIRST MOTIONS

	Dilatational	Compressional

(ii) $h < 200$ km		
(a) $d \geq 2{,}500$ fm	5	1
(b) $d < 2{,}500$ fm	8	36

Table 2 NUMBERS OF EARTHQUAKES ($h < 200$ KM, $d < 2{,}500$ FM) WITH DILATATIONS AND WITH COMPRESSIONS DOMINANT IN THE OBSERVED FIRST MOTIONS

	Dilatational	Compressional
Insular	1	12
Coastal	6	18
Continental	1	6

regions, as exemplified here by deep offshore trenches, the diastrophic tendency is one of subsidence, and implosive earthquakes prevail.

Because the disturbed regions of the world are by no means all alike, it is to be expected that the boundary between deep and shallow earthquakes (defined as h = 200 km in Table 1) and the boundary of ocean trenches (defined as d = 2,500 fm in Table 1) will actually differ somewhat from place to place. Furthermore, in the range of focal depth 200–700 km it is likely that a number of different polymorphic transitions would occur, and it is also conceivable that some might be explosive rather than implosive. Such variations may well account for some of the observed exceptions to the global rule given in Table 1.

The observed polarities could well be interpreted as arising not from a spherical component but from a hemispherical or higher-order one. On this supposition, I am unable to suggest how it would be possible to account for the correlations with focal depth and geographical location.

Earthquake Source

I propose that earthquakes can be classified as dominantly explosive or implosive, and that the observed polarity is in accord with the hypothesis that earthquakes are caused by sudden polymorphic transitions.

In the present investigation of the first motions observed in sixty-five well-recorded earthquakes the ratio of dilatations to compressions, or vice versa, is typically about 3 : 1. It is not suggested, however, that the minority observations are in error and that the pattern of first motions at the source is simply spherical. Higher-order components are presumably present. These in turn may perhaps be accounted for by the phase-change hypothesis; for example, a quadrantal distribution of compressions and dilatations is produced if a spherical body changes shape to an ellipsoid[9].

The conclusions arrived at in this study can be tested as observations of first motion of further earthquakes become available.

I thank Dr. R. M. Hamilton and other colleagues for their advice.

ORIGIN OF HIGH-ENERGY ELECTRONS BEYOND THE MAGNETOSPHERE

By C. S. SHEN
Department of Physics, Purdue University, Lafayette, Indiana
AND
C. C. CHANG
Department of Space Science and Applied Physics, The Catholic University of America, Washington, D.C.

EVIDENCE of the existence of high-energy electrons with energy $E \geq 30$ keV in the transition region beyond the magnetosphere was reported recently by Fan, Gloeckler and Simpson[1] and also by Anderson, Harris and Paoli[2]. As there can be no possibility of prolonged geomagnetic trapping in this region, the origin of these high-energy electrons is a problem of considerable interest. We suggest that, because of the characteristic geometry and distorted structure of the interplanetary magnetic field near the magnetopause in the transition region, these electrons are locally accelerated by means of a Parker–Wentzel version of the Fermi mechanism[3–5]. (Parker considered the acceleration of charged particles trapped between two shocks which cross each other. Wentzel considered the case that charged particles trapped ahead of a single shock wave which moves into a stronger magnetic field.) The general picture is illustrated in Fig. 1*a*, a modification of Ness *et al.*'s Fig. 40 (ref. 6). In the transition region II, which starts at the shock front, the solar wind and magnetic field can be considered as frozen-in and both are influenced by the downstream magnetosphere. The solar wind compresses interplanetary magnetic field against the magnetosphere. The field strength increases with distance. According to Ness *et al.*[6], it was observed to be turbulent and unsteady with finite amplitude. The unsteadiness can be considered as magnetohydrodynamic waves[7] propagating toward the downstream magnetopause. Because of the low density, the waves suffer no dissipation until they meet each other and build up a large amplitude pulse. The total field strength along the field lines inside the transition region may be expressed as:

$$B(Z,t) = B_0(Z,t) + \sum_i H_i(Z)\,\delta\,(Z - Z_i - U_i - t) \qquad (1)$$

where Z is the distance measured downstream from shock front along the line of force, $B_0(Z,t)$ is the background magnetic field, the strength of which in general increases as Z increases and depends weakly on the time t, that is, the interplanetary magnetic field is compressed against the magnetopause (compare Fig. 1*a* and Fig. 1*b*). Z_i is the position of the ith magnetic pulse with strength $H_i(Z)$ at $t=0$, and U_i is the parallel component of Alfven wave velocity of the travelling magnetic pulse along the field line based approximately on B_0. In such a collisionless region, the thickness of these large amplitude hydromagnetic waves is expected to be of the order of the Larmor radius of a thermal ion[7], which is much larger than the electron's Larmor radius. Thus the local electrons with pitch angles larger than

$$\tan^{-1}\left[\frac{B_0(Z)}{H_i(Z)}\right]^{\frac{1}{2}}$$

will be trapped by the advancing pulse and be pushed toward the stronger magnetic field. The equation of motion for a charge particle in an adiabatically varying magnetic field is:

$$\frac{\mathrm{d}}{\mathrm{d}t}(mV_{\parallel}) = -\mu\,\frac{\partial B(Z,t)}{\partial Z} \qquad (2)$$

Here, $V_{\parallel}$ is the parallel (to the field line) component velocity of the particle and

$$\mu = \frac{W_{\perp}}{B}$$

is an adiabatic invariant, where $W_{\perp}$ is the transverse component of the particle's kinetic energy.

Equation (2) indicates, as is well known, that the longitudinal motion of a particle in an adiabatically varying field is mathematically equivalent to that of the motion of a particle under the force of a one-dimensional potential $\mu B(Z,t)$. In our case, μ being an invariant,

the potential is related to two parts of the magnetic field. One part is a "hill", that is, the background magnetic field B_0, and the other part is a series of barriers, that is, the magnetic pulses $H_i(Z)$, which move up the hill with velocity U_i. Note that the transverse kinetic energy of the particle is identical with the potential μB. Therefore the kinetic energy of the particle in this one-dimensional model is the actual longitudinal kinetic energy $W_\parallel$ in the three-dimensional space, while its potential energy is the actual transverse kinetic energy, $W_\perp$.

The collision of the particle with the advancing pulse pushes the particle up the hill until all its kinetic energy is converted into the potential energy, then the particle starts to move backward and meets with the pulse again. Each collision increases the particle's energy by an amount of $4V_\parallel U + 4U^2$. Because the pulse is moving up the hill toward a stronger field, a part of this energy is transformed to potential energy.

The collision process repeats itself until the kinetic energy of the particle becomes larger than the height of the pulse or "barrier", at the point Z_2, $W_\parallel(Z_2) \geq \mu H(Z_2)$ then the particle will roll over the crest of the pulse and go down the hill. (Some of the particles with large longitudinal kinetic energy may overcome the "hill" and leak to the dark side of the Earth.) Let Z_1 be the point where the particle was first trapped by the pulse. We have:

$$W_\perp(Z_2) = \mu B_0(Z_2) = \frac{B_0(Z_2,t_2)}{B_0(Z_1,t_1)} W_\perp(Z_1) \qquad (3)$$

$$W_\parallel(Z_2) \geq \mu H(Z_2) = \frac{H(Z_2,t_2)}{B_0(Z_1,t_1)} W_\perp(Z_1) \qquad (4)$$

On the other hand, the particle can be trapped by the pulse at Z_1, only if:

$$\frac{W_\perp(Z_1)}{W_\parallel(Z_1)} \geq \frac{B_0(Z_1,t_1)}{H(Z_1,t_1)} \qquad (5)$$

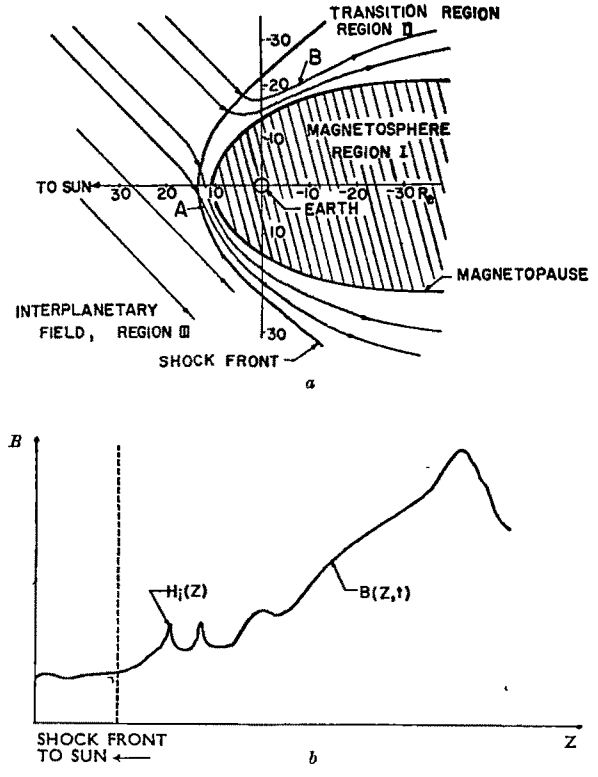

Fig. 1. *a*, The structure of magnetic field outside the magnetosphere on the ecliptic plane. Charged particles move along the field line where the line drifts towards the east because of rotation of the Sun. *A* and *B* are bottlenecks of magnetic field. *b*, Total magnetic field stength $B(Z,t)$ along the magnetic line. $H_i(Z)$ refers to the position of the pulses

Combining (3), (4) and (5) we obtain:

$$W(Z_2) \geq \frac{B_0(Z_2,t_2) + H(Z_2,t_2)}{B_0(Z_1,t_1) + H(Z_1,t_1)} W(Z_1) \qquad (6)$$

Equation (6) gives the energy gain of the particle in a single trip.

Consider Z_1 to be some point in the outer transition region and Z_2 to be some point along the background magnetic lines where the magnetic field increases in strength near the shoulder of the magnetopause. We may assume some values of B_0 and H consistent with *Explorer* 18 measurements: $B_0(Z_1) \sim 7\gamma, H(Z_1) \sim 7\gamma, B_0(Z_2) \sim 30\gamma$ and $H(Z_2) \sim 7\gamma$.

This gives $W(Z_2) \approx 3W(Z_1)$.

Clearly it is unlikely that electrons trapped only once can be accelerated to 30 keV energy.

Now consider the situation after the particle rolls over the crest of the pulse; as it moves down the hill, its transverse kinetic energy is converted into longitudinal kinetic energy. Without some kind of effective redistribution mechanism of the longitudinal energy, the particle just rolls backward over successive pulses and can scarcely be trapped again. We propose that superimposed on B_0 are small-scale magnetic turbulence or irregularities due to local current loops. These irregularities scatter electrons and randomize their energy distribution[8]. The transfer of energy by scattering from one component to another is proportional to the degree of anisotropicity. Parker[8] also found out that scattering efficiency diminishes as the scale of irregularity becomes either large or small compared to the Larmor radius of the particle and is maximum when the scale is comparable with the Larmor radius. Thus, whether the particle can be retrapped or not depends on the density of irregularities or the average scale of the magnetic eddies. If the condition

$$\frac{W_\perp}{W_\parallel} > \frac{B}{H}$$

can be re-established before the particle escapes from the transition region (that is, across the shock boundary), the particle will again be trapped by the wave train of advancing pulses and be pushed up to the stronger field. Under ideal conditions, this process of acceleration and redistribution will repeat itself and boost up the kinetic energy of the electron until its Larmor radius becomes comparable with the thickness of the magnetic pulse, which is estimated to be of the order of the Larmor radius of a thermal ion ($W \sim 1$ keV). This gives the electron energy an upper limit of 2×10^3 keV.

The time required to boost the energy of an electron to 30 keV can also be estimated. The electrons are trapped by the magnetic pulse in the outer portion of the transition region and penetrate the pulse near the magnetopause. Thus the distance travelled by the pulse is 10,000 km. Assume the propagation velocity of the pulse is ~ 100 km/sec (the Alfvén velocity in the transition region), then it takes 100 sec to triple the energy of the electron. Therefore, for an electron with initial energy X in eV, $10^2 \log_3 \frac{(3 \times 10^4)}{X}$ sec are needed to increase its energy to 30 keV. For example, to reach 30 keV energy a 10 eV electron has to be trapped seven times and the time required is ~ 10 min.

In this calculation we have assumed μ to be a constant as the particle was trapped ahead of the magnetic pulse and advancing toward a stronger field. The scattering of the small-scale field with the particle will change the value of μ and, in general, will increase the energy gain per trip. An elaborate calculation included this effect, and the effect of attenuation of large amplitude waves was carried out and will be published elsewhere[9]. However, the inclusion of these factors does not affect the basic assumptions and the major consequences of the proposed acceleration process. They may be listed as follows.

Basic assumptions. (1) There are large amplitude waves propagating toward the magnetopause causing the trapping of electrons. (2) There are small-scale magnetic irregularities or turbulences causing the redistribution of the energy of the electron. (3) The interplanetary magnetic field in the transition region is, in general, stronger near the magnetopause through compression than in the outer portion of the region.

Major consequences. (1) Only electrons are accelerated. (2) The accelerated electrons tend to bunch in the magnetic valleys because the trapping regions are ahead of the wave. (3) The velocity distribution of the accelerated electrons is anisotropic. (4) The intensity of the high-energy electrons is closely correlated with the degree of disturbance of the magnetic field in the transition region (the evidence of the presence of large amplitude waves). After the transition region is hit by a magnetic storm, there should be a time lag of the order of a few minutes before any increase in the intensity of high-energy electrons. (5) The accelerated electrons may leak out of the shock front to interplanetary space immediately after a magnetic storm. They may also be pushed over the "hill" (the bottleneck part of the field shown in Fig. 1*a*) and leak to the dark side of the Earth.

Comparison with the existing experimental measurement[1,2] indicates good qualitative agreement for consequences (1), (2), (4) and (5). The angular distribution of the high-energy electrons, so far as we know, has yet to be measured. So there is no comparison for consequence (3) now. However, we think this is the most interesting consequence. According to the proposed mechanism, after the particle has been pushed up the "hill" and is about to penetrate the magnetic pulse at Z' (compare with Fig. 2)

$$W_{\parallel} \approx \frac{H(Z')}{B(Z')} W_{\perp} \text{ and } \tan^2\theta \approx \frac{B(Z')}{H(Z')} > 1$$

But after it penetrates the pulse and moves down the hill, most of its energy is transformed to the longitudinal component. Conservation of energy gives:

$$W_{\parallel}(Z'') \approx \frac{H(Z') + B(Z') - B(Z'')}{H(Z') + B(Z')} W$$

$$\text{and } \tan^2\theta \approx \frac{B(Z'')}{H(Z') + B(Z') - B(Z'')} < 1$$

As it moves further away from the magnetopause toward the outer transition region the scattering with small-scale irregularities gradually smears out the asymmetry and and $\tan^2\theta$ approaches unit.

A measurement of the pitch angle along the field line would strongly indicate the correctness of our conjecture.

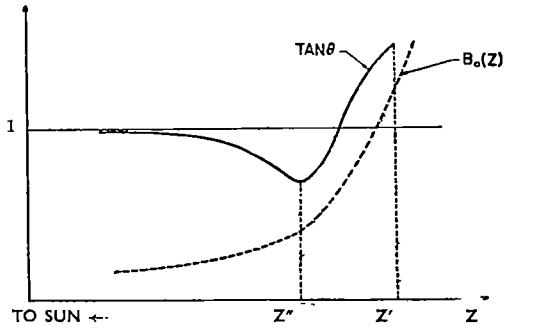

Fig. 2. Estimated distribution of pitch angle θ and the background $B_o(Z)$ along the magnetic line

Jokipii and Davis have suggested[10] that these high-energy electrons are accelerated outside the shock front (that is, in the region III) by a Fermi mechanism similar to that discussed in our model. As they pointed out, it takes 200 reflexions to accelerate a 1-keV electron to 50 keV in their model. Because the strength of the background magnetic field in the interplanetary region is more or less flat, reflexions between magnetic fluctuation and shock front increase only the longitudinal energy of electrons. Thus it requires extremely efficient randomization to keep the electrons trapped for 200 reflexions. In the model we discussed, the acceleration occurs inside the transition region near the shoulder of the magnetopause. Because of the gradual increase of the field strength there, the pitch angle of the electrons can be kept from decreasing even without efficient randomization. This is required only when the electrons are not trapped by but roll over the advancing magnetic pulse. The distance travelled then is many times that in a single reflexion, and a 1-keV electron needs to be trapped only three or four times to increase its energy to 30 keV. Thus comparatively the requirement on randomization efficiency is more relaxed in our model than in that of Jokipii and Davis.

ON THE ORIGIN OF THE MICROWAVE BACKGROUND RADIATION

By DR. D. W. SCIAMA
Department of Applied Mathematics and Theoretical Physics, Silver Street, Cambridge

THE recently discovered microwave background radiation[1–3] is far more intense than was expected, and its existence has led to many speculations. Between 3·2 cm and 20·7 cm its spectrum is approximately thermal with an effective temperature $\sim 3°$ K. Dicke *et al.*[4] have suggested that it is in fact black-body radiation at $\sim 3°$ K, and that this radiation is a residue from the "hot big bang" origin of the universe (this residue would be expected to consist of black-body radiation, except possibly in the neighbourhood of 300μ and 30 cm[5]). In support of this suggestion, Field and Hitchcock[6] have argued that the observed[7,8] excitation of interstellar CN molecules indicates a radiation temperature $\sim 3°$ K at a wave-length of 2·6 mm, which again is far more intense than that due to any known sources.

The demonstration that the microwave background consists of black-body radiation would be of the utmost importance for cosmology. In the first place it would almost certainly enable the steady-state model to be ruled out. Secondly, it would give considerable information about the early stages of the universe which would be of interest in itself and of importance for a number of problems, such as the formation of galaxies[9,10] and of helium[11–13], and the role of quarks[14] (if they exist) in the early stages. Thirdly, the resulting universal radiation density of ~ 1 eV cm^{-3} would be large enough to have

several important direct effects, such as inverse Compton collisions with relativistic electrons in galaxies, radio galaxies and intergalactic space[15–18], absorption of high-energy cosmic γ-rays[19,20], and the slowing-down of the highest energy cosmic ray particles[21]. In view of all these consequences of the universal existence of a 3° K blackbody radiation field it is important to be sure that there is no alternative explanation of the observations. My aim in this article is to show that an alternative explanation does in fact exist.

In the first place the CN excitation could arise from collisions with protons and electrons, as Thaddeus and Clauser[8] have shown. They find that the ionized gas density required ~ 1 cm^{-3} (not 100 cm^{-3} as Field and Hitchcock state), which is reasonable[22] if the CN molecules are formed in the vicinity of an HI/HII boundary, as Münch[23] had previously suggested. A similar suggestion has recently been made[24] for the place of origin of OH molecules. Admittedly two different regions in the galaxy show[6] a similar degree of CN excitation as would be expected if the excitation mechanism were universal, but such studies will have to be extended before this evidence becomes conclusive. Now the maximum of the blackbody spectrum at 3° K occurs near 1 mm, so if the radiation temperature at 2·6 mm is far less than 3° K, the total energy density of the universal microwave radiation field will be far less than 1 eV cm^{-3}. If, for example, the spectrum of the radiation drops sharply at wavelengths less than, say, $\sim 1{\cdot}5$ cm, the energy density will only be $\sim 3\times 10^{-4}$ eV cm^{-3} and all the scattering phenomena already described will become negligible. In this connexion, note should be made of Greisen's[21] remark that the fact that even one cosmic ray event with an energy of 10^{20} eV has been observed[25] is surprising if the blackbody radiation is present.

There remains to consider the radiation in the wavelength range 3·2–20·7 cm. The natural suggestion is that it represents the integrated radiation from a population of radio sources the spectra of which peak at centimetre wavelengths. This possibility led Shapiro and Weinreb[26] to observe at wavelengths of 2 cm and 3·75 cm the blue stellar objects with large red-shifts discovered by Sandage[27]. Their results were negative, the upper limits at the two wavelengths being 2 and 0·5 flux units, respectively (1 flux unit is 10^{-26} Wm^{-2} (c/s)$^{-1}$). In addition Howell and Shakeshaft[3] assert that it is "most unlikely to be the explanation of the 20·7 cm excess since Kellermann and Read[28] have carried out a survey of radio sources at 21 cm wavelength in an area of 1 steradian and found no such population. The integrated emission from all the radio sources at this wavelength is thought to be less than 0·1° K".

This statement of Howell and Shakeshaft's overlooks the fact that the sources which contribute most to surveys which have a limiting flux density may not be those which contribute most to the integrated background. For example, if we have two populations with concentration ρ_1, ρ_2 per unit volume and intrinsic radio luminosity P_1, P_2, their contributions to a source survey depend on their relative values of $\rho P^{3/2}$, and their contributions to the background on their relative values of ρP. We might then have $\rho_1 P_1^{3/2} \gg \rho_2 P_2^{3/2}$ and $\rho_2 P_2 \gg \rho_1 P_1$. If also the intrinsically weaker sources have a different spectrum from the intrinsically stronger ones, then the background will have a different spectrum from most of the discrete sources observed in a particular survey.

Let us see if we can construct a plausible model by exploiting this fact. In the first place we note that it is not unreasonable to postulate a population of sources the flux density of which increases with frequency at high frequencies. Sources with such spectra are already known[29–31] (the Seyfert galaxy *NGC* 1275(3*C*84), the quasar 3*C*279, 2145+06 and 0430+05). These sources actually have a minimum in their spectrum in the range 1,000–3,000 Mc/s, and it is probable that they are composite, the low-frequency radiation coming mainly from an extended envelope and the high-frequency radiation coming mainly from a compact quasi-stellar region. The compact components are probably[32,33] suffering from synchrotron self-absorption at all frequencies up to $\sim 10{,}000$ Mc/s (if these sources were thermal or were undergoing absorption by ionized gas the associated optical emission would be far greater than is observed). The sources we shall introduce must not have a minimum, however, or they will make too large a contribution to the background temperature at low frequencies. We shall therefore suppose that a quasi-stellar source which is self-absorbed out to high frequencies can form without its envelope radiating an appreciable amount of low-frequency radiation.

Secondly, we must consider the spectrum of the integrated radiation from such self-absorbed sources. An individual source will have a special index of $\sim +2{\cdot}5$ up to some maximum frequency ν_0. We shall assume for simplicity that at higher frequencies the spectral index is -1, but our results will not be sensitive to this choice. In the steady-state model the spectrum of the integrated radiation is then:

$$\nu^{2\cdot5}\left(1-\tfrac{7}{8}\left(\frac{\nu}{\nu_0}\right)^{\frac{1}{2}}\right). \qquad \nu \leqslant \nu_0$$

(In other models we would have to specify the intrinsic evolution of the sources.)

This spectrum peaks at $0{\cdot}9\ \nu_0$ and differs insensibly from the observed spectrum only in the decade of frequencies from $0{\cdot}07\ \nu_0$ to $0{\cdot}7\ \nu_0$. (A modest dispersion in ν_0 would not affect these results significantly.) We must therefore assume that the CN excitation is collisional in origin, and take $\nu_0 \sim 20{,}000$ Mc/s. Accordingly, the background radiation should peak at $\sim 18{,}000$ Mc/s (1·7 cm). In view of the uncertainty in the spectral index of the sources for $\nu > \nu_0$, and the effect of a dispersion in ν_0 and intrinsic luminosity, we may round these numbers off and predict that the background and sources will peak in the general vicinity of 20,000 Mc/s (1·5 cm).

The next question to consider is whether there are enough of these self-absorbed sources to account for the observed intensity of the background. In view of the illustrative nature of our model we shall assume that all these sources have the same intrinsic radio luminosity $P_2(\nu)$, and number density ρ_2. Similarly we shall represent the bulk of the radio sources observed down to a given limiting flux density by the quantities $P_1(\nu)$ and ρ_1. The Kellermann–Read[28] (K–R) survey at 1,420 Mc/s is consistent with the choice.

$$P_1(1{,}420) \sim 10^{25}\ \text{W (c/s)}^{-1}\ \text{ster}^{-1}$$
$$\rho_1 \sim 4\times 10^{-25}\ \text{pc.}^{-3}$$

This choice is also consistent with the median radio luminosity at 178 Mc/s of Longair and Scott[34] (based on optical identifications) and with the spectra[28,35] of these sources, and gives an integrated background temperature at 1,420 Mc/s of $\sim 0{\cdot}05°$ K, in agreement with the estimate of Howell and Shakeshaft.

Our main problem is now to estimate ρ_2 and P_2. We do this by determining whether any K–R sources which have a flux density $S \geqslant 2$ flux units are not in the 4*C* catalogue (the first part of which to be published[36] covers the regions of sky studied by Kellermann and Read). Since the 4*C* survey is complete down to a limiting flux density of 2 flux units at 178 Mc/s, such sources would have a positive spectral index between 178 Mc/s and 1,420 Mc/s, and we might assume that they are of type 2. In determining their number we excluded K–R sources in the region between 19h 35m and 20h 20m because of the confusing effects of Cyg *A*. We find then that there are no sources of type 2 out of a total of 30 K–R sources with $S \geqslant 2$ flux units. Thus at most ~ 3 per cent of the sources at 1,420 Mc/s can be of type 2. We provisionally adopt this upper limit and set:

$$\rho_2 P_2^{3/2} \sim 0{\cdot}03\ \rho_1 P_1^{3/2}$$

To account for the microwave background we need:

$$\rho_2 P_2 \sim 60\ \rho_1 P_1$$

Thus

$$P_2 \sim 3 \times 10^{-7}\ P_1$$

and

$$\rho_2 \sim 2 \times 10^{8}\ P_1$$

We thus find

$$P_2(1{,}420) \sim 3 \times 10^{18}\ \text{W (c/s)}^{-1}\ \text{ster}^{-1}$$

and

$$\rho_2 \sim 8 \times 10^{-17}\ \text{pc.}^{-3}$$

If the fraction of type 2 sources is actually $3x$ per cent, then P_2 and ρ_2 must be multiplied by the factors x^2 and x^{-2}, respectively.

A population of sources with these properties would show self-absorption out to $\sim 20{,}000$ Mc/s if they have a radius $\sim 4 \times 10^{16}$ cm, and a magnetic field strength $\sim 0{\cdot}1$ gauss. As their concentration is rather high (see later), we assume that their lifetime is long, say 10^{17} sec. Then they must be stabilized by gravitation and we would expect equipartition of energy to be set up between the relativistic electrons and the magnetic field. The total energy content at any time in these forms $\sim 10^{48}$ ergs (the radiation rate being $\sim 10^{39}$ ergs sec^{-1}). The total energy converted into radiation in 10^{17} sec is the mass-equivalent of $\sim 100\ M_\odot$. The energy content of 10^{48} ergs could be confined if the source consisted of a central mass of, say, $10^7\ M_\odot$ surrounded by a gas filling the radio-emitting region with a density of $\sim 10^4$ atoms cm^{-3}. Such sources would contribute only 5×10^{-32} g cm^{-3} to the mean density of matter in space.

The individual sources thus appear to have a reasonable structure which results in their possessing a radio luminosity at 1,420 Mc/s which is rather less than that of a normal spiral galaxy. What is more striking is that they are required to be about 3,000 times as numerous as normal galaxies. Is this a reasonable requirement? In this connexion we note that the radio sources must be very compact if they are to be self-absorbed out to 20,000 Mc/s (radius $\sim 4 \times 10^{16}$ cm). Moreover, because at low frequencies they have to be very weak radio sources, they are unlikely to be surrounded by an extensive envelope (in contrast to *NGC* 1275). We might thus expect the associated optical object to be also rather compact. Such compact optical sources are indeed known[37–39]. Arp[37], for example, has discovered a galaxy which is only 70 parsecs across. As he emphasizes, we do not know the lower limit of the amount of matter that can form an isolated galaxy. Moreover, the number of galaxies per unit volume increases rapidly as fainter galaxies are considered. The problem involved here is exactly the same as for the radio sources; surveys of galaxies down to a limiting apparent magnitude are quite inadequate for determining the contents of a unit volume of space. Furthermore, with the parameters we have adopted here, our sources would look like stars rather than galaxies. I therefore do not regard it as an impossible requirement that the faint compact sources must be 3,000 times as numerous as galaxies, although I recognize, of course, that my proposal is entirely speculative, and must be tested by direct observation.

I shall finally consider the question of the optical appearance of the sources. It does not seem possible to estimate their absolute magnitude with any reliability, although a lower limit would be provided by the likely[32,40] operation of the inverse Compton scattering of the radio photons by relativistic electrons in the source. Arguing by analogy with quasi-stellar radio sources and quasi-stellar galaxies[27] (some of which have recently been found[41,42] to be weak radio sources) we might expect our sources too to have the characteristic ultra-violet excess and to be numbered among the blue stellar objects. This would be consistent with the negative result of Shapiro and Weinreb[26] as they observed blue stellar objects with large red-shifts. At the corresponding large distances our sources would be much too faint to have been detected by them.

This discussion may be summarized as follows. If the CN excitation is collisional in origin it is possible to account for the background microwave radiation field as the integrated effect of a population of radio sources. These sources are required to have the following properties: (i) They must show self-absorption out to their peak at $\sim 20{,}000$ Mc/s. (ii) Their intrinsic radio luminosity at high frequencies must be somewhat less than that of a normal galaxy. (iii) They must be at least $\sim 3{,}000$ times as numerous as normal galaxies. (iv) Optically they may be blue stellar objects. Their integrated radiation would then have the following properties: (i) Its spectrum would be "thermal" from 1,400 Mc/s (~ 2 cm) to 14,000 Mc/s (2 cm). (ii) Its spectrum would peak at $\sim 20{,}000$ Mc/s (1·5 cm). (iii) Its energy density would be $\sim 3 \times 10^{-4}$ eV cm^{-3}, so that its scattering and absorptive power would be negligible.

Finally, I would like to point out that if my explanation is correct the existence of the microwave background would be consistent with the steady-state model of the universe.

I thank G. B. Field and J. L. Hitchcock, P. Thaddeus and J. E. Clauser, and T. Howell and J. R. Shakeshaft for informing me of their results in advance of publication. This work was begun at the Laboratorio di Astrofisica in Frascati, and I thank Prof. L. Gratton for his hospitality. I would also like to thank M. J. Rees, W. C. Saslaw, and J. R. Shakeshaft for their helpful advice.

LETTERS TO THE EDITOR

PHYSICS

A Dense Packing of Hard Spheres with Five-fold Symmetry

MR. B. G. BAGLEY'S interesting letter[1] on this topic, by making contrasts with quintuple twins, seems continually to argue that his structure should be regarded as one pentasymmetric crystal. I suggest that this notion is invalid on two distinct grounds.

By definition, a crystal is an aggregate of particles such that each identical or 'equivalent' particle has an identical spatial environment, which includes not only co-ordination number—here always 10—but also co-ordination angles and distances. Also, by definition, the symmetry elements of a single, continuous crystal lattice can be found at 'any' place within such a structure. In the assemblage proposed by Bagley: (*a*) all the identical particles (his 'hard spheres') do not have identical spatial environments, and (*b*) the symmetry elements of one 'place' in the assemblage differ from those at other 'places'. His assemblage has, in fact, three distinct types of 'place': (1) a 'general' place; (2) a planar place; (3) an axial place—the last two being normal to the plane of the diagram (Fig. 1). Place (1) has orthorhombic symmetry; place (2) has monoclinic (*m*, 'Domatic'); place (3) pentagonal symmetry.

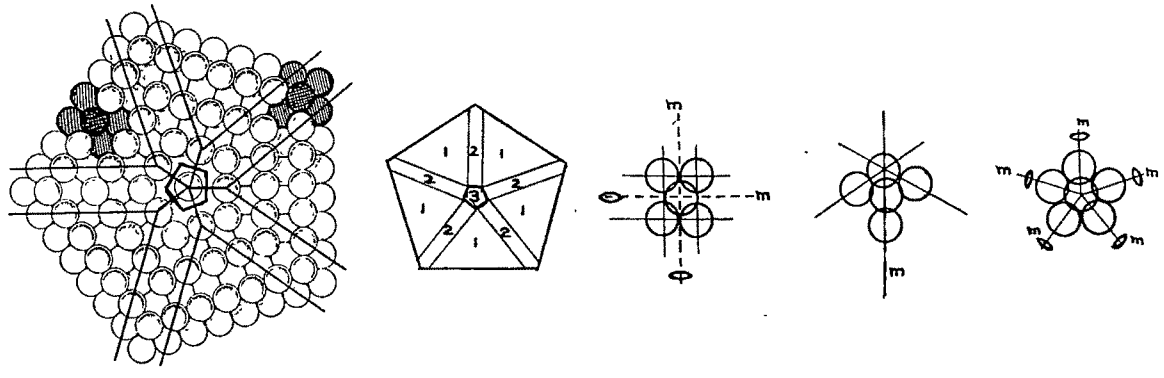

Fig. 1. *A*, "A layer of hard spheres based on a packing sequence of concentric pentagons." *B*, The three symmetry places. *C*, Orthorhombic unit from place (1). *D*, Monoclinic (*m*) unit from place (2). *E*, Pentagonal unit from place (3)

Because only place (1) is 'general', in being three-dimensional, this seems to show quite unequivocally that the assemblage is, and must be regarded as, a perfect quintuple orthorhombic twin, the five distinct portions joining each other at place (2) and place (3). Even Bagley does not seem fully convinced, as he makes a point of remarking (end of second paragraph) that the assemblage "has a *unique* axis, the *single* 5-fold rotation axis" (my italics).

Any notion that the structure is one crystal because a particular tetrahedron (Bagley's 5·15 per cent distorted one) can be found *throughout* the structure is quite invalid as (*a*) this is also true of any twinned crystal, and (*b*) the conjunctions of identical tetrahedron are different in the three regions of the assemblage. Finally, as in this structure the co-planar 'concentric' pentagons do not touch each other, no known packing mechanism would account for the continual planar growth of these concentric pentagons—a fact strongly supporting the purely five-fold axis propagation direction of extremely 'narrow' quintuple-twin 'whiskers', from some initial (and fortuitous ?) five-sphered planar ring.

PROF. J. D. BERNAL * writes:

"I agree with Mr. Clarke's criticism of Mr. Bagley's communication. The arrangement he illustrates is definitely a twin in terms of classical crystallography for the reasons which he gives. However, this seems to me more a matter of amending precise definitions of the laws of crystallography than of insisting on them. If precise equality of interatomic distances is not required, arrangements forbidden by these laws can occur. They do, in fact, occur, not only in the cases mentioned by Mr. Bagley but also in structures of many polyhedral viruses, as discussed by Dr. A. Klug and Dr. D. L. D. Caspar[1]. Furthermore, the arrangement Mr. Bagley shows is quite a special one of pentagonal symmetry in a plane. Far more general is the arrangement in an icosahedral shell which has been described by Dr. A. L. Mackay (see Fig. 7, ref. 2). This possesses not a single five-fold axis but six of them. In other words, it has symmetry 532 but is nevertheless strictly a polysynthetic twin with orthorhombic elements. The origin of twins is not, in my opinion, at all difficult to explain. Ideally, a crystal lattice consists of an infinite number of particles all similarly situated. When the number is finite, it is impossible to satisfy the condition for each particle. It can never be similarly surrounded by others. Surface effects are bound to influence the arrangement of the particles when they are only of the order of a few hundreds of them. I have discussed the existence of such nuclei which I have referred to as pseudonuclei[3] which can never grow extensively and all crystallographers will have noticed that precipitated nuclei are often twinned from the start."

Space-group Representation in Condensed Models of Inorganic Close-packed Structures

EARLIER I described some condensed models of inorganic close-packed structures[1]. These were based on standard transparent sheets of film, representing layers of the main types of close packing, in which the occupied holes could be marked out. An approximate three-dimensional representation was obtained by placing these sheets at equal distances in an appropriate supporting rack. It became apparent that the conventional symbols for the elements of symmetry of space groups could also be marked out on these sheets, completing the information contained in the models. The top layers of two of these models, olivine and spinel, are represented in Fig. 1*a* and *b*. When the layers are placed in the appropriate supporting rack, screw axes, inversion axes, glide planes, etc., can be easily visualized and related to the actual structure.

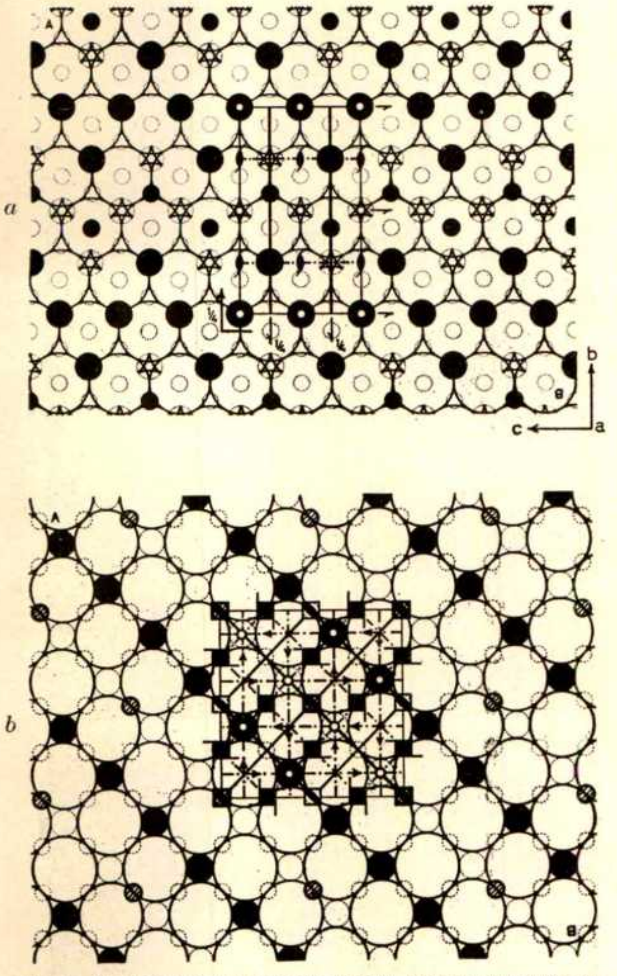

Fig. 1. Top layers of two examples of space-group representation in condensed models of close-packed structures. *a*, Olivine, Mg_2SiO_4, space group *Pbnm*; oxygen (large open circles) in hexagonal closest packing; magnesium (large filled circles) in octahedral holes; silicon (small filled circles) in tetrahedral holes. *b*, Spinel, Al_2MgO_4, space group *Fd3m*; oxygen (large open circles) in cubic closest packing ((001) face); aluminium (large filled circles) in octahedral holes; magnesium (small shaded circles) in tetrahedral holes. In the case of spinel, to facilitate the reading of the picture, only a partial representation of the space group is given (for example, triad axes, diad axes, etc., are not represented). The centres of symmetry that are marked out are at 7/8; those at 5/8 are omitted because they belong to the layer immediately underneath. The inversion tetrads that are at 3/4 are also omitted—they also belong to the layer immediately underneath

A complete representation of the orthorhombic space group of olivine is easily achieved, but in the complex example of the cubic space group of spinel a partial representation is more satisfactory. Such a partial representation enables the location in this structure of the complete representation which appears in the work of Buerger[2].

Ice Nucleation by Proteins and Surface Films

DURING an investigation of the icing characteristics of solid surfaces, Schaefer[1] observed that certain protein films induced supercooled water drops to freeze at temperatures near zero. The possible importance of proteins as a source of natural ice nuclei cannot be over-emphasized because proteins are able to concentrate irreversibly at water surfaces and thereafter find their way into the atmosphere in particles large enough to act as ice nuclei. The ocean surface, in particular, would be an immense source of air-borne protein[2]. Furthermore, protein films are of great fundamental interest because they possess the unique property that their state of compression, and therefore their geometric similarity to an ice lattice, can be varied continuously, thus providing a means of testing the relationship between 'fit' and nucleation temperature. It is therefore surprising that while several authors[3–5] have accepted proteins as ice nucleators, no confirmation or extension of Schaefer's work has been reported.

Schaefer observed ice formation on films of egg albumen and pepsin when these films were prepared in the form of 'dipped out' layers on a chromium plated glass slide. In the present work this experiment has been repeated, the proteins (twice recrystallized, Mann Laboratories) being spread from solution on to iso-electric substrates as described by Langmuir, Schaefer and Wrinch[6]. Films of the types *PRA*, *PRB* and *PRAB* (terminology of Langmuir *et al.*) were prepared, and tested as ice nuclei by placing the film-coated slides in a cold stage and passing moist air over them until condensation appeared on the slide. On no occasion was any ice detected on the protein film unless the temperature was below $-10°$ C, this behaviour not being different from that of slides without the protein coating.

A possible reason for the failure of these protein films to nucleate ice was the lack of order resulting from the complex arrangement of amino-acids in the peptide chains. Therefore, a number of poly-amino-acids were tested as nucleators in the form of "dipped out" layers, the expectation being that the uniformity of the peptide chains might confer on the film enough two-dimensional crystallinity to promote nucleation. However, no ice nucleation was detected on either *PRA* or *PRB* films of the following polymers—poly-*l*-leucine (molecular weight of 12,000), poly-*dl*-leucine (mol. wt., 8,000), poly-*l*-alanine (mol. wt., 3,000), poly-*dl*-alanine (mol. wt., 2,500), and poly-*l*-tyrosine (mol. wt., 130,000) (supplied by Yeda Research and Development, Israel).

As cholesterol was known to be a good ice nucleator with an onset temperature of $-5°$ C (ref. 7), it was of interest to investigate its nucleating properties when deposited on chrome-plated slides using the technique of Langmuir, Schaefer and Sobotka[8]. Again no ice nucleation was obtained, even on 'built-up' layers of cholesterol up to 100 monolayers in thickness. This was perhaps to be expected because, although the packing of the interlayer spacing of the layer is almost identical with that of the cholesterol crystal[8], the molecules of the outermost monolayer are all oriented with their hydrocarbon tails facing outward, whereas the equivalent plane of a cholesterol crystal has half the molecules oriented with the hydroxyl group outward[9]. Even a 'built-up' layer which had been

scratched, split or etched showed no nucleation ability, but after the layer had been recrystallized by melting, the normal onset temperature of $-5°$ C was obtained.

To study the nucleation behaviour of some monolayers at various surface pressures, a different technique was used which enabled these monolayers to be examined *in situ*. Small gold cups, 1 mm in diameter, were rendered hydrophobic by treatment in hot chromic acid followed by ignition to red heat. After lowering the cups into a surface trough, the monolayer was spread on the water surface and compressed to the appropriate pressure. Cups were then withdrawn through the surface layer so that they were brimming with water covered by the monolayer at the pressure chosen. The freezing point of the water in each cup was determined on a cold stage. The following films were tested:

(*a*) Poly-*l*-leucine, poly-*dl*-leucine, poly-*l*-alanine, poly-*dl*-alanine and poly-*l*-tyrosine.

(*b*) Mixed films of cholesterol and lanostane in proportions ranging from 1 : 2 to 2 : 1. (The non-polar lanostane reduces the surface density of hydroxyl groups in the monolayer.)

(*c*) Atactic copolymers of vinyl benzene with methacrylic acid, the composition ranging from 5 to 20 per cent methacrylic acid (mol. wt., 30,000).

(*d*) Polyvinyl acetate, hydrolysed to various extents (80–98 per cent), thus introducing hydroxyl groups into the polyester chain.

None of the foregoing monolayers induced freezing at a temperature higher than the freezing point of the film-free water ($-20°$ C). Thus in the whole survey no surface film showed any ability to nucleate ice even though the surface density of hydrogen-bonding groups was varied over a wide range. Indeed, if polymer films were good ice nucleators they would constitute an anomaly owing to the fact that all the recognized ice nucleators, with the possible exception of the colloidal silicas[10], are crystalline.

At first sight, the present finding that pepsin and egg albumen do not nucleate ice would seem to contradict the finding of Schaefer[1]. However, Schaefer actually observed that these materials formed films which ". . . would develop a thin frost coating which would instantly seed condensed water drops as they cooled below 0° C". This observation has been confirmed, but the 'frost coating', which is a sheet of non-oriented fine-grained ice crystals, is not the result of numerous nucleation events 'on the film', but arises from spontaneous nucleation elsewhere on the slide, after which the ice front creeps slowly (0·5 mm/sec) through the fog condensed on the protein film, leaving in its wake myriads of tiny crystals. The advance of the ice front is detected only by careful observation under the microscope. Thus Schaefer's statement is true but should not be interpreted as 'ice nucleation' in the present-day sense.

The conclusion is, therefore, that pepsin, egg albumen, and a whole wide range of long-chain surface films do not promote ice nucleation, but this statement does not preclude the possibility that a condensed surface film with the correct two-dimensional geometry may yet be found to nucleate ice.

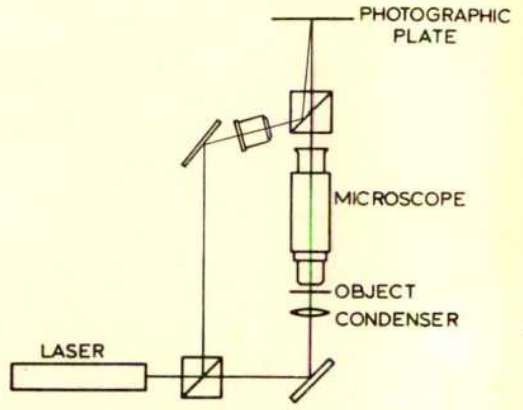
Holographic Microscopy

THE use of holography[1] on a restricted class of objects in the visible spectrum was recognized by Gabor[2] and Parrent *et al.*[3], but a problem occurred in the contrast of the reconstructed image owing to the presence of zero-order light, as no angular interference of the object



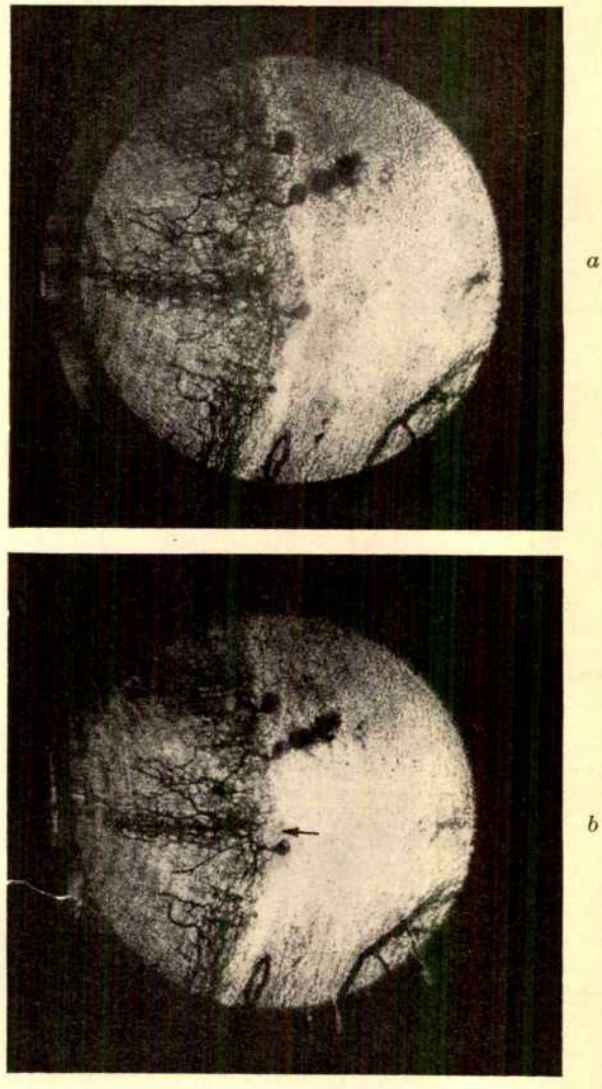


Fig. 1. Schematic diagram showing the holographic microscope

a

b

Fig. 2. *a*, Reconstruction from a hologram containing the three-dimensional record of a microscopic specimen. *b*, Reconstruction from the same hologram as in *a*, but now 40μ away in depth. The arrow indicates a fibre of about 1μ

and reference beams was used. Leith and Upatnieks[4] as well as Lohman[5] have described a technique which makes possible holography on more general and non-microscopic objects. This same technique was used to perform holography without the use of a lens on small objects by Leith and Upatnieks[6]. In experiments which we have carried out on more general objects, the optimum lower level of detectability was about 12μ when holography was performed without a lens. However, the experimental difficulties of obtaining a resolution of about 5μ are very serious. We have used a microscope (objective lens) to record holographically microscopic images of a general character. Although the attractive feature of 'lens-less' imagery was not used, the ability to record a substantial depth, as well as phase information in the object, has been preserved.

Fig. 1 shows a schematic diagram of the experimental arrangement. Fig. 2 shows a reconstruction of a stained specimen of neurones. The difference between Fig. 2*a* and 2*b* is that they are derived from the same hologram, but in planes at different depths. In the specimen this difference in depth corresponds to a de-focusing of 40μ. The arrow in Fig. 2*b* points to two fibres that have a diameter of about 1μ. In both reconstructions a set of concentric ring sections appear which result from multiple reflexions in the optics producing the reference beam.

The hologram was produced on Eastman Kodak '649-*F*' spectroscopic plate. The exposure time was 20 sec with a 4 mW output from a helium-neon laser.

Half-lives of Barium-137*m*, Silver-109*m* and Rhodium-106 measured with Calculable Overall Accuracy

A FEW years ago, Wasserman, Twardock and Comar[1] investigated the metabolic dissociation of caesium-137–barium-137*m* in animals. A value for the half-life of barium-137*m* could be estimated from their data; it appeared to be about 2·52 min, compared with the 2·60 min previously measured by Mitchell and Peacock[2].

By separating daughter from parent by cation-exchange elution and using the ratio-method of measurement[3], an accurate value for the half-life of barium-137*m* has now been determined with a known degree of contaminational uncertainty. In this respect, any long-lived caesium-137 in the sample introduces virtually no bias into the measured half-life, despite the fact that it increases the background counting rate. Using a crystal of sodium iodide, several mutually consistent series, each comprising fifteen to thirty single measurements, gave the average value $t_{\frac{1}{2}} = 2{\cdot}557 \pm 0{\cdot}005$ min, where the stated standard deviation covers the over-all contaminational uncertainty involved. The standard deviation excluding contaminational uncertainty is lower by a factor of three, as shown in Table 1.

The presence of a contaminant with a half-life, $t_{\frac{1}{2}}^{*}$ (differing from $t_{\frac{1}{2}}$), must induce a bias on the measured value. When the ratio-method is used and the measurements are duplicated with samples 2^n times stronger at the moment of production, but $n \times t_{\frac{1}{2}}$ min older at the start of the counting period, the bias, b, on the mean, $T_{\frac{1}{2}}$, of fresh and aged samples is given by:

$$b = \frac{2^{n-n^*} + 1}{2^{n-n^*} - 1} \tfrac{1}{2}\Delta \qquad (1)$$

where Δ denotes the apparent increase in half-life due to ageing the sample for $n \times t_{\frac{1}{2}}$ min, and $n^* = (n \times t_{\frac{1}{2}})/t_{\frac{1}{2}}^{*}$.

Denoting the standard deviation by σ, we have $\sigma_{T_{\frac{1}{2}}} = \frac{1}{2}\sigma_{\Delta}$, whence, according to equation (1):

$$\sigma_b = 3\sigma_{T_{\frac{1}{2}}} \text{ for } \left| n - n^* \right| = 1 \qquad (2)$$

For barium-137*m*, Δ was found to be nil. I have made the arbitrary assumption that a null value of Δ indicates that $T_{\frac{1}{2}}$ is unbiased by any contaminant(s) for which $\left| n - n^* \right| \geqslant 1$. As can be seen from equation (2), this criterion of radio-purity only increases the over-all uncertainty of $t_{\frac{1}{2}}$ (through σ_b) by a limited factor of three. Concerning the possible contaminants for which $\left| n - n^* \right| < 1$, a thorough search through all known nuclides[4] disclosed only a few that were of sufficiently long-lived parentage to survive the year-long ageing of the caesium-137 used. Samples of barium-137*m* were carefully examined for these possible contaminants, using a γ-spectrometer, and in each case the contaminants were found to be absent, that is, so small an upper limit to their amounts could be set that the contribution to the uncertainty of $t_{\frac{1}{2}}$ was negligible.

A chain of genetically related contaminants might, conceivably, make $\Delta = 0$, and yet induce a bias on $T_{\frac{1}{2}}$. However, all significant chains would include α-emitters, and careful scannings of nuclear emulsions, into part of which samples of barium-137*m* were absorbed, revealed no α-tracks above background. After checking the method with uranium-treated emulsions, an upper limit to chain-contamination was established and was found to be negligibly small.

In the case of silver-109*m*, which was separated from cadmium-109 by a modification of Sunderman's method of isotopic exchange[5], the possibility of chain-contamination was disregarded since the parent was not a fission-product like caesium-137. Otherwise, the investigation of radio-purity was quite analogous to that already described.

In the case of rhodium-106, ruthenium-106 material purified by Glendenin's distillation procedure[6] was re-distilled, and it was found feasible to trap ruthenium tetroxide in cold 70 per cent perchloric acid, which meant that a sequence of rhodium-106 samples could be prepared by successively re-cycling parental material through the still (taking up the distillational residue in a counting container resembling a slightly V-shaped pipette with capillary stems). Some ruthenium-103 was probably present in the parental material, but rhodium-103*m* could not be detected by the stilbene crystal used. No trend was seen in thirty non-stop measurements of half-life based on thirty redistillations of a single portion of parental material and, consequently, contaminational uncertainty was assumed to be negligible in comparison with the uncertainty involved in extrapolating the observed values of $t_{\frac{1}{2}}$ to the point of zero dead-time loss of counts.

Table 1

Nuclide	Present value $t_{\frac{1}{2}}$ (sec)	Standard deviation excluding contaminational uncertainty (sec)	Standard deviation including over-all contaminational uncertainty (sec)	Previous value (ref. 7) $t_{\frac{1}{2}}$ (sec)
Barium-137*m*	153·4	0·1	0·3	156
Silver-109*m*	39·80	0·06	0·19	40
Rhodium-106	30·36	0·15	0·15	30

Flux Relationships for Diffusion in Microcapillaries

IT is well known that flux ratios in small capillaries, that is in capillaries where the Knudsen number (N_k, defined as the ratio of capillary diameter to the mean free path of the diffusing molecule) is much less than one, vary as the square root of the inverse molecular weight ratio for binary systems. It has been shown[1] that for counter-diffusion in an 'open' system, corresponding to the physical situation in most transport experiments of the Wicke–Kallenbach type[2], flux ratio may vary from dependence on the square root to the first power of the inverse molecular weight ratio for the bulk diffusion mechanism alone. For capillaries of a fixed length, the progression from square root to first power dependence is associated with increasing Knudsen numbers, the latter mechanism corresponding to $N_k \gg 1$. It is clear, then, that at $N_k \ll 1$ the predominant mechanism of transport is that of Knudsen diffusion, and flux ratios are equal to the square root of inverse molecular weight ratios, and at $N_k \gg 1$ the predominant mechanism of transport is that of bulk diffusion. Flux ratios for sufficiently large N_k will then be equal to the first power of the inverse molecular weight ratios (provided capillary length–diameter ratios do not approach the order of unity).

In the transition region, $0{\cdot}01 < N_k < 100$, where both types of transport are of importance, it is not known whether a range of capillaries of larger diameter might be included in which under some circumstances the flux ratio for Knudsen transport (always the square root proportionality) would differ from that for the bulk mechanism (tending toward the first power proportionality for sufficiently large diameters). The overall flux ratio would depend on the relative contribution of each mechanism to the overall transport process.

We resolve this problem by determining, under specified conditions, the fraction of total momentum transfer within the capillary due to molecule-wall interactions. This fraction represents the probability, ψ, that a molecule in transit will interact with the wall. In pure Knudsen diffusion all momentum transport is due to molecule wall collisions, and this probability is unity. Conversely, for the purely bulk transport mechanism this probability is essentially zero, and in the transition region $0 < \psi < 1$. A simple momentum balance for binary diffusion under isothermal, isobaric conditions in the capillary yields:

$$N_A = \left[\frac{1}{D_A} + \frac{1 - y\alpha}{\mathcal{D}_{AB}}\right]^{-1} \nabla C_A \qquad (1)$$

in which N_A is the flux of component A in moles/time-area, D_A the Knudsen diffusion coefficient for A within the capillary, $\mathcal{D}_{AB}$ the bulk diffusivity of the A–B pair, y the mole fraction of A, C_A the concentration of A in moles/volume and α defined as $(1 + N_B/N_A)$. The bracketed term in this equation is proportional to total momentum transfer. On integration over total capillary length for unity Δy, it may be shown that ψ as obtained from the ratio of the Knudsen contribution to the total is:

$$\psi = \left(\frac{1}{N_k \alpha}\right) \ln \left\{\frac{N_k + 1}{N_k (1 - \alpha) + 1}\right\} \qquad (2)$$

If it is desired to define the transition region in terms of set limits on ψ, as above, then equation (2) provides the means for computing corresponding capillary dimensions under specified conditions of temperature and pressure. For a given value of ψ, the capillary diameter corresponding is directly proportional to temperature and inversely proportional to pressure. Capillary dimensions corresponding to the upper bound of transition zone diffusion (at $\psi = 0{\cdot}1$, for example) are of the same order of magnitude as those reported as characteristic of many porous structures, particularly those used in catalysis (with the exception of very high pressure conditions). These diameters range generally from 1000 Å to 10,000 Å, and transition region diffusion is thus probably the predominating transport mechanism in such structures.

Flux ratios for counter-diffusion in the transition region can be determined as a linear combination of flux ratio for pure Knudsen diffusion, R_k, and that for the bulk process, R_B, under the conditions of operation. The probability determined from equation (2) is utilized in this computation:

$$R_T = \psi R_k + (1 - \psi) R_B = 1/(\alpha - 1) \qquad (3)$$

in which R_T is the observed flux relationship for the combined process. R_k is, of course, always equal to the square root of inverse molecular weight ratio, and the proportionality of R_B to the inverse molecular weight ratio is determined by methods outlined previously[1]. This is a trial-and-error solution, since ψ depends on the flux ratio, as specified by equation (2).

Figs. 1 and 2 show the results of such computations for the helium–argon (I) and hydrogen–argon (II) systems, which are typical of those used in the study of diffusion through porous structures. The computations are based on an argon mean free path of 1100 Å at 300° K and one atmosphere, and, in Fig. 2, a capillary diameter of 2000 Å, and $L/D = 50$, which is an appropriate average value for catalyst support structures as discussed below. Fig. 1 demonstrates the form of ψ in terms of the Knudsen number as a function of the overall flux ratio, R_T (equation (2)). In Fig. 2 it is seen that as diameter is varied the deviation of α (or R_T) from the square root of inverse molecular weight ratio becomes apparent only for low values of (L/D). Our investigations of porous structures[3,4], however, indicate that characteristic values of (L/D) are normally of the order of 50–100, and one would expect to observe, in general, no deviations. For (L/D) of these magnitudes, indeed, further computation indicates that flux ratio deviations would never become apparent, other

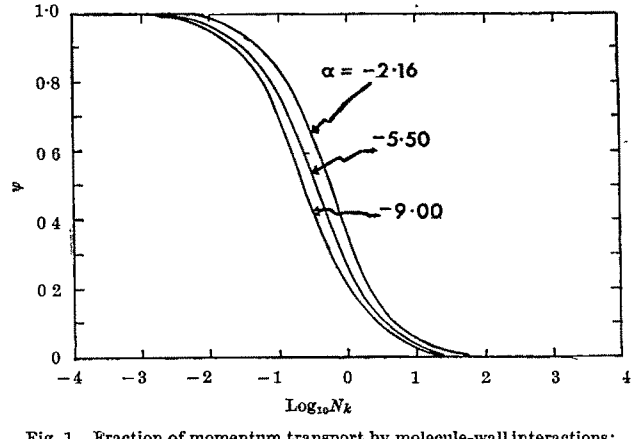

Fig. 1. Fraction of momentum transport by molecule-wall interactions: helium–argon system (equation 2)

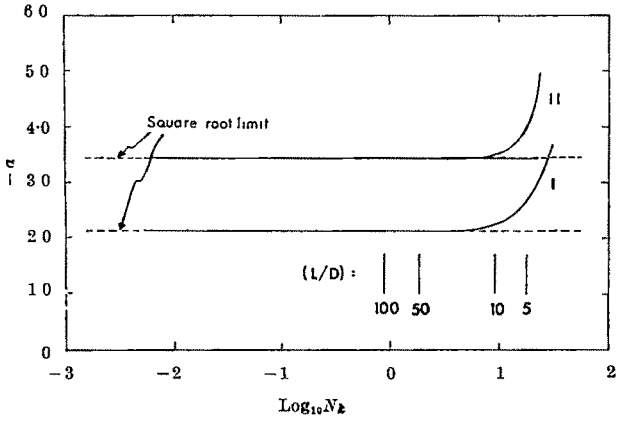

Fig 2. Overall flux ratio for capillary of typical dimensions; helium–argon (I) and hydrogen–argon (II) at 1 atm., 300° K

than at extreme conditions of pressure or temperature—in which case selective surface migration would probably be an important transport mechanism and flux ratios would be determined by other considerations.

ASTRONOMY

Evidence of an Ephemeral Earth Satellite

The possibility that the Earth could acquire natural satellites from the debris of large meteoritic impacts on the Moon has been discussed by O'Keefe[1]. A possible capture mechanism for bodies into temporary Earth orbit has been investigated by Baker[2]. On February 9, 1913, a widely observed, long duration procession of meteors and fireballs gave rise to the suggestion by Chant, Mebane, and others[3] that they actually were such ephemeral Earth satellites which were finally consumed at perigee. More recently, a long, extremely narrow field of both craters and meteorites in Argentina was investigated by Kohman *et al.*[4] and they suggested that these were the end-result of a captured Earth satellite finally spiralling into the denser atmosphere.

During the mid-fifties I analysed evidence of two swarms of such objects in retrograde orbits[5]. However, it has never been conclusively proved that such an ephemeral satellite, with a perigee in the upper atmosphere, has been observed while in orbit and before its final revolutions. I now suggest that the Earth has had such a satellite and that it was observed at least eight times during the period 1956–65. Fortunately, these eight known observations were recorded with sufficient accuracy to permit the determination of an orbit. These observations are listed in Table 1.

The first three observations were accidentally made by Metcalfe and forwarded to me[6] as possible evidence of an inner planet. The brilliance of the objects to the naked eye caused most persons contacted to doubt that they were astronomical despite the fact that this was confirmed with optical aids. However, when Kayser and I made the fourth observation (also with optical aid) I computed an approximate orbit, assuming all four observations to be of an Earth satellite. Continued surveillance over the next 60 days during every possible evening twilight period resulted in the fifth and sixth observations being made.

π	$27-0\cdot130\,t-1\cdot52\times10^{-6}\,t$	$347-0\cdot139\,t-5\cdot50\times10^{-6}\,t^2$	$300-0\cdot172\,t-1\cdot52\times10^{-3}\,t^2$
Period	$294-3\cdot03\times10^{-3}\,t$	$285-3\cdot03\times10^{-3}\,t-4\cdot45\times10^{-4}\,t^2$	$244-0\cdot270\,t-2\cdot70\times10^{-2}\,t^2$
Epoch	Nov. 17 0, 1956	Dec. 29 0, 1964	Oct. 25.0, 1965

In the equations: the semimajor axis (a) is in km; the eccentricity (e) would be 0 00 for a circular orbit and 1 00 for a parabolic orbit; the inclination (i) exceeds 90° due to the retrograde sense of the orbit; the longitude of perigee (π) is the algebraic sum of the right ascension (R A.) of the node and the argument of perigee: the anomalistic period is in mean solar minutes; and the symbol t is the number of mean solar days elapsed since the epoch.

The fifth observation was made with optical aid, but the sixth was by naked eye only. These further observations made it possible to improve the determination of the orbits, and osculating orbits were distributed to about twenty individuals and astronomical agencies.

During most of 1965, no one else reported to me that they had seen the object. Then Hartmann and I made the seventh observation, and this further extended the orbit description. It also led to another period of evening twilight surveillance, which resulted in an eighth observation being made and further orbital refinement. These new results on orbits were recently distributed to thirty individuals and astronomical agencies, but so far no one else has reported an observation to me. It is probable that the object decayed in the Earth's atmosphere during January 1966. The orbital elements are given in Table 2.

GEOPHYSICS

Temperature and Fractional Melting in the Upper Mantle

The velocities of compressional (V_P) and distortional (V_S) seismic waves, through the Earth's upper mantle, were computed with much detail by Gutenberg[1], who found the existence of a low-velocity layer at depths greater than about 70 km.

At least in the lower mantle, where the thermal gradient is expected to be nearly constant, Bullen[2] found that the bulk modulus ($\varkappa$) and the rigidity (μ) have a reasonably linear variation with depth, or with pressure which may be considered proportional to depth. Therefore, it was

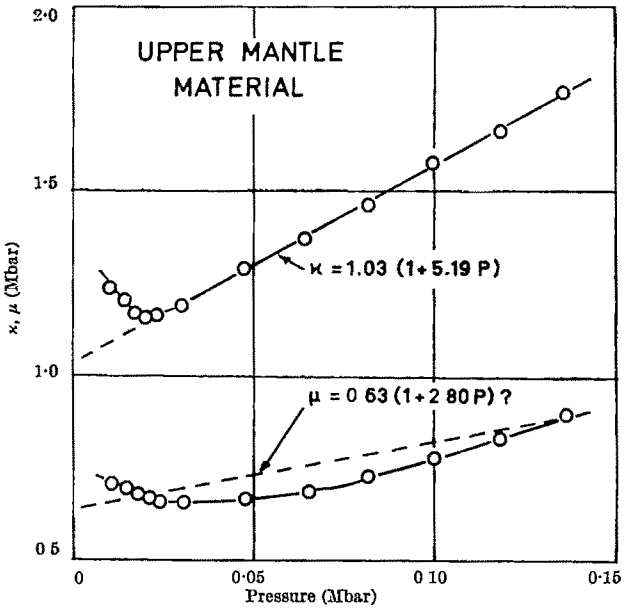

Fig 1. Variation of the bulk modulus (κ) and of the rigidity (μ) in the Earth's upper mantle

found convenient to derive these elastic moduli from Gutenberg's velocities, by the usual equations:

$$V_P = \sqrt{[(\kappa + 4\mu/3)/\rho]}$$
$$V_S = \sqrt{(\mu/\rho)}$$

ρ being the density, for which Bullen's values were adopted; equivalence of depth and pressure was also taken from the same author[3]. The results are shown in Fig. 1.

We see that at depths greater than 70 km the bulk modulus (plotted against pressure P) gives a good fit to a straight line; but no similar fit can be obtained for the rigidity. These facts were interpreted as being due to the presence of a molten interstitial fraction, in accordance with a suggestion of Wager[4]. I have considered various aspects of this elsewhere[5].

Assuming that the material is completely solid at depths of 70 km and of 400 km (which is in reasonable agreement with the relative frequency of earthquakes at the various depths[6]), the values of the rigidity of the mantle material, without partial melting, will probably obey the linear equation $\mu = 0{\cdot}63\ (1 + 2{\cdot}80P)$, with μ and P in megabars.

Knowledge of the law connecting the rigidity of a mixture with the rigidities and the proportions of the components would permit the determination of the amount of interstitial liquid at every depth. Using Eshelby's[7] equation for small spherical inclusions, the maximum liquid fraction (with $\mu = 0$) is estimated at 4·5 per cent at a 200 km depth, where $P = 0{\cdot}065$ Mbars. If, alternatively, the rigidity could be averaged proportionally to the volume of each component, the estimated liquid fraction reaches about 9 per cent. It is most desirable that some laboratory should determine the exact form of this law, as it has considerable implications for various upper-mantle models.

Concerning the thermal effects, the variation of κ and μ with the temperature T is described by the equations:

$$d\kappa/dz = (\partial\kappa/\partial P)_T \rho g + (\partial\kappa/\partial T)_P dT/dz$$
$$d\mu/dz = (\partial\mu/\partial P)_T \rho g + (\partial\mu/\partial T)_P dT/dz$$

where z is depth, g is gravity and, as usual, the subscripts T or P denote that the derivatives were carried out at constant temperature or at constant pressure.

As the upper-mantle material is at present assumed to be dunite (or some closely related peridotite), the partial derivatives can be determined in laboratory experiments on that rock, under the pressure and temperature conditions prevailing in the upper mantle. Unfortunately, not much work of this kind has been done; the most complete measurements on dunite appear still to be those of Hughes and Cross[8], who determined V_P and V_S under pressures up to 5 kbars and temperatures up to 300° C (subsequent data by Hughes and Maurette[9] confirmed the previous results). With their values for pressures greater than 1·5 kbars and temperatures of 100° C or above, the moduli κ and μ were computed and plotted on Fig. 2 (the values at pressures lower than 1·5 kbars would have been still more erratic, probably because they are affected by residual porosity). A least-squares adjustment gave

$(\partial\kappa/\partial P)_T = 16{\cdot}5 \pm 2{\cdot}8$, $(\partial\kappa/\partial T)_P = -(33{\cdot}4 \pm 4{\cdot}9) \times 10^{-5}$ Mbars/deg, $(\partial\mu/\partial P)_T = 5{\cdot}5 \pm 0{\cdot}9$, and $(\partial\mu/\partial T)_P = -(12{\cdot}7 \pm 1{\cdot}6) \times 10^{-5}$ Mbars/deg

The values of ρ and g are given by Bullen[10], and $d\kappa/dz$ and $d\mu/dz$ can be derived from the curves of Fig. 1 (it should be noted that $dz = dP/\rho g$).

Using all these values (for $z > 70$ km, $d\mu/dz$ was obtained from the aforementioned linear equation), the thermal gradient shown in Fig. 3 was computed. By a graphical integration, the temperature can also be derived and this is shown on the same figure.

The temperature obtained by this means appears to be rather high; in fact, it would imply complete melting of the mantle material below a depth of about 90 km. This is contradicted by the transmission of distortional waves, which confirms a non-zero rigidity through the whole mantle. It would seem, then, that the thermal gradient is generally high by some 7 or 8 deg/km (whereas the standard error, for most values, is only 3–5 deg/km).

It is concluded that the extrapolation of the partial derivatives of κ and μ, from a few kilobars and 100°–300° C up to 20 kbars or more, and to temperatures close to 1,000° C, is probably not valid, and laboratory work under higher pressures and temperatures is certainly desirable.

Of course, there are at least two other possibilities: one is that Gutenberg's velocities are affected by some systematic error, and the other is that dunite and its elastic properties are not representative of the solid material in

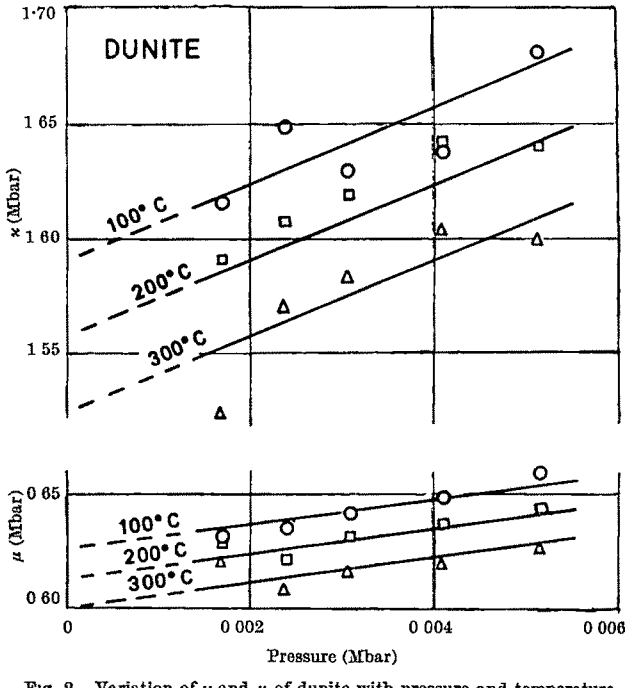

Fig 2 Variation of κ and μ of dunite with pressure and temperature (circles, squares, and triangles refer, respectively, to temperatures of 100, 200, and 300° C)

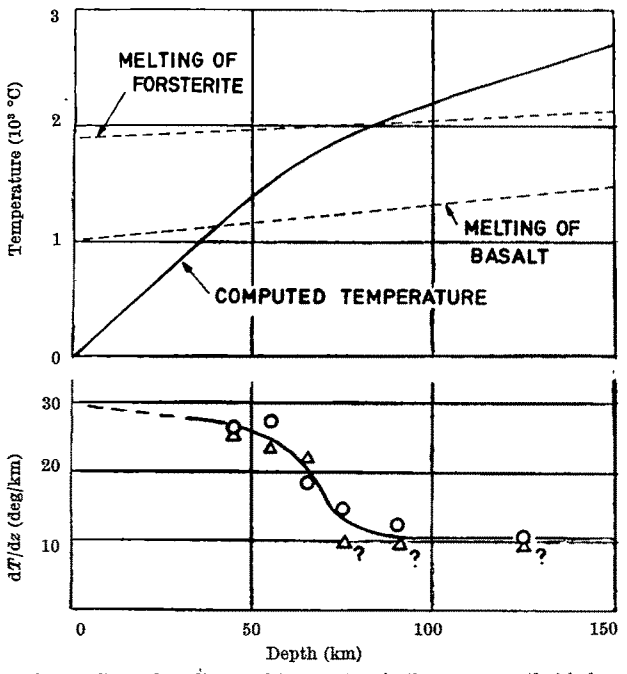

Fig. 3. Thermal gradient and temperature in the upper mantle (circles are values derived from $d\kappa/dz$; triangles are values derived from $d\mu/dz$)

the upper mantle. At present, however, both these possibilities seem to be unlikely.

This report was prepared during a visit to the Department of Geology and Mineralogy of the University of Oxford.

Southern Storm Centres and Ocean Wave Spectra

COLLECTION of tide and wave data at Macquarie Island (54·30 S., 158·50 E.) was resumed in March 1964, 50 years after Leslie Blake operated his tidal gauge on the Island, when a simple pressure recorder was installed near the permanent Australian National Antarctic Research Expedition station. It was destroyed 6 weeks later by a severe storm after recording the Tsunami of the Alaskan earthquake of March 28, 1964[1]. An improved type of pressure recorder with wider frequency response was installed early in 1965 and began to yield satisfactory records a few days before the relief ship returned to Australia. The present communication refers to the analysis of these preliminary data and their interpretation.

Power spectra[2] computed from 20 min of sea surface records yielding approximately 800 ordinates are shown in Fig. 1 for 0000, 1200, 2400 h E.A.S.T. (Eastern Australian standard time) on March 13, 1965. After removal of the tidal trend, the autocorrelations involved lags up to 80 ordinates. Fig. 2 shows the verification of the location of the peaks in the power spectra using the high pass filter

$$Y_t = -(\tfrac{1}{4})X_{t-1} + (\tfrac{1}{2})X_t - (\tfrac{1}{4})X_{t+1}$$

applied to the original data X_t.

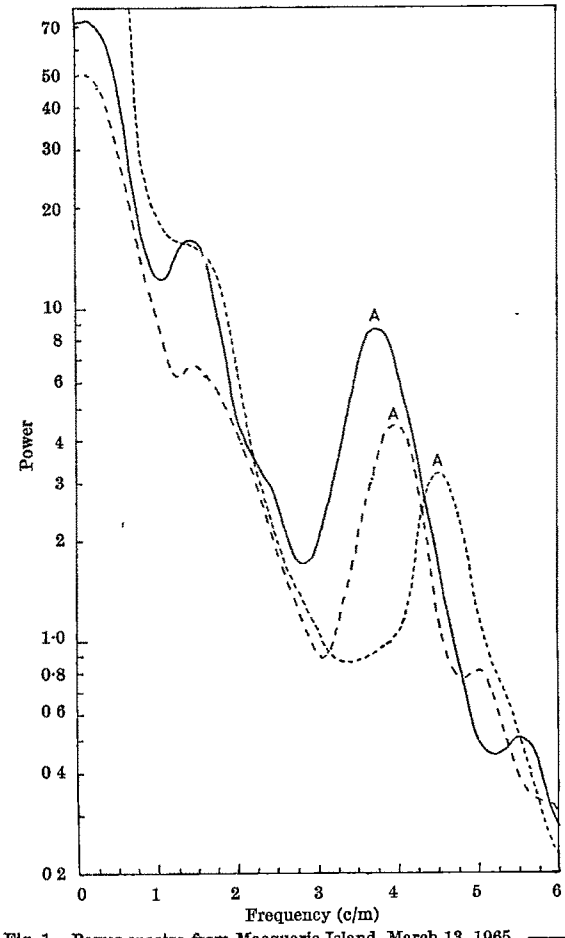

Fig. 1. Power spectra from Macquarie Island, March 13, 1965. ———, 0000 h E.A.S.T.; — · — · —, 1200 h E.A.S.T.; – – –, 2400 h E.A.S.T.

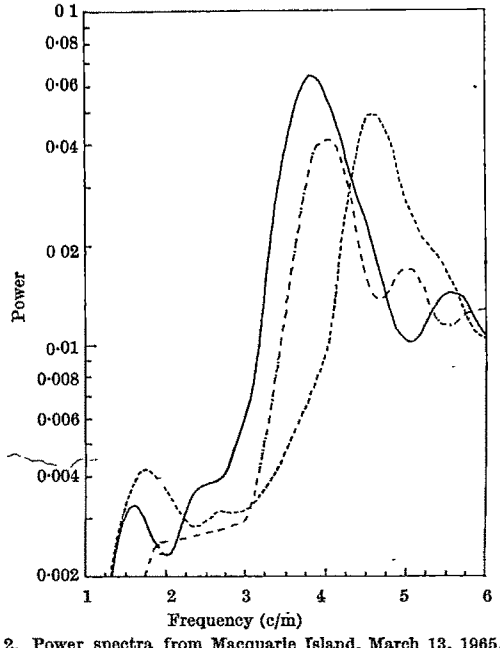

Fig. 2. Power spectra from Macquarie Island, March 13, 1965, after high-pass filtering. ———, 0000 h E.A.S.T.; — — —, 1200 h E.A.S.T., – – –, 2400 h E.A.S.T.

The peak marked A in Figs. 1 and 2 has moved during the 24 h covered by the records from a frequency $f_1 = 3{\cdot}75$ to $f_2 = 4{\cdot}5$, indicating that the corresponding waves may have originated from a storm a distance

$$X = (g/4\pi)/(\mathrm{d}f/\mathrm{d}t) \approx 2{,}500(t_2 - t_1)/(f_2 - f_1) \qquad (1)$$

from Macquarie Island, where it has been assumed that the motion of the storm centre is negligible, the depth of the ocean is constant, and the times t_i are given in days. Hence the distance of the storm centre from Macquarie Island is 3,400 miles.

Since the group velocity C_g equals half the phase velocity

$$C_g = (gT)/4\pi \simeq 2{,}500/f \qquad (2)$$

where T sec is the period corresponding to the frequency of f c/m, and C_g is given in statute miles per day, the swell of frequency $f_1 = 3{\cdot}75$ travelled approximately 670 miles/day, that is, it took 5 days to reach Macquarie Island and must have been generated on March 7.

Isobaric charts of the Commonwealth Weather Bureau in Melbourne showed a depression of 975 mbar near Kerguelen Island at 1800 E.A.S.T. on March 6, with recorded winds of 30 knots, which subsequently subdivided into two depressions of 962 and 968 mbar on March 7 (see Fig. 3). It is suggested here that this was the source of the swell recorded at Macquarie Island on March 13.

M_2 and S_2 Tidal Components at Hyderabad

As reported earlier[1] the 'Askania *GS*.11' gravimeter has been in continuous operation at Hyderabad as part of the extended programme of earth tide investigations. In its present location the instrument rests on a separate pier with a shallow concrete foundation. The 'Askania' tide recording equipment is now being used instead of the photographic registration described earlier[2]. The results of harmonic analysis of tidal data by Pertzev's method for 29 days of observation[3] (after elimination of drift by the running mean method[4]) are presented. Considering the latitude of this station (17° 26′ N.) it is expected that only the semidiurnal components would yield reliable results. So far only the two important semidiurnal components, namely, M_2 and S_2, have been evaluated and the corresponding gravimetric factor G has been calculated. In the case of the S_2 wave it should be noted that the results are only a first approximation. Using the values of G obtained, the tidal elastic constants have been calculated and are tabulated in Table 1, where h and k are love numbers, l is the Shida number, D is the diminishing factor, L is Lambert's constant and μ is the rigidity of the earth in 10^{12} dynes/cm^2.

The mean gravimetric factor is 1·17 for M_2 and 1·19 for S_2. The value of G equal to 1·17 for M_2 is in very good agreement with the results reported by Harrison *et al.*[5]

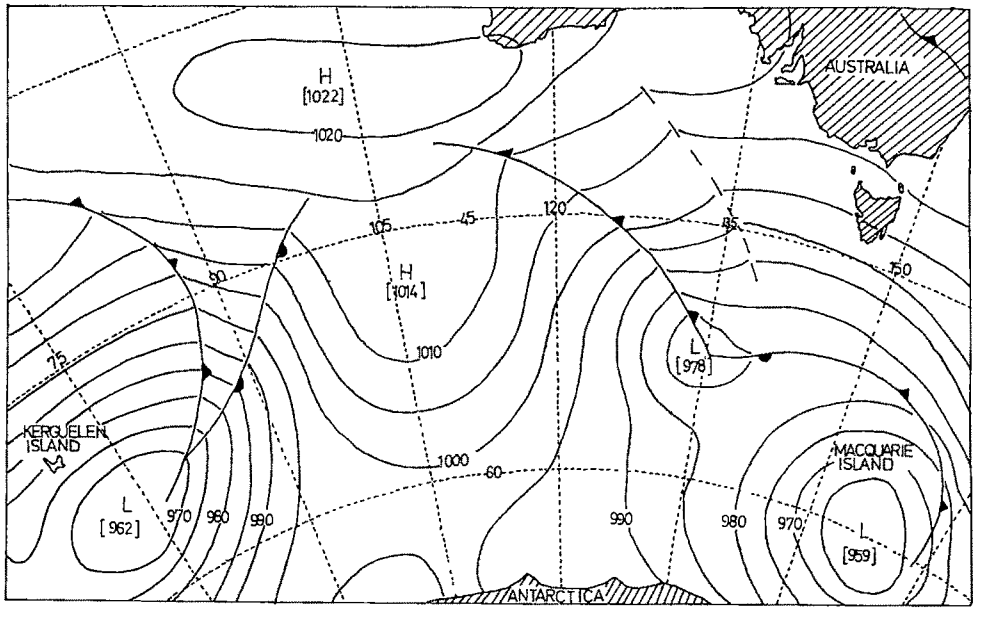

Fig 3. March 7, 1965

In the near future, similar wave recorders are to be installed at Cape Sorrell (Tasmania), Cape du Couedic, Kangaroo Island (South Australia), and a number of other locations along the Australian south coast and on Kerguelen Island. Eventually, it is hoped to separate local and global effects by auto- and cross-correlations of these records and thus to achieve a firmer basis for this method of focusing of storm centres.

GEOCHEMISTRY

Identifying the Geographical Source of Artefact Obsidian

DURING an avocational search for means of identifying the geographical source of artefact obsidian, what appears to be a functional tool has been found. It was postulated that, because the concentration ratio

$$\frac{\Sigma \text{ strontium}}{\Sigma \text{ rubidium}}$$

in rocks is determined by the origin and age of the rock, it would also be diagnostic of material from a given locality. This communication reports the results of preliminary experiments designed to test the feasibility of the hypothesis.

* Ranges include either replicate analyses on the same sample or analyses on more than one sample from the same site, or both.

† Little Glass Mountain comprises at least two flows. Samples 1–5 were taken at least ¼ mile apart around the outer perimeter of one flow. Sample 7 is from what would seem to be a second flow. The total distance from site 1 to site 7 is about 1 mile.

‡ The samples from Mount Konocti were taken from several road cuts in a distance of about 2·5 miles. The series representing several depths were taken from the side wall of a borrow pit.

Obsidian samples were collected from three regions in California, each including several local outcrops, as illustrated in Fig. 1. X-ray spectroscopy was used to estimate the strontium/rubidium ratio on samples prepared simply by sawing or grinding appropriately shaped pieces from hand specimens. The sawn or ground surface was 'X-rayed' without further treatment. A Norelco X-ray spectrograph, equipped with a tungsten target fluorescence tube, was used under the following conditions: X-ray tube excitation, 45 kV, 45 m.amp; crystal, lithium fluoride; detector, scintillation, operated at 0·95 kV; pulse height analyser, 9-V base, 16-V window; air path, 0·005 in. beam collimator, 0·040 in. detector collimator; scanning rate, 1° per min.

Fluorescent X-ray intensity was continuously recorded as 2 θ was scanned from 24·50° to 27·50° to include the strontium $K\alpha$ and rubidium $K\alpha$ emission lines. The ratio of the heights of the recorded X-ray intensity peaks was used as a measure of the strontium/rubidium concentration ratio in the sample. No attempt was made to calibrate in terms of actual amounts of strontium and rubidium present, and the ratios are labelled $(Sr/Rb)_a$ as a reminder of this fact. Our results are summarized in Table 1.

In the Clear Lake region, Cole Creek drains Mount Konocti. The obsidian from Cole Creek, which occurs as rounded pebbles in contrast to the sharp angular pieces found on Mount Konocti, apparently originated on Mount Konocti. This conclusion is supported by the close agreement in $(Sr/Rb)_a$. It is clearly possible to decide whether a sample of material known to be from the Clear Lake region came from Borax Lake or Mount Konocti. Similarly, it is easily possible to distinguish within the Medicine Lake area among samples originating from Grasshopper Flat, Little Glass Mountain or Tickner Road, but probably

not between Tickner Road and Grouse Hill. It would also seem possible to distinguish one crater from another in the Mono Crater complex, although confirmation is needed in view of the small number of samples considered.

The three regions investigated were among the most important sources of obsidian for the Indians of Northern California. Before the geographical source of artefact obsidian can be identified with confidence, however, it will be necessary to survey more completely all quarries of known or suspected significance.

When a more complete compilation of strontium/rubidium ratios is attempted, it will probably be found that greater precision in determining strontium/rubidium is needed. To permit interchange among investigators, the analyses should be calibrated so that the actual concentration ratio is reported. Refinement is possible in geological sampling, in X-ray sample preparation, and in statistical treatment of data.

Careful geological sampling is necessary to prove that variations in the strontium/rubidium ratios within a locality or outcrop are smaller than differences among localities. Our preliminary results (Table 1) indicate that this is so.

Improved sample preparation will reduce the range of values observed in replicate analyses on the same sample[2]. It is conceivable that an X-ray spectrographic technique could be developed to provide non-destructive analyses of artefacts. If this is attempted, however, attention should be paid to possible alteration in the strontium/rubidium ratio by weathering of exposed surfaces. Powdered samples prepared by grinding several small chips taken from inconspicuous places on a single artefact should prove entirely adequate.

With careful refinement of technique, it should prove possible to locate the geographical origin of obsidian artefacts with confidence and precision.

We thank the School of Earth Sciences at Stanford for the opportunity to use school facilities on an extra-curricular project. We also thank Dr. H. J. Moore for his help in collecting the samples from the Mono Lake region.

METALLURGY

Ageing and the Bauschinger Effect in Mild Steel

As part of a larger programme of study of anisotropy and the Bauschinger effect in cold-worked metals, I conducted a series of tests on deformed and age-hardened mild steel. Only a limited series of tests were carried out and so the generality of the results has not been confirmed. However, it was considered worthwhile to report on these with the view of establishing whether such a phenomenon had been observed previously.

The experiments were carried out on annealed semi-killed 0·2 per cent carbon steel having the following composition (per cent): carbon, 0·21; manganese, 0·53; silicon, 0·23; sulphur, 0·032; phosphorus, 0·032; chromium, 0·20. Specimens in the form of strips 0·2 in. thick, 3/4 in. wide, with a 1 in. gauge length were deformed under tension to a strain of about 0·35 per cent, corresponding to a yield strength of about 50,000 lb./in.^{2}. After this advance deformation, the test pieces were subjected to ageing for 1 h at temperatures of 100° C, 200° C, and 300° C, respectively. Some test pieces were then tested again under tension while others were tested in compression. The results of these tests are shown in Fig. 1, which also shows the results of a compression test on a specimen which had not been aged. The time between deformation and subsequent testing was made as short as possible in order to avoid additional age-hardening.

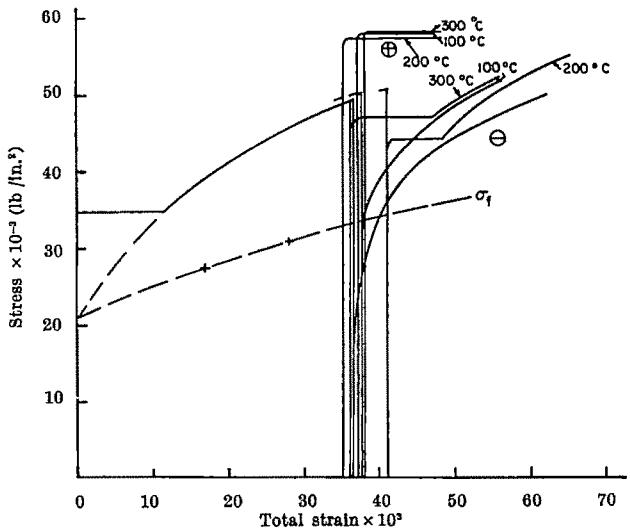

Fig. 1

If the flow stress required to maintain plastic deformation is the sum of a "frictional" stress σ_f required to overcome local stress fields and a back stress σ_b due to piled-up dislocation arrays, then:

$$\sigma = \sigma_f + \sigma_b$$

On reversal of deformation, then we may write:

$$\sigma_r = \sigma_f - \sigma_b$$

as the back stress will assist the deformation. In addition to these, ageing of body-centred cubic metals leads to locking of dislocations by solute atoms contributing a locking stress σ_l. Thus after ageing at temperature T:

$$\sigma_T = \sigma_f + \sigma_{bT} + \sigma_{lT}$$

and:

$$\sigma_{rT} = \sigma_f - \sigma_{bT} + \sigma_{lT}$$

where it is assumed that the locking stress and the back stress both depend on the ageing temperature.

Since σ_f will depend on the mean density of dislocations, it will be assumed that it is independent of ageing temperature. On the other hand, it will be further assumed that, in the limited time allowed, no dislocation locking will occur at room temperature and, therefore, $\sigma_{l_0} = 0$. As a consequence, the various components of the stress can be evaluated from the equations:

$$\sigma_f = \frac{\sigma_0 + \sigma_{r_0}}{2} \qquad \sigma_{b_0} = \frac{\sigma_0 - \sigma_{r_0}}{2}$$

$$\sigma_{lT} = \left(\frac{\sigma_r + \sigma_{rT}}{2}\right) - \sigma_f \qquad \sigma_{bT} = \frac{\sigma_T - \sigma_{rT}}{2}$$

where σ_0 is the stress at the end of pre-strain and σ_{r_0} the reversal flow stress in the absence of age-hardening. The variations of σ_{bT} and σ_{lT} have been determined from the results already presented and demonstrated in Fig. 2.

These results would seem to demonstrate an interaction between the presence of piled-up arrays and the diffusion of solute atoms. Thus, the higher interaction potential field surrounding the piled-up arrays will lead to a preferred diffusion to the head of the array. One effect of this is to relax the strain energy field leading to a reduction in σ_b, and the other is to reduce the rate of build-up of the locking stress. However, as the ageing temperature is raised, the piled-up arrays relax further and a greater proportion of solute atoms becomes effective in locking dislocation sources. Thus, σ_b decreases and σ_l increases.

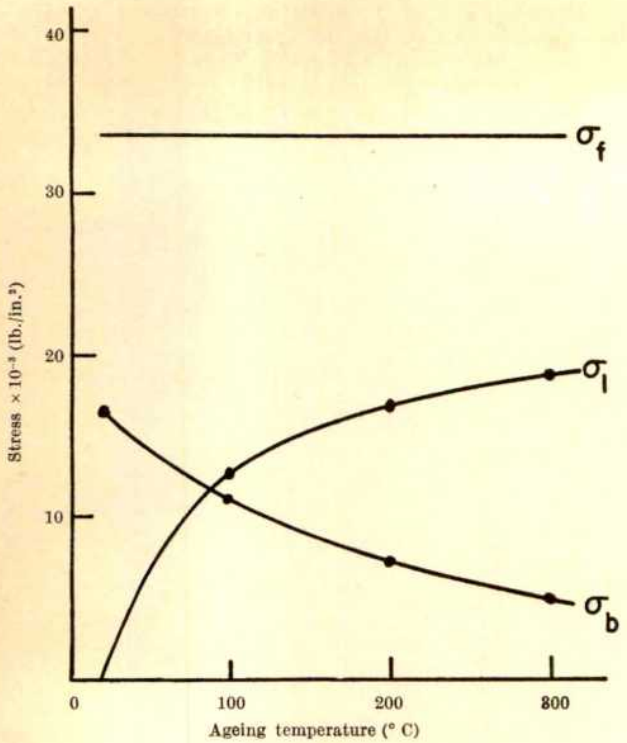

Fig. 2

Further tests indicate that the recovery temperature for this material was about 500° C. A reasonable extrapolation of the σ_b curve gives a value of zero at this temperature, that is, the Bauschinger effect would then be completely eliminated.

It may be observed that the value of σ_f so calculated is close to the value of the initial yield stress. On further investigation of other tests, however, it is seen that this agreement is a coincidence because of the pre-strain chosen. However, if the same procedure of calculating a frictional stress σ_f and a back stress σ_b is applied to these results, the variation of σ_f is shown by the dotted line in Fig. 1. As it may be observed, this curve may be extrapolated back to the zero strain axis where it meets the flow stress curve extrapolated below the flat yield plateau.

The form of the analysis then suggests that the flow stress is the sum of three components ($\sigma = \sigma_f + \sigma_b + \sigma_i$) where the locking stress has been eliminated. It is then of a higher magnitude than normally considered (for example, it is normally taken as $(\sigma_T - \sigma)$). I am planning to carry out further experiments to verify the validity of this approach.

High-temperature Embrittlement of Stainless Steel irradiated in Fast Fluxes

IT has been widely demonstrated that irradiation in thermal fluxes results in the loss of high-temperature tensile ductility in stainless steels[1–9], and strong evidence has been advanced to support the contention that helium produced from the boron-10 ($n\alpha$) reaction with thermal neutrons is responsible for this loss in ductility[9,10]. Development of bubbles in irradiated stainless steels has been observed by thin foil electron microscopy (Fig. 1), and consideration of mechanical property, metallographic and electron microscope data led to the formulation of a theory of high-temperature embrittlement[11–13]. This was based on the weakening of grain boundaries by the migration to these areas, under stress, of helium to form bubbles larger than a critical size, failure occurring as the bubbles grew and linked together.

In predominantly fast fluxes, such as those found in the Dounreay fast reactor, capture cross-sections are, in general, much lower than in thermal fluxes, so that the production rate of helium from boron-10 is very much slower (the fast reactor rate is about 1 per cent of the thermal reactor rate). However, at high neutron energies (greater than about 3 MeV) ($n\alpha$) reactions occur in nearly all materials[14], so that helium production in a fast flux environment is not reduced by as much as might be expected. Furthermore, whereas the production of helium in a thermal flux is critically dependent on the boron content and virtually ceases when all the boron-10 has been burnt up, that is, after a thermal dose of about 10^{21} neutrons/cm², helium production in the fast flux is not so dependent on the boron content and increases approximately linearly with time—this is because every atom is a potential helium source (Fig. 2).

has been carried out to neutron doses within the range 10^{21}–5×10^{22} *nvt*. At test temperatures >600° C (the temperature range in which high-temperature loss in ductility was observed in stainless steels irradiated in thermal fluxes), little degradation in ductility occurred with doses less than 10^{21} *nvt*. Further increase in dose above 10^{21} *nvt* resulted in losses in ductility which, over the dose range examined, were linear with log total dose (Fig. 3). Strength properties were in general little affected by increasing dose; there was, however, an increase in yield stress at 600° C, due to irradiation hardening.

It has also been shown that ductility decreases linearly with the log calculated total helium content (Fig. 4); helium contents determined in irradiated specimens by means of mass-spectrographic techniques correlated well with values calculated from reactor physics data[15].

Helium produced in thermal reactors during low-temperature irradiation does not seem to exert its full damage potential. In specimens of the same material, tested at temperatures above 600° C, the helium content required to produce the same effect on elongation in fast irradiations as that observed in thermal flux irradiations was less. One possible explanation of this is the segregation of boron in boron-rich segregates, or oxide or carbide inclusions[16], leading to localized hold-up of helium in thermal irradiations, in contrast to predominantly fast flux irradiations where the helium is formed homogeneously throughout the matrix.

Electron Microscopic Observation of Coatings on Titanium Dioxide Pigments

IT is common practice in the final stages of the manufacture of titanium dioxide pigments to apply coatings to the crystal surfaces, in order to reduce their photochemical activity and improve their dispersibility in various media. These coatings often take the form of 1–3 per cent of oxides or hydrated oxides precipitated in an aqueous dispersion of the pigment. It is important to know whether the products are truly coated pigments, merely mixtures of the pigment and coating material, or something between the two extremes. For a uniform coating,

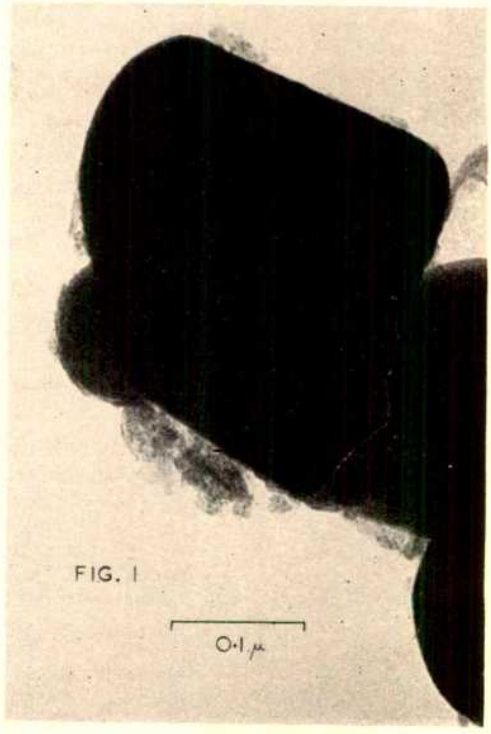

Fig. 1

Fig. 2

the thickness to be expected is about 50 Å, or one-fiftieth of the crystal diameter.

The coatings may be observed directly in the electron microscope by sprinkling the pigment on to a carbon membrane, and taking the usual precautions to minimize build-up of contamination layers. Fig. 1 shows a very uneven deposit on rutile, contrasting with the considerable degree of uniformity on pigment (Fig. 2) which is in agreement with the improved technological performance of the second pigment. Replacement of the coating by a carbon–platinum technique[1] to give enhanced contrast does not appear to be necessary, and could lead to erroneous estimations of the coating thickness.

CHEMISTRY

Pulse Radiolysis Investigations of Unimolecular Elimination Reactions in Free Radicals produced by OH Addition to Hydroxybenzenes

During the course of the experimental research programmes in pulse radiolysis carried out independently at the Mount Vernon Hospital and the Paterson Laboratories, a new series of unimolecular free radical decomposition reactions has been observed. Some of the separate findings have been combined and are summarized in this introductory communication.

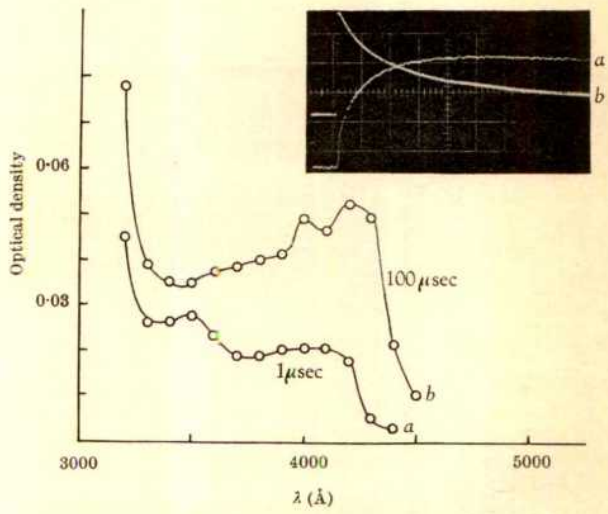
In investigations of the kinetics of the formation of quinonoid free radicals from quinones and hydroquinones[1] a reaction has been characterized which involves the unimolecular elimination of a water molecule from the OH adduct of hydroquinone (trihydroxy*cyclo*hexadienyl radical). The product of this reaction is the benzsemiquinone radical. A similar water elimination reaction has been found for the dihydroxy*cyclo*hexadienyl radical obtained by OH addition to phenols[2].

These reactions are analogous to the well-known dehydration reactions of aromatic dihydrols to form phenols in that the facility of these reactions is related to the increase in resonance energy gained when the molecules change to the completely aromatic form. Similar reactions have been observed for the OH adducts of *p*-cresol, tyrosine, β-naphthol and resorcinol. The general phenomenon is illustrated by specific reference to investigations with *p*-benzhydroquinone and phenol. The pulse radiolysis techniques used in this work have been fully described in earlier communications[3,4].

p-Benzhydroquinone. Previous investigations have shown that OH radicals react rapidly with *p*-benzhydroquinone (QH_2)[5] ($k = 1{\cdot}2 \times 10^{10}$ M^{-1} sec^{-1}). Pulse radiolysis studies, at various concentrations of neutral solutions of QH_2 saturated in nitrous oxide, however, showed the formation of two transient absorbing species. One of these species was formed during a 0·2-μsec pulse of 1·8-MeV electrons, whereas the second developed more slowly (Fig. 1). Under the conditions where all hydrated electrons react with nitrous oxide, the yield of oxidizing radicals was increased about two-fold and, because similar results were obtained when nitrous oxide was replaced by hydrogen peroxide which also converts e^-_{aq} to OH radicals, it was tentatively concluded that the first transient was formed by addition of OH radicals to the aromatic ring.

The transition to the species with an absorption maximum at 4250 Å was kinetically first-order under all conditions and, since the reaction order was unaffected by the absolute value of dose/pulse, doses of between 1 and 2 krads were generally used. The experimental rate constant of $4{\cdot}6 \times 10^4$ sec^{-1} at 20° C was independent of solute concentration but showed a small temperature coefficient. An activation energy of 4·2 kcal M^{-1} was obtained. The reaction became very rapid at values of *p*H on either side of neutrality indicating strong acid-base catalysis.

The second transient species disappeared by simple second-order kinetics, but the absolute rate was slower in neutral solution compared with that at *p*H 2. Salt effect studies demonstrated that the species decaying in neutral solution carried a unit charge consistent with its assignment to the anion of the benzsemiquinone radical.



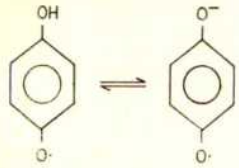


Fig. 1. Transient absorption spectra after pulse radiolysis of 5 mM hydroquinone saturated with nitrous oxide. Curve *a*, Absorption immediately after the pulse; curve *b*, absorption after 100 μsec delay. *Inset*, Oscillogram showing: *a*, transition from the OH adduct to the semiquinone ion ($\lambda = 4180$ Å); *b*, decay of the semiquinone ion. Ordinate, percentage absorption, 2·6 per cent per large division; abscissa, (*a*) build-up, 20 μsec per large division; (*b*) decay, 1 msec per large division

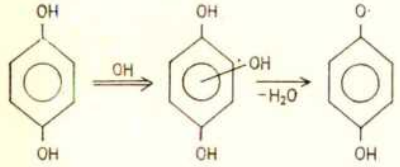
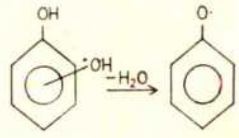


The absorption spectrum was similar to that previously attributed to semiquinone anions[6,7,11].

Investigations of the effect of *p*H on the absorption at 4300 Å have shown that the *p*K of the equilibrium (1) is 4·0.



(1)

The foregoing evidence supports the view that the oxidation of hydroquinone by OH radicals proceeds according to equation (2).

(2)

Phenol. Previous investigations[8] have shown that OH radicals react very rapidly with phenol to form dihydroxy*cyclo*hexadienyl radicals, λ_{max} 3200 Å. Pulse radiolysis of aqueous solutions of phenol (10^{-3} M) saturated with nitrous oxide showed that in addition to the adduct radical formed immediately with λ_{max} at ~3300 Å a secondary transient species with maxima at 4000 Å and 2950 Å built up during the first few hundred μsec after the pulse (Fig. 2). The spectrum of the secondary species was consistent with it being due to the phenoxyl radical Φ0· (ref. 9). In this case, a low pulse dose (13 rads) was necessary in order to reduce second order radical-radical reactions to an insignificant level, Φ0 being relatively unstable compared with the benzsemiquinone anion. The rate of build-up of Φ0· at 4000 Å was found to follow first-order kinetics ($k \sim 5 \times 10^3$ sec^{-1} at 20° C), and was about equal to the rate of decay of the 3300 Å absorption, when these low doses were used (Fig. 3). The reaction was temperature-dependent and acid-base catalysed, as was the formation of $\dot{Q}^-$ from trihydroxy*cyclo*hexadienyl radicals. These results suggest that elimination of water accounts for the decay of most if not all of the OH adduct radicals formed (3).

(3)

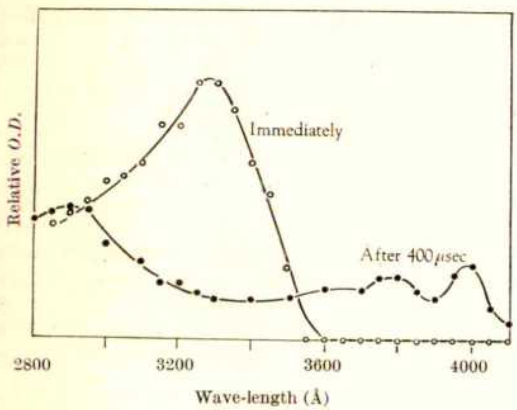


Fig. 2. Transient absorptions after pulse radiolysis of 10^{-3} M phenol in water, saturated with nitrous oxide (dose ~140 rads)

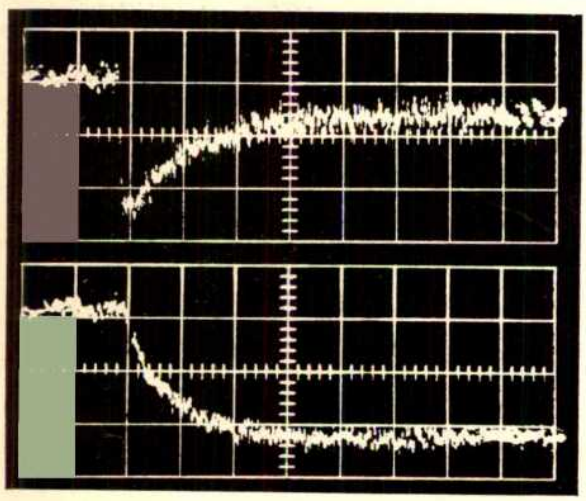

Fig. 3. Oscilloscope traces of decay of initial transient absorption at 3300 Å (top) and formation of secondary transient absorption at 4000 Å (bottom). Dose ~13 rads. Vertically upward displacements, increasing transmission. Horizontal displacements, time (1 large division = 200 μsec)

These investigations are being extended to aqueous solutions of aromatic amines, and preliminary pulse radiolysis experiments on solutions of aniline and *N*,*N* dimethyl aniline show the eventual analogous formation of highly resonance stabilized anilino radicals[10].

Ionization Detector for Gas-phase Titration

GAS-PHASE titrations are rarely used because of the lack of suitable and sensitive titration end-point detectors. We have found that ionization detectors[1] are eminently suitable to follow the course of a gas–gas reaction in a continuous flow system. The response of such detectors is, in general, unspecific. A number of detectors were investigated; the following discussion deals with ionization cross-section detectors.

These detectors respond to all gases and their output current is directly proportional to gas concentrations from 0 to 100 per cent and to the ionization cross-section of the gas molecules. Changes in the flow rate and the polarizing voltage have negligible effect on the output when the detector is operated at the plateau of its current-voltage characteristic.

Fig. 1 shows a schematic diagram of the titration system. A carrier gas flowing with constant velocity is continuously mixed, in a reaction chamber (*A*), with a sample gas, also flowing with constant velocity, and with a titrant gas. The gas mixture then enters the cross-section detector (*B*). The detector is polarized by the voltage supply (*D*) connected in series with the current meter (*C*). The flow rate of the titrant is varied from zero to a value significantly larger than that corresponding to the end-point; the current values are plotted against the flow rate of the titrant introduced into the carrier flow.

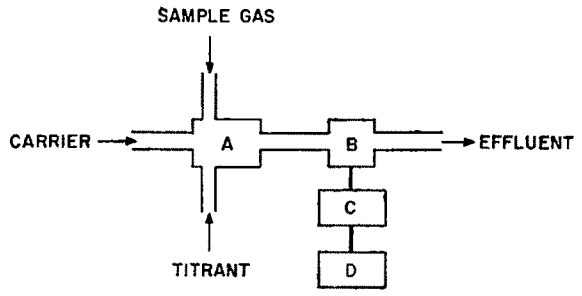

Fig 1. Schematic arrangement of gas–gas titration system with ionization cross-section detector *A*, Mixing and reaction chamber; *B*, ionization detector; *C*, current meter; *D*, voltage supply

Assuming perfect mixing of all gases introduced in the system, 100 per cent yield of reaction, and collection and production of ions in the detector without losses, the detector current is:

$$I = K \frac{PV}{RT} \sum_i Q_i x_i \qquad (1)$$

where P is the pressure in the detector, V its active volume, R the gas constant, T the absolute temperature and K a constant determined by the dimensions of the detector and the radiation intensity. Q_i and x_i represent the ionization cross-section for the type of ionization present in the detector and the molar fraction of the constituents of the gas mixture entering the detector.

The process for the calculation of the detector current is shown in Fig. 2 for a reaction:

$$A + B \rightarrow C \qquad (2)$$

where A is the unknown sample, B is the titrant and C is the product of the reaction. Fig. 2*a* shows how the molar concentration of each of the components of the reaction changes during the titration. The concentrations of the carrier and of the product decrease after the end-point because of an increase of the total flow rate.

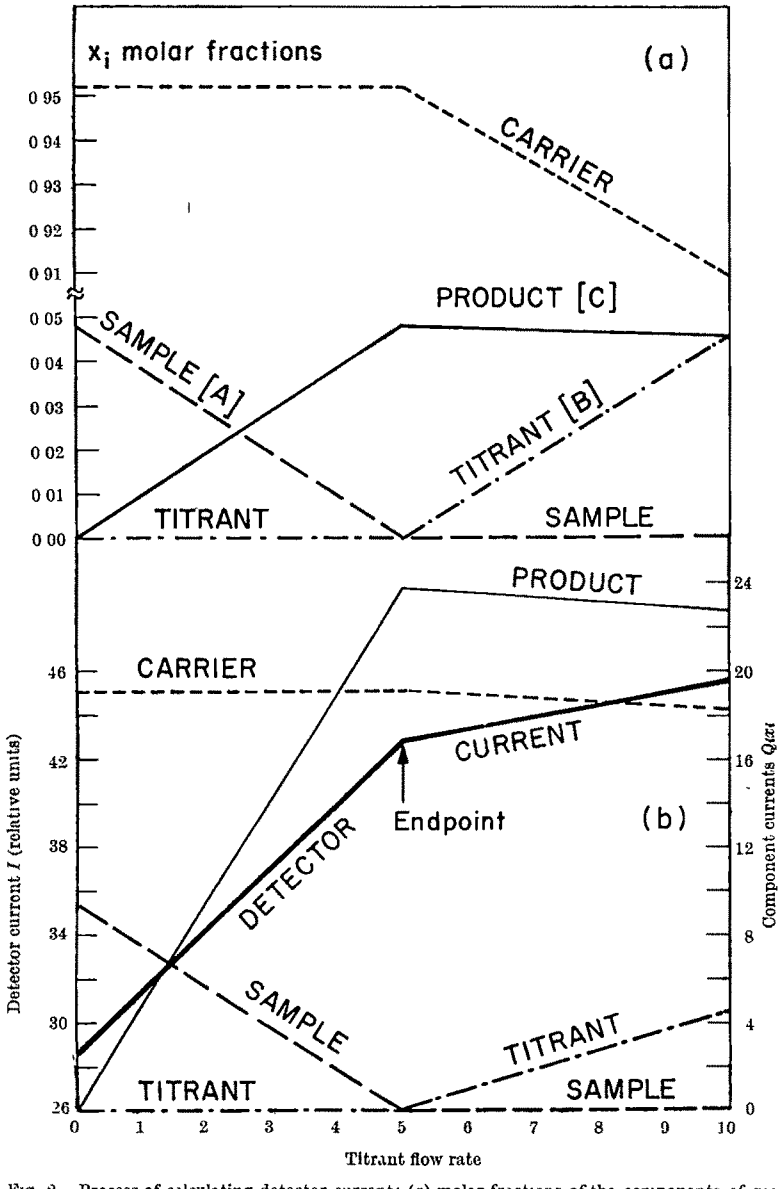

Fig 2 Process of calculating detector current: (*a*) molar fractions of the components of gas flow systems, (*b*) component and detector currents

In Fig. 2*b* the independent current contributions of each of the components are plotted according to equation (1), and assuming the following values of relative ionization cross-sections:

$$Q_A = 2,\ Q_B = 1,\ Q_C = 5 \text{ and } Q_{\text{carrier}} = 0{\cdot}2$$

These values are closely related to possible experimental conditions. The ionization cross-section detector current I is the sum of all the component currents at each value of titrant flow rate. The titration end-point appears as a change in the slope of the plot of current against titrant flow rate.

The slope of the titration curve is directly related to the cross-section, concentration and ratio of the components of the titration and to the rate of the reaction. The greater the difference between the cross-sections of the reacting species and the product, the sharper the break will be at the end-point. A carrier with much lower cross-section than the other components of the reaction will decrease the background current.

The method provides a new technique for the analysis of gases. Appropriate selection of the titrant can provide specific determination of a reacting gas in a mixture. Furthermore, the direct relation between the detector current and the concentrations and cross-sections of gases present during a reaction can be used in kinetic studies of gas-phase reactions.

Several gas-phase titrations have been measured. An example, the result of the gas–gas titration, measured with an ionization cross-section detector, of oxygen with nitric oxide represented by the reaction:

$$O_2 + 2NO \rightarrow 2NO_2 \qquad (3)$$

is shown in Fig. 3. Additional research is being conducted.

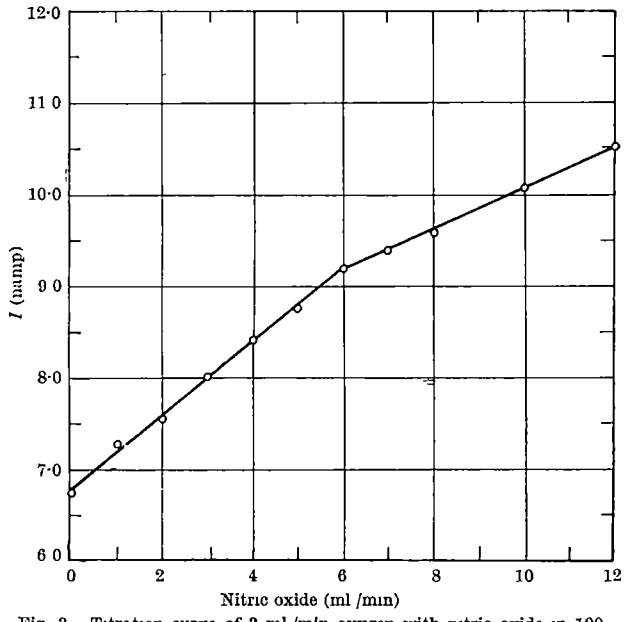

Fig. 3. Titration curve of 3 ml./min oxygen with nitric oxide in 100 ml./min helium carrier (*T*, 150° C)

Isotope Fractionation of Methyl Esters by Gas–Liquid Chromatography

THE radiohomogeneity of tritium- and carbon-14-labelled methyl linoleate *in vivo* and the stability of the labelled methyl esters during gas–liquid chromatography has recently been investigated[1]. It was shown that the tritium : carbon-14 ratio of the entire peak was unchanged by gas–liquid chromatography. However, when portions of the effluent peak were collected the tritium : carbon-14 ratio varied. In view of the separation potentialities of gas chromatography, it seemed worthwhile to investigate whether or not any difference in the mobilities of the two isotopic molecules during chromatography caused these variations. Accordingly, several columns containing commonly used polar and non-polar phases were used and a number of methyl esters labelled with both tritium and carbon-14 were chromatographed. The tritium : carbon-14 ratios obtained for successive fractions were examined for evidence of any difference in the mobilities of the two compounds.

Linoleic acid labelled with tritium at the 9, 10, 12 and 13 positions was prepared as reported earlier[2]. Linoleic-1-^{14}C acid was purchased from California Corporation of Biochemical Research and it was purified on a silica–silver nitrate column[3]. Stearic and oleic acid doubly labelled with both isotopes were prepared as described[3]. Methyl esters of all fatty acids were formed by reaction with diazomethane. Gas–liquid chromatography was performed by means of an Aerograph model *A*-90-*C* (Wilkens Instrument and Research, Inc.) equipped with a thermal conductivity detector. Copper columns 3·5 in. × 6 ft. were packed with either 20 per cent diethylene glycol succinate polyester (DEGS), 14 per cent ethylene glycol succinate or 1 per cent *SE*-30 on 'Gas Chrom *P*' operated at temperatures ranging between 160° and 190° C. The column effluents were collected on cartridges packed with *p*-terphenyl impregnated with 5 per cent *DC*-550 silicon oil[5]. An automatic fraction collector (Packard 'Tri-Carb' model 830) was used and fractions were collected every 20 sec throughout the fatty ester peak. At the completion of the analysis each cartridge was removed from the fraction collector and was placed in a scintillation vial[4]. The background radioactivity of the column was checked before analysis, and whenever it was found to be higher than the normal the column was replaced.

Scintillation counting was carried out in a Packard 'Tri-Carb' model 314 *EX*. Channel settings were: lower channel 400–100 division, gain 500: upper channel 76–400, gain 1,000: coincidence monitor *A'* setting 7·6, gain 1,000 : voltage setting 1,150. Computation of the number of disintegrations (d.p.m.) tritium, d.p.m. carbon-14 and the isotope ratio tritium : carbon-14 from the counts in each channel was made according to the method of Kabara *et al.*[5]. In addition, three forms of computation were applied, that is, probit analysis based on cumulative percentage, fraction by fraction, of each isotope eluted, ln φ (φ = ratio of tritium : carbon-14) and MODI-φ based on the isotope ratio of successive fractions by using an established programme in the IBM/620 computer[6].

The tritium : carbon-14 ratios among the fractions throughout the fatty ester peak in a number of chromatographic runs are presented in Table 1. A progressive decrease in the tritium : carbon-14 values indicated that fractionation occurred during the chromatographic process and that the tritium-labelled methyl ester moved ahead of the carbon-14-labelled methyl ester. The presence of one or two double bonds in the fatty acid chain did not seem to be critical as the effects were similar for methyl stearate, oleate and linoleate. These effects were more apparent in non-polar than in polar columns, becoming almost negligible when an aged polar column was used. Frequently, the tritium : carbon-14 ratio increased in the tail of the peak.

* Not determined.

The results of the runs recorded here were carefully examined for artefacts. Radiochemical artefacts were excluded when the methyl esters were subjected to several criteria for radiochemical purity[3]. Instrumental artefacts were examined and were found to be absent. For this purpose, radioactivity of either type was added to each fraction and it was fully recovered. On the other hand, the same mixture at several count rates gave the same tritium : carbon-14 ratio excluding any dependence

of the isotope ratio on count rate. The possibility of chromatographic artefacts was given special consideration. Chromatographic fractions from all regions of the peak were rechromatographed on a 'Hy-Fi' Aerograph model 600 *B* equipped with a flame detector. In all cases, no other peak than that anticipated appeared. Memory effects due to a binding of the labelled methyl ester on the column and subsequent elution in the following chromatographic run were ruled out when cold methyl arachidate (Applied Science Corporation State College, Pennsylvania) was included in the injected sample and its entire peak was collected and measured for radioactivity. Only traces of tritium and carbon-14 were present in the methyl arachidate eluate.

It seemed reasonable that fractionation of the two differently labelled methyl esters occurred during the chromatographic process. Calculation of the displacement of either isotope from the other was made by the three methods indicated and the results using data from chromatographic runs of doubly labelled methyl linoleate are recorded in Table 2. It is evident that the tritium-rich molecule displaced the carbon-14-labelled molecule (M_1 M_2) in all cases where displacement was observed.

These results were in accord with those obtained in previous investigations and demonstrated that gas–liquid chromatography, utilizing commonly used columns, has sufficient resolving power to segregate isotopic molecules that differ less than 2 per cent in mass. Although the existence of isotopic fractionations in many chromatographic processes[3,6–12] may be possible, the mechanism by which these effects occur is unknown in most cases.

I thank Dr. P. D. Klein, Division of Biological and Medical Research, Argonne National Laboratory, Argonne, for the computation of the data and for helpful discussions. I also thank Carolyn Duguid for technical assistance.

Osmotic Emergency Purifier of Sea Water

WHEN a hypertonic solution is separated from a hypotonic one by a semipermeable membrane, solvent will flow from the hypotonic to the hypertonic system until equilibrium is established. Sea water is essentially a 0·6 N solution of polar solutes in water. A membrane which would, under certain conditions, reject sodium and larger ions and allow migration of water free of solutes can be obtained[1]. Cellulose acetate, for example, fulfils the condition of rejection of sodium chloride[2]. A semipermeable membrane system for concentrating beverages was conceived some 30 years ago[3], but practical development has awaited the advent of appropriate membranes.

When a concentrated solution of hexoses and organic acids such as a fruit juice concentrate is placed on one side of a cellulose acetate membrane and immersed in sea water, water will enter the system and continue flowing across the membrane until equilibrium is reached. The pressure drop across the membrane appears to be largely a function of membrane thickness (Table 1).

Dialysis bags for a preliminary test were fashioned by heat-sealing cellulose acetate, cellulose acetate butyrate, and cellulose triacetate. A small sample of invert sugar was placed in each bag and the bags were immersed in sea water collected at the south-western tip of the San Francisco Golden Gate Bridge. The sea water sample was 0·6 N as the sodium ion. This normality corresponds to 10·8 per cent invert sugar. Tables 1 and 2, however, show a flattening out of the dilution curve at values closer to 20 per cent sugar than to the theoretically correct one. A possible explanation of this reaching of a "point of diminishing return" is that energy losses from the passage of water across the membrane gain in prominence with decrease of the driving force, that is, decrease in the osmotic pressure difference between the solutions on the *cis* and *trans* sides.

Absence of the sodium and chloride ions from the dilute sugar in the dialysis bag shows that the membrane excludes soluble salts. It is clear that the membrane would also exclude the relatively long-lived radioactive debris such as calcium, strontium, iodine, etc. This means that water contaminated by radioactivity can be a source of a potable beverage.

The rejection of strongly polar solutes indicates that the membrane would even more readily reject organic substances unless they attack the membrane. It is likely to remove organic toxins from both sea water and fresh water. Such a device might prove useful where water is contaminated by either man or Nature.

The rejection of organic matter by a cellulose acetate membrane was tested by placing a dialysis bag with concentrated sugar into fresh water to which phenolphthalein was added. The water uptake followed the pattern of acetate in Table 2. No phenolphthalein passed through the membrane. This means that compounds with

Table 2. DILUTION OF SUGAR BY WATER PASSING THROUGH DIFFERENT MEMBRANES

Contact time (h)	Membrane type: Acetate	Acetate butyrate	Triacetate
1	76·4° Brix	76·5° Brix	76·4° Brix
2	70·9	75	—
20	45·4	65·3	64·0
44	33·8	65	—
48	26·4	55	54

The starting material is invert sugar with citric acid at 78° Brix and *p*H 3·8.

fairly high molecular weights and of such a nature as not to dissolve cellulose acetate will tend to be rejected.

Table 2 shows clearly that the fastest rate of water transfer occurred across the cellulose acetate membrane, and further work was done with that type of membrane only. 5 ml. of commercial grape juice concentrate at 46·8° Brix was placed in each of three dialysis bags, the immersed area of which was 115·2, 230·76 and 576 cm², respectively. Water uptake was found to be an area function. A thirst-quenching dilution was obtained in 30 h.

Other experiments dealt with more concentrated juice, necessary for preservation without a can. The results are given in Table 1.

It is possible to obtain by dialysis of sea water or contaminated water a sustaining beverage which is potable and, unlike fish juices, is culturally acceptable. Cellulose acetate (88 mils thick) appears to be an acceptable dialysis membrane.

The method might also be useful for hydration of, for example, "Incaparina", edible jellies, and similar foods in areas with unsafe water.

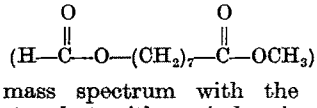
Identification of Methyl Octanoate Derivatives from Autoxidized Methyl Linoleate by Mass Spectrometry, Nuclear Magnetic Resonance and Infra-red Spectroscopy

From our investigations on the volatiles from the mild autoxidation of methyl linoleate, we have already reported the isolation and identification of methyl octanoate[1]. Frankel *et al.*[2] postulated a mechanism for the decomposition of unsaturated hydroperoxy esters that predicts the formation not only of methyl octanoate but also of 8-formyl methyl octanoate, and 8-hydroxy methyl octanoate from 9-hydroperoxy methyl linoleate. Ellis[3] also postulated the formation of semi-aldehydes from oxidation of unsaturated fatty acids. This communication reports further results on an extract of the autoxidized oil which show the presence of 8-formyl methyl octanoate and the formate of 8-hydroxy methyl octanoate (8-formoxy methyl octanoate).

Frankel *et al.*[2] identified 8-formyl methyl octanoate from oxidized methyl oleate, methyl linoleate, methyl linolenate, and linseed oil methyl esters, establishing their identity by measuring their retention times on several gas-liquid chromatographic columns. Nonaka[4] identified some semialdehydes from oxidized fish oil, oleic acid and linolenic acids, but not from linoleic acid.



20 g of methyl linoleate (97 per cent as analysed by gas-liquid chromatography) on purified glass wool was oxidized by passing purified oxygen through it at the rate of 10 ml./min at room temperature in laboratory light. The ester had a peroxide number after oxidation of approximately 1,000. The methyl linoleate from five oxidations was combined and extracted with 500 ml. of isooctane by stirring for 2 h at room temperature. The isooctane solution was then concentrated to a volume of about 25 ml. with a rotary evaporator under water aspirator vacuum. Appropriate volumes, 25–40 μl., of the concentrated isooctane solution were chromatographed on a 4-ft. × 1/4-in. stainless-steel column packed with 20 per cent 'Apiezon *M*' on 'Chromosorb *P*' at 172° C. Two components which had not been present in our investigations of the volatile fraction[1] were separately collected for mass spectrometry, infra-red spectroscopy, and nuclear magnetic resonance analysis. The component with the shorter retention time was designated as *A* and the other as *B*.

Compound *A*, 8-formyl methyl octanoate:

gave a mass spectrum with all the important characteristics of a methyl ester[5], except that the molecular ion was not sufficient for certain identification. In addition, other peaks at mass 171, 178, 158, and 136 indicated an additional functional group. Nuclear magnetic resonance data indicated the presence of an aldehyde, a finding which proved consistent with the observed mass spectrum. Prominent bands in the infra-red spectrum at 2,720 cm^{-1}, 2,820 cm^{-1} and 1,735 cm^{-1} indicated the presence of ester and aldehyde groups in compound *A*. Assuming a molecular ion of mass 186, then the loss of the CH_3 group gives mass 171; loss of water and C_2H_4 (aldehyde characteristics[6]) gives mass 168 and mass 158. Presumably 136 arises from a loss of 18 (water) followed by a loss of 32 (formaldehyde). 8-Formyl methyl octanoate was thus indicated. An authentic sample of this compound gave an identical mass spectrum to that of the unknown compound. The infra-red spectrum of the authentic compound was also identical to that of compound *A*.

Compound *B*, 8-formoxy methyl octanoate:

also gave a mass spectrum with the characteristics of a methyl ester, but with no indication of the parent ion. Prominent ion currents were observed as masses 171, 124, and 96 which were assumed to result from the presence of an additional functional group. Nuclear magnetic resonance data revealed a formate group, but traces of impurities made the estimation of chain-length unreliable. The infra-red spectrum of compound *B* showed prominent bands at 1,735 cm^{-1} and 1,180 cm^{-1} indicating the presence of ester and formate groups. The mass peak at 171 indicated one ether-type oxygen, but whether the fragment lost was CH_3O— or HCO_2— could not be decided without comparison with authentic samples.

A sample of 8-formoxy methyl octanoate was not readily available, but samples of 9-formoxy methyl nonanoate, 10-formoxy methyl decanoate, and 10-formoxy ethyl decanoate were synthesized and analysed in the mass spectrometer. The mass spectrum of the nonanoate showed a mass peak at 185 due to the loss of CH_3O, and both the decanoate spectra showed a mass peak at 199 due to the loss of CH_3O and C_2H_5O, respectively. These corresponded to the mass peak at 171 in the unknown compound and established the compound as an octanoate. The other characteristic peaks (masses 124 and 96) were similarly shifted by 14 and 28 mass units in the nonanoate and decanoate, thus confirming the unknown compound as 8-formoxy methyl octanoate.

8-Formyl methyl octanoate was synthesized by cleavage of threo-9,10-dihydroxystearic acid by periodate[7] and treatment of the half-aldehyde acid with diazomethane. 9-Formoxy methyl nonanoate was prepared by the following series of reactions: 8-formyl methyl octanoate was reduced with sodium borohydride in methanol at room temperature, then formylized in a mixture of formic acid and acetic anhydride[8]. 10-Formoxy methyl decanoate and 10-formoxy ethyl decanoate were synthesized from a sample of authentic 10-hydroxydecanoic acid. The methyl ester was prepared by treating the hydroxy acid

with diazomethane. The ethyl ester was synthesized by refluxing the hydroxy acid with excess absolute ethanol and a catalytic amount of concentrated sulphuric acid for 2 h. Both the methyl and ethyl esters of 10-hydroxydecanoic acid were converted into formates by Reber's technique[8].

All intermediate compounds used in the synthesis, as well as the final products, were purified by means of preparative gas-liquid chromatography with the 4 ft. × 1/4 in. 20 per cent 'Apiezon *M*' column at 172° C.

The three related compounds we have identified, methyl octanoate, 8-formyl methyl octanoate, and 8-formoxy methyl octanoate, appear to form by decomposition of the 9-hydroperoxy ester of linoleic acid. This experimental evidence supports the hydroperoxide theory of oxidation of unsaturated fatty acid esters and lipids that contain unsaturated fatty acids. The isomeric 13-hydroperoxide of methyl linoleate should produce two unsaturated semialdehydes and an unsaturated methyl ester, but our investigation did not detect these compounds. These unsaturated semialdehydes and the unsaturated ester should be unstable under the conditions used and they probably decomposed during isolation The formate may form by reaction of the ω-hydroxy ester with formic acid; however, no free 8-hydroxy methyl octanoate was found. Therefore, it seems more probable that the formate was formed by a concerted mechanism, that is, from 8-hydroxy methyl octanoate and a hydroperoxide[10].

Yields are presented in Table 1; for each the ketone (1 mole) was heated with a representative borane, *tris*-butylaminoborane (1·1 mole) under reflux in benzene.

Table 1

Ketone	Time	Yield (per cent)*
Acetophenone†	20 h	78
*Cyclo*hexanone	8 min	61
Diethyl ketone	8 h	77 5
Methyl isopropyl ketone	24 h	76

* The yield given is of isolated, characterized product
† Pentane solvent.

Excellent yields of amide were produced by heating the reagent (1·5 mole) with a monocarboxylic acid (1·0 mole) in benzene, as shown in Table 2.

Table 2

Acid	Time (h)	Yield (per cent)*
Hexanoic	3·5	98
Pivalic	21·5	90
Phenylacetic	4·0	90
Benzoic	5 0	94

*The yield given is of isolated, characterized product.

Using dicarboxylic acids (Table 3), 5 mole equivalents of the reagent to 1 mole of the acid were used, the solvent being tetrahydrofuran. In this case the salts separated out initially and could be examined. It is noteworthy that no succinic anhydride was produced, and that the reaction time for complete reaction (diamide produced) was shortened. This latter factor may arrive from the somewhat larger excess of reagent used.

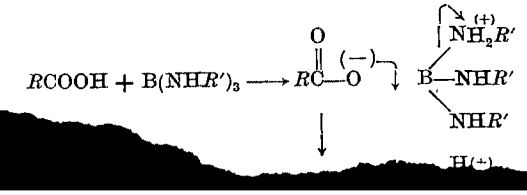

Table 3

Acid	Time (min)	Yield (per cent)*
Succinic	30	83
Adipic	45	74

*The yield given is of isolated, characterized product.

That mechanism of amide formation involved initial salt formation was ascertained by examination of the infra-red spectrum immediately after mixing. The carbonyl stretching frequency at 1,710 cm^{-1} was absent; it had been replaced by a broad band at ~1,540 cm^{-1}, which was associated with the carboxylate anion. However, addition of mineral acid regenerated the carboxylic acid; little amide had been formed at this stage.

The mechanism may be formulated as in Fig. 1.

carbonyl group, leaving it highly susceptible to nucleophilic attack. With suitable substituents X and Y (obviously $X=Y=NHR$ cannot be generally useful), many uses for such mixed anhydrides present themselves. Reports on the systematic variation of X and Y, together with applications of the compounds produced, will be presented shortly.

N-Butylphenylacetamide. Phenylacetic acid (0·51 g) in dry benzene (6 ml.) was added to *tris*butylaminoborane (1·4 g) and the solution heated under reflux for 4 h. The reaction mixture was diluted with ether (5 ml.) and extracted with 3 N hydrochloric acid (2 × 5 ml.), water (5 ml.), saturated aqueous potassium carbonate (2 × 5 ml.) and water (2 × 5 ml.). The acid extract was brought to *p*H 9, saturated with sodium chloride and re-extracted with ether. The organic phases were combined, dried with magnesium sulphate, filtered and the solvent removed to yield 0·65 g (90 per cent) of a pure product with a melting point of 54°–55° C and which was identical in all ways with an authentic sample.

N-Butylisopropylidene imine. Diethyl ketone (0·518 g), *tris*butylaminoborane (1·5 g) and benzene (10 ml.) were heated under reflux for 8 h. The benzene was removed at water-pump vacuum, and the remaining solution brought over at 0·1 mm into a cooled (−75° C) receiver. Fractionation gave 0·554 g (77·5 per cent) of a product with a boiling point of 86°/42 mm; its molecular weight was 141·1515 (and that required for $C_9H_{19}N$ is 141·1517).

Effect of Hydrogen-containing Impurities on Ionization Times in Shock-heated Argon

THE mechanism by which impurities influence the time for shock-treated argon to reach equilibrium ionization has been considered on numerous occasions[1–4]. No results have as yet been published, however, describing the effect of specific impurities. To remedy this situation, I am now making measurements of the total ionization times (see Fig. 1) in primary shocks through argon to which controlled amounts of various gaseous impurities have been added. The degree of ionization is mon[illegible] by following the time dependence of th[illegible] continuum emission at 900 Å. Pr[illegible]

Previously it has been assumed that the sole effect of an impurity I is to increase the rather slow ionization rate in the atom–atom region by a catalytic mechanism:

$$I + Ar \rightarrow I^* + Ar$$
$$I^* + Ar \rightarrow I^+ + \varepsilon^- + Ar$$
$$I^+ + Ar \rightleftharpoons I + Ar^+$$

While hydrogen can participate in such a scheme, it seems unlikely that the overall rate of ionization would be increased to an extent large enough to explain the observed results.

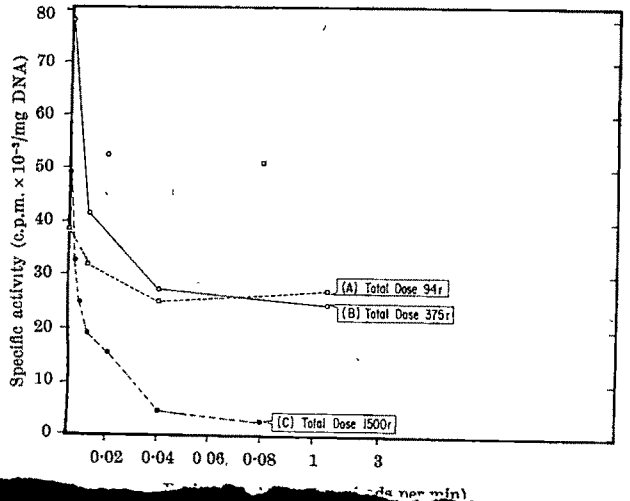
In the electron–atom region, the rate of ionization is limited by the rate at which energy can be transferred from the translationally hot argon atoms and ions to the electrons, which lose a considerable amount of energy in the ionization process:

$$Ar + \varepsilon^- \rightarrow Ar^* + \varepsilon^-$$
$$Ar^* + \varepsilon^- \rightarrow Ar^+ + 2\varepsilon^-$$

The dominant term in the rate of energy transfer at temperatures about 10,000° K is that between the electrons and argon ions, and can be written:

$$Q_{Ar^+} = \frac{N_{Ar^+}N_e e^4}{m_{Ar^+}}\left(\frac{8\pi m_e}{kT_e}\right)^{\frac{1}{2}}\left(\frac{T_{Ar^+}}{T_e} - 1\right)\ln\left[\frac{9(kT_e)^3}{8\pi N_e e^6}\right]$$

where m_e, N_e and T_e are the electron mass, number density and temperature respectively, and $m_{Ar}+$ and $T_{Ar}+$ can be taken equal to the corresponding atomic values. Because the hydrogen ion H^- is about forty times lighter than the argon ion, this term will be increased in the presence of hydrogen to:

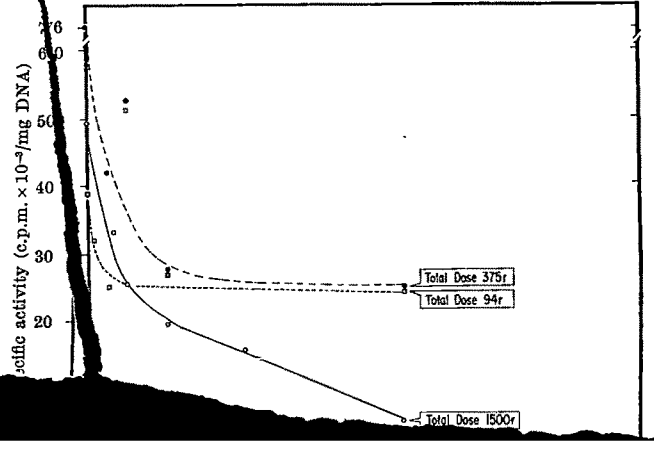


$$Q_L = \left(1 + \frac{N_{H^+}m_{Ar}}{N_{Ar+}m_{H^+}}\right)Q_{Ar^+}$$

At 10,000° K, the mechanism changes[1] from atom–atom to electron–atom at a degree of ionization, α, of about 5×10^{-4}. The presence of one part in 10^5 of H^+ will not only nearly double the rate of ionization at this point, but will extend the range over which the electron–atom mechanism is dominant to a lower value of α. It should also be pointed out that, while the commonest hydrogen-containing impurities in a shock tube are molecular hydrogen and water, molecules with many atoms of hydrogen, for example pump oil, may well play an important part, especially since their presence may not be detected.

At concentrations above 5 parts in 10^4, this effect can lead, in addition to a considerable reduction in the ionization time, to an increase in the ionization rate over [illegible]

on DNA synthesis in 21 h regenerating rat liver: (*a*) A small dose of radiation (94 rads) produces a significant depression in DNA synthesis; (*b*) for a specific total dose, the slower the dose rates of irradiation, the greater is the depression in DNA synthesis within certain limits; and (*c*) the time period of irradiation is a major factor in producing this change, while the effect of total dose is secondary within the range of the experiments.



Experimental design and analytical procedures have been described in detail in an earlier publication[4]. Lewis strain male rats, weighing about 200 g, were used. The irradiation was given locally to the liver by using a 200 kVp. X-ray machine of half value layer, filtered with 1 mm copper and positioned by a 3-cm cone. The experiments were so designed that all periods of radiation, with variations in dose rate, ended at 21 h after partial hepatectomy. Total doses of 94, 375 and 1,500 rads, at the dose rates of 300, 200, 100, 50, 25, 12·5, 6·2, 3·1 and 1·6 rads/min, have been used. Fifty μc. of tritiated 5-methyl thymidine (3 c./mM) were given at the end of the period of irradiation. The animals were killed 1 h after administration of labelled thymidine. A modified Schneider method[5] was used for the extraction of DNA, and the DNA content was determined by the diphenylamine method[6]. Radioactivity was assayed by liquid scintillation counting.

the asynchronous cells of the intestines of the rat[7,8]. A total radiation dose of 1,500 rads was given to four groups of animals at rates of 300, 50, 25 and 12·5 rads/min. There was a consistent lowering of the rate of DNA synthesis with increasing slower rates of radiation delivery. However, these data are not in agreement with the results obtained in regenerating liver under different sets of experimental conditions[9], in which it was found that a dose of 300 rads at 40 rads/min gave a greater depression of incorporation of 6-(¹⁴C) orotic acid into DNA than at 19 and 10 rads/min. The 6 h time period between irradiation and labelled-precursor administration and the 12 h period between irradiation and killing make the two experiments difficult or impossible to compare. Changes in the cell population of both irradiated and control animals, as well as such factors as recovery, would obviate any direct comparison between two sets of data.

Total radiation dose, within the range investigated here (Table 1), seems of secondary importance to dose rate in the depression of DNA synthesis. Total doses of 94 rads at 25 rads/min, 375 rads at 50 rads/min, and 1,500 rads at 300 rads/min resulted in the comparable depression of DNA synthesis to approximately one-third of control values.

An alternative view is that the time period of irradiation seems to be most important in the inhibition of DNA synthesis (Fig. 2). The primary depression of DNA synthesis occurred in the first 5 min. After that, little difference is noted between total doses of 94 rads and 275 rads; however, the depression at the total dose of 1,500 rads continues downward.

in the depression of DNA synthesis in *in vivo* studies of local radiation over a dose range of 94–1,500 rads and a dose rate range of 1·6–300 rads/min. The most pronounced effects of radiation occur during the first few minutes (3·75). Depression of DNA synthesis occurs at total dose (94 rads) equivalent to the D_{37} dose for cell survival for mammalian cells. The process of DNA synthesis is not radio-resistant when the three parameters, (*a*) total dose, (*b*) dose rate and (*c*) duration of radiation, are taken into consideration.

Toxic Effects of Irradiated Foods

THE report by Holsten *et al.*[1] on the direct and indirect effects of radiation on plant cells has produced many comments in both popular and specialist scientific journals. These comments, however, were not brought about by the results reported, as similar data were published earlier (see work referred to in ref. 1). Instead, they arose owing to the statement "The work has other and obvious implications for the radiation sterilization of food . . . .".

Cook and Berry[2], and also Goldblith[3], recently rejected the suggestions that the findings by Holsten *et al.* have such implications for the radiation preservation of food. Cook and Berry first imply that even produced toxic substances

food can cause a slight, age-dependent lymphopenia in rats and also possibly an effect on the thymus[7,8], thus indicating that reactive, radiation-induced compounds can perhaps by-pass the detoxification process in animals.

It has repeatedly been stated that no other method for food preservation by additives (the 'additives' are formed *in situ* in the case of irradiation) has and is being scrutinized as thoroughly as that by radiation. However, there are good reasons for this, as (*a*) for irradiation the 'additives' are largely unknown and are likely to remain so for a long time; (*b*) the additives are not the same in any two different foods owing to the different radiation chemical reactions; (*c*) the amount of additives given in a feeding test cannot be increased beyond a certain value, limited by the ingested amount of food and the non-linear dose dependence of most radiation chemical yields at higher doses.

Most chemical food additives can be tested at concentrations 100 or 1,000 times greater than those technically necessary and thus an acceptable safety factor can be attained. There are two possible ways of avoiding the dilemma regarding the safety factor for irradiated food

(1) Each food could be prepared exactly as it would be for human consumption and then tested on a large number of animals for a long time. If, for example, none of a test group is found to be affected in any harmful way by the treatment, this only tells that within a 90 per cent confidence limit 2·3 cases could have been caused by the treatment[9]. In a hypothetical test with 100,000 animals the true frequency will be $2{\cdot}3 \times 10^{-5}$ with the chosen confidence limit[9]. So far, not more than 1,000 animals have been investigated thoroughly after feeding with any single, tested and cleared, irradiated food[10]. This means that the true frequency of possibly deleterious effects could be as high as $2{\cdot}3 \times 10^{-3}$ at a 90 per cent confidence limit.

(2) More easily scored systems, such as cytotoxic investigations of plant cells and cell cultures *in vitro*. could be resorted to as a primary step towards the evaluation of the eventual wholesomeness of an irradiated material[4,11]. Foods passing these primary tests can then be investigated on 'large' numbers of animals—'large' as the available resources for each food might increase with the decrease in the number of foods likely to be thought worthwhile to test on animals. For example, genetical and teratogenic effects require the development of more elabor

BIOLOGY

Influence of Electrostatic Fields on Seed Germination

RECENT investigations have stimulated wider interest in the possible biological significance of naturally occurring electric fields and related phenomena. Murr[1-3] has shown that high intensity electric fields appear to inhibit development in grass seedlings; he points out, however, that earlier workers, notably Jorgensen and Priestley[4], and Shibusawa and Shibata[5], observed increases in plant growth under electric field conditions, although the frequent occurrence of contradictory results in much of the early work on this subject has been emphasized by Lund[6]. The physiological effects of air ionization have been studied by a number of workers[7]. Krueger *et al.*[8] report that exposure to positively or negatively ionized air produced more rapid germination in *Avena sativa* seeds with subsequent increases in growth and dry weight; slight increases in growth were also noted with seedlings placed in positive or negative electric fields of 955 V over 30 cm; in these experiments, however, the seed containers were grounded to prevent the accumulation of surface charge. The present communication directs attention to an apparent dependence on polarity of the response of germinating seeds to induced electrostatic charges.

Four batches of 100 seeds of lettuce (*Lactuca sativa*), variety 'Cluseed Borough Wonder', were sown on filter paper laid on each of four 6 cm square sections of aluminium foil attached by a thin film of 'Vaseline' to the upper surface of a sheet of glass 45 cm × 7·5 cm. Foil sections were similarly attached to the under-surface of a second sheet of glass resting on spacers so arranged as to separate the two sets of 'field plates' by a vertical distance of 0·5 cm. Two pairs of plates were connected to 90 V batteries arranged in series to give a potential difference of 180 V, one pair positive over negative and the other pair negative over positive; the remaining pairs were left uncharged as controls; the relative positions of charged and uncharged plates were changed after each replication. After sowing, each batch of seeds was moistened with 1·5 c.c. of water, the apparatus being then enclosed in a polythene container and placed in a constant-temperature room for 24 h. Most of the experiments were conducted either in total darkness or with 12/12 photoperiod, but no attempt has been made to discriminate between the two conditions in the results given in Table 1. A comparison is given in Table 2 between twenty paired replications carried out in light and dark rooms simultaneously.

The criterion of germination in these experiments was taken as the emergence of the radicle when viewed under a × 15 lens. The margin of error inherent in purely visual determinations of this type must obviously be so great as to preclude the possibility of obtaining any precise estimate of the magnitude of the electrostatic response. Sufficient results have, however, been obtained to provide some indication of the general pattern of response, although it must be emphasized that considerable variation occurs in the germination level within any one treatment.

The results of 150 replications (Table 1) are in agreement with the work of Murr[1], in that a positive field

Table 1. DIFFERENCE IN PERCENTAGE GERMINATION AVERAGED OVER 150 REPLICATIONS

Difference from control		Difference between polarities
+ / −	− / +	
−4·9468	+0·9863	5·9331

Variance-ratio = 3·95 (5 per cent significance point = 3·00).

Table 2. COMPARISON OF GERMINATION BETWEEN TWENTY REPLICATIONS EACH IN LIGHT AND DARK

	Difference from control		Difference between polarities
	+ / −	− / +	
Dark	−12·2	+4·65	16·85
Light	+0·85	+6·4	5·55

appears to inhibit plant development, but from the present work it is further apparent that the nature of the plant response is dictated by the sign of the electrostatic field, and not merely by the presence of the field *per se*. The possible influence of light in reducing the magnitude of this polarity effect may be significant (Table 2). A comparison with the work of Krueger *et al.*[8] is not possible in the absence of ion-density and current measurements, but Edwards[9] found that a positive field slowed down the rate of development of *Nepytia* pupae; he also suggested that contact-induced electrostatic charges might influence insect behaviour[10,11].

The present experiments were initiated in an attempt to provide a possible basis for correlation between geoelectric phenomena and the manifestation of psychiatric disturbance symptoms, assuming such a relationship to be mediated through variations in neuro-hormone activity resulting from electrostatically induced changes in tissue respiration levels. Preliminary gas-analysis studies appear to indicate a possible polarity-dependent electrostatic influence on the rate of production of carbon dioxide in germinating seeds. Further work along these lines is in progress.

I thank D. G. Heathcote for carrying out the statistical analysis; I also thank Prof. G. F. Asprey, Dr. J. R. Etherington and Dr. A. G. Lyon for their advice and encouragement.

Some Responses of *Drosophila* to Weak Magnetic and Electrostatic Fields

A VARIETY of reactions of organisms to natural levels of electromagnetic fields has been reported in recent years. This communication reports an investigation of the responses of *Drosophila melanogaster* to magnetic and electrostatic fields of low intensity. Previously, Barnwell and Brown[1,2] cited unpublished work showing that *Drosophila* responded to weak magnetic fields. Edwards[3] reported that electrostatic fields depressed the activity of *Drosophila*.

An orientational–statistical approach was used in this investigation because it was thought that the response to these fields would be weak. Oregon *S* wild type flies were allowed to emerge from a 'Plexiglas' and 'Masonite' corral, through a narrow corridor, into an expanded field. The amount of turning from a straight line was determined by noting the 10° sector crossed by the insect 3 cm from the corridor exit. The flies were returned to the corral by shaking after they had all emerged. About fifty flies were allowed to orient for each sample. The orientation chamber was inclined 30° and centred under an illumination of 2 lux in a black compartment. The flies were raised under an 8 a.m.–8 p.m. light–dark cycle. Experimental runs were conducted between April 4 and August 25, 1962, from 9.30 to 11.30 a.m. and 2.30 to 4.30 p.m. C.S.T.

The amount of turning was noted in the measured 2-G horizontal field of an 18 cm alnico magnet centred under the experimental chamber in a rotatable standard. The flies emerged headed toward true 'Earth' magnetic north under the following configurations of the experimental

magnet: (1) Aligned with the Earth's field. (2) The reverse of the Earth's field. (3) "Compass north" to the east. (4) "Compass north" to the west.

In another series, a horizontal 3 V/cm electrostatic gradient was established by aluminium plates sandwiched in black painted glass, located to the right and left of the orientation chamber. When not in use the plates were switched off, interconnected and grounded.

Additional runs were made with the orientation device in a grounded Faraday cage of brass shim stock and 1-mm copper screening.

The experimental series were arranged in randomized order preceded and followed by a control. A total of 24,825 fly orientations were recorded during 618 replicate runs.

Analysis indicated a statistically significant response to all the magnetic configurations (Table 1). No significant differences were found between the morning and afternoon samples. Daily variations in the response of mud snails to magnetic fields have been reported[4].

The distribution of the control sample means about zero during semi-monthly periods indicated that the flies turned most strongly to the left during the new moon and first quarter (Table 2). All the magnetic configurations showed a reverse pattern of response with the major difference being an increased left deviation from the control during the full moon–third quarter period. This suggests that the effect of a superimposed magnetic field is to prolong the normal left turning response through the full moon–third quarter period. Lunar rhythms in similar responses have been found in snails[5,6], *Paramecium* and planarians[7].

A summary of the results from a group of twenty replicates run in an electrostatic field with the flies headed north as they emerged from the corridor is presented in Table 3. An increased left turning was noted. Brown[8] reported that planarian worms headed north in an electrostatic field also tend to turn counterclockwise.

Table 1. ORIENTATIONAL RESPONSES OF *D. melanogaster* TO VARIOUS MAGNETIC FIELD CONFIGURATIONS AS INDICATED BY ANALYSIS OF PAIRED SAMPLES OF FIFTY FLY ORIENTATIONS

Configuration	Mean difference*	T_D†	P	$S.E.$	N

* +, Right; −, left.

Table 4. CHI SQUARE ANALYSIS OF THE DISTRIBUTION BY SEMI-MONTHLY PERIODS OF CONTROL REPLICATE MEANS COMPARED WITH THOSE RUN IN A FARADAY CAGE WITH NATURAL FIELDS

	Semi-monthly period: New moon—first quarter				Full moon—third quarter			
	Right	Left	χ^2	P	Right	Left	χ^2	P
Control	9	22	4·65	< 0·05	3	21	13·44	< 0·01
Faraday cage	9	23	6·10	< 0·05	13	10	0·17	—

Classification of the control and Faraday-cage means (Table 4) indicates that the lunar variation is the reverse of that mentioned for the controls in the magnetic series (Table 2). This is interpreted as a result of the control means being obtained in August while the control means of the magnetic series were obtained in April–June. This implies that there is some sort of variation with periods longer than a month. This interpretation is supported by a least squares regression line using all the magnetic series control samples. This line indicated that the average value of the control mean tended to move to the left by 0·01° per day. When this is extrapolated to the end of August, an expected mean control value of −2·3° (+, right; −, left) is given. The actual value of the August controls was −3·2°. The shift would be enough to obscure the semi-monthly effect. The Faraday-cage experiments showed a reverse pattern of orientation (Table 4) during the full moon–third quarter period.

The effectiveness of the Faraday cage was checked by using the cage in an imposed electrostatic field. The response in the Faraday cage with an imposed field did not differ significantly from the response to the cage without the field.

A limited amount of data collected concerning orientation in a Faraday cage in a 2-G magnetic field did not reveal significant differences between the samples within the cage as compared to the magnetic series outside the cage.

During a series of ten replicates, the apparatus was turned so that the flies emerged from the corral in each of the four cardinal directions. No significant differences were found.

This investigation was aided by grants from the National Science Foundation and the National Institutes of Health.

Propylene Phenoxetol as a "Preservative" for Living Holothurians

A WELL-KNOWN disadvantage of the use of the holothurian *Stichopus moebii* for the preparation of isolated organs for physiological experimentation is the process of local degeneration[1] initiated in the body wall by the trauma of dissection. If the dissection is at all prolonged, the connective tissue begins to 'deliquesce' and the body wall flows out in an ooze, much as it does when subjected to heat. It seems useful as well as of some interest to know that an agent used for narcotizing invertebrates and fish can also retard the local degeneration reaction.

Because the anti-oxidant[2] propylene phenoxetol is so effective in relaxing living molluscs[3] it was chosen for relaxing *Stichopus moebii* while making preparations of the isolated cloaca. If the severed hind end of a "sea pudding" is allowed to remain an hour or more in a container of sea-water to which propylene phenoxetol has been added to form a globule from which it gradually diffuses, the specimen will become unreactive and expanded, although the body wall retains normal tone. It is then possible to proceed leisurely with dissection without encountering the local degeneration response. Viscera and longitudinal retractors appear normal after

the treatment with propylene phenoxetol; for example, rhythmicity persists for as long as 48 h in isolated cloacas used for a student laboratory project. After dissection, the severed hind end left moist with propylene phenoxetol remained as firm to the touch as a normal intact animal on the sea bottom. After 5 days, oozing had only occurred immediately under the integument of such a specimen whereas one moistened with clear sea-water degenerated to ooze in minutes.

Propylene phenoxetol is useful as a preservative only for fixed specimens[4,5] and it is thus surprising that it can also be used to retard deterioration of a living animal.

Successful Transplantation of a Frog Bladder-fluke from One Host Species to Another

GOODCHILD[1] described experiments in which adult bladder-flukes, *Gorgodera amplicava* and *Gorgoderina attenuata*, were successfully transplanted from one species of *Rana* to another. Healthy transplanted flukes were capable of attaching themselves to the bladder of their new host, and they survived for periods of up to 3 weeks, which was as long as the experiment lasted. Furthermore, Goodchild[2] successfully transplanted individuals of the same two species into the bladders of painted turtles, *Chrysemys picta*, and newts, *Triturus viridescens*; these parasites survived in their new habitats for periods of up to a week. In contrast to these results, Goodchild found that the same adult trematodes were incapable of survival when transplanted into the rectum or into the abdominal coelom of *Rana pipiens*. The flukes in the rectum were unable to grip the mucosa and were soon eliminated with the faeces. Those in the abdominal coelom were encapsulated by host cells and died within 24–72 h.

The experiments described here were carried out using *Gorgoderina vitelliloba* from the common frog, *R. temporaria*.

In the first series of experiments the donor host, which had been fed with infective metacercariae more than a month previously, was pithed and the bladder opened under 65 per cent amphibian Ringer's solution. Careful teasing of the bladder caused the flukes to release their grip and they were then drawn into a smooth-ended Pasteur pipette, the tip of which had been curved slightly. It was found possible to transfer the parasites into a lightly anaesthetized recipient host by sliding the tip of the pipette along the mid-ventral line of the cloaca until it entered the bladder.

When *R. temporaria*, *Bufo bufo* and *B. viridis* were used as recipient hosts, the adult parasites survived and developed normally for periods of up to 8 months, which probably approximates to the normal life-span of the adult fluke[3].

At the time of transplantation, certain of the flukes were small and contained few eggs in the uterus. When such individuals were recovered from the recipient host several weeks later they had increased considerably in size and their uteri had become packed with embryonated eggs.

Within the definitive host, the juvenile form of *G. vitelliloba* spends some time in the kidney before entering the bladder[4]. A second series of experiments was therefore performed in which juvenile flukes teased from the kidneys of a recently infected common frog were used. Such juveniles were transferred to the bladder of the recipient hosts, as described for bladder to bladder transplantations, and their subsequent development was observed. The young flukes were found to leave the bladder and migrate up the ureters to enter the kidneys. They eventually left the kidneys and returned to the bladder at intervals of time corresponding to the normal movements in the donor hosts. Within the bladder of their recipient hosts the parasites completed their normal growth and commenced egg production.

A further series of experiments has been carried out using the European tree frog, *Hyla arborea*, as the recipient host. In this frog the kidney behaves as a physiological barrier to the normal course of experimental infection[5]. Individuals which had been transplanted bladder to bladder succeeded in establishing themselves and remained healthy for at least a week. On the other hand, kidney to bladder transplanted parasites migrated to the kidneys where they were destroyed.

Several attempts have been made to transplant adult specimens of *G. vitelliloba* into the rectum of various amphibians. Although most of the parasites were eliminated from the hosts on defaecation, a few managed to establish themselves in the recta of *R. temporaria*, *R. pipiens* and *Bufo viridis*. They were found to be grasping the rectal mucosa firmly and appeared quite normal at the time when the hosts were killed, 4 days after transplantation. The main problem confronting the parasite seems to have been the initial grasping of the mucosa. Once the parasite has established its grip on the rectal mucosa it seems capable of maintaining its position there successfully.

The final experiment consisted of transplanting juvenile flukes from the kidneys of one specimen of *R. temporaria* into the abdominal coelom of another. This was accomplished by injecting the juvenile flukes through a small incision in the latero-ventral body wall of the recipient frog. When the recipient hosts were examined after 24–84 h no live flukes were recovered. Recognizable remains of dead flukes were found encapsulated in host tissue and firmly adherent to various organs and mesenteries of the body cavity.

Susceptibility of Pigs to Infection with *Schistosoma haematobium* from Egypt

PIGS have been incriminated as natural hosts for *Schistosoma japonicum*, *S. incognitum* and *S. bovis*[1–3]. Various attempts to infect pigs with *S. mansoni* attained limited success[4–7]. Hill and Onabamiro[8] reported natural infections of two pigs with *S. haematobium* in Nigeria. The present experiment was carried out to investigate the susceptibility of pigs to infection with *S. haematobium* from Egypt.

Two pigs about 8 weeks old obtained from a local breeder in St. Albans were selected for the experiment. Each pig was exposed by tail immersion to about 1,000 cercariae shed by experimentally infected *Bulinus* (*B.*) *truncatus* for about 20 min. One week later, each of the two pigs was re-exposed to about 500 cercariae, this time by applying the cercarial suspension to the shallow groins of the abdomen and the mucous membranes of the buccal cavity. The pigs were re-exposed for the second time 1 week later by the subcutaneous injection of about 500 cercariae per pig. By that time each pig had been exposed to a total number of about 2,000 cercariae. When the pigs were exposed to infection, control albino mice were also exposed to cercariae shed by the same group of infected snails.

After the first cercarial exposure, the pigs were observed to twitch their tails vigorously. After the second exposure there was more evidence of cercarial penetration in the form of minute red papules on the skin of the groins. Urine and faecal samples were negative when examined twice weekly from the tenth to about the twenty-seventh week after exposure. One of the pigs was killed 28 weeks after exposure and a thorough search for eggs or adults of the parasite in various internal organs was undertaken. However, no macroscopic lesions which could be attributed to *Schistosoma* infection were observed in any of the visceral organs. The liver, lungs and spleen were normal in size and appearance. Examination of small pieces of these organs between two slides under the microscope was negative for worms, eggs and bilharzial pigment. The small and large intestines were searched carefully for eggs but none was found. The mesenteric veins and the hepatic portal vein were dissected carefully, but no worms were observed. The urinary bladder was also negative. The control mice exposed to infection were killed and dissected 13 weeks after exposure. All showed evidence of successful infection. Eggs of the parasite were demonstrated in press preparations of the liver and small intestine. Coupled worms were also collected from the liver and the superior mesenteric veins.

The results of the present experiment show that *S. haematobium* from Egypt failed to develop in pigs. On the other hand, albino mice became infected when exposed to the same batches of cercariae used for infecting the pigs. *S. haematobium* has a marked host specificity when compared with other human schistosomes and only a few mammals can easily be infected with this species[9]. For this reason, it was of great importance to verify experimentally the report of Hill and Onabamiro. A critical review of their report has revealed that there are various questions which have to be answered before accepting that report as final. They reported that one of the pigs had haematuria and passed eggs of *S. haematobium* type in the urine. This pig continued to have haematuria for 47 days and was then slaughtered. No gross lesions attributable to bilharziasis had been observed in any of the internal organs and no worms were found in the blood vessels. In my opinion, it seems rather improbable that the haematuria was caused by *S. haematobium* with no deposition of eggs in any of the internal organs, particularly the urinary bladder. The second pig with haematuria was treated with 'Nilodin' and when it was killed they observed pin-point haemorrhagic foci in the mucosa of the urinary bladder. However, all the organs were free from adult worms and eggs and the histopathological examination of the urinary bladder was also negative. It is well known that after treatment the *Schistosoma* worms are usually swept from the mesenteric veins into the liver, where they may die or revive and return to their normal habitat in the mesenteric or vesical veins. If they die in the liver, they usually stimulate a strong tissue reaction there. However, Hill and Onabamiro maintained that all the organs were negative for worms or any pathological reaction. This seems rather improbable for any genuine schistosome infection. Moreover, Hill and Onabamiro attempted unsuccessfully to infect two young pigs experimentally with *S. haematobium* from Nigeria. The presence of *S. haematobium* eggs in the urine of pigs having haematuria but no adult worms or eggs in any of the internal organs cannot be explained, although contamination of the urine of the pigs cannot be excluded.

It should be noted here that if the authenticity of Hill and Onabamiro's report can be convincingly verified, then the failure of the Egyptian strain of *S. haematobium* to establish itself in the pigs might be due to differences in the strain of the parasite. There is considerable evidence from work on *S. mansoni* to demonstrate the importance of the strain of the parasite in the determination of the degree of association between it and the definitive host[10,11].

I thank Prof. J. J. Buckley for his interest and advice and acknowledge a scholarship from the University of A'in Shams, Cairo.

BIOCHEMISTRY

Characteristics of α-Amylase Formation by *Bacillus subtilis*

ALTHOUGH there are a large number of reports dealing with the formation of α-amylase by *Bacillus subtilis*, the nature of the mechanism which controls its synthesis has not been subjected to a detailed examination.

Fukumoto, Yamamoto and Tsuru[1] showed that α-amylase is produced in the culture medium in the presence of a wide variety of carbon sources, the total amount of enzyme formed after prolonged incubation showing considerable variation with the different carbon compounds. These workers also studied the progress of α-amylase formation in relation to cell growth and found that enzyme production lagged slightly behind cell growth, maximum accumulation occurring when cell autolysis was just beginning[2]. This was supported by the work of Coleman and Elliott[3], who found the enzyme to be produced maximally in the post-logarithmic phase of growth. However, Nomura, Maruo and Akabori[4] reported experiments which showed a distinct separation of several hours' duration between the end of the logarithmic phase of growth of *B. subtilis*, during which no α-amylase production was observed, and the phase in which the enzyme was secreted in significant amounts. They concluded that α-amylase formation occurs only in old cells in which normal cellular multiplication no longer occurs.

A more critical investigation has now been made of the relationship between increase in cell mass and α-amylase formation in the presence of different carbon sources. This work was carried out in order to answer two questions. First of all, is α-amylase formed in appreciable amounts during the logarithmic phase of growth? Secondly, is α-amylase synthesized by an inducible system?

The organism was grown aerobically at 30° C in a medium containing a mixture of L-amino-acids, vitamins and salts with either starch, maltose, glucose or glycerol, at a concentration of 1 per cent, as the carbon source (see legend to Fig. 1). In each case increase in cell mass and α-amylase secreted into the medium were determined over a 14 h period. It was found that, irrespective of the carbon source used, the cells grew logarithmically until a cell density of 0·3 mg dry weight/ml. was achieved and after this time growth occurred at a reduced rate until the end of the experimental period. The differential rate of α-amylase formation, that is, the relationship between enzyme formation and increase in cell mass, in the presence of each of the carbon sources is shown in Fig. 1. It can be seen that a low linear differential rate of enzyme synthesis occurs with all the carbon sources tested until the end of the logarithmic phase. During this period the rate is higher in the presence of starch and maltose

Table 1. MAXIMUM AND MINIMUM DIFFERENTIAL RATES OF α-AMYLASE FORMATION IN THE PRESENCE OF VARIOUS CARBON SOURCES

Carbon source	Differential rate of enzyme formation (Amylase units formed/mg dry wt. increase in cell mass) Minimum (during log phase)	Maximum (post-log phase)
Starch	43	375
Maltose	43	374
Glucose	17	345
Glycerol	20	354

(doubling time 2·2 h) than with either glucose or glycerol (doubling time 1·6 h and 1·7 h, respectively). However, after the end of the logarithmic phase the rate increases to very nearly the same high level in all cases (Table 1).

In the absence of the carbon source cell growth and α-amylase formation occurred, but the results are not directly comparable as amino-acids were utilized as a source of energy and logarithmic phase growth ended when a cell density of 0·18 mg dry wt./ml. was reached. However, the general characteristics, of a low rate of enzyme secretion during the logarithmic phase and a much higher rate after logarithmic growth had ceased, were observed.

So far as the question of inducibility of the enzyme is concerned it is not possible to give a clear-cut answer. The higher rate of enzyme synthesis during the logarithmic phase in the presence of the substrate, starch and maltose, an end-product of the enzyme action, than with glucose or glycerol might be regarded as evidence of inducibility. However, the greatly increased rate of production achieved in the post-logarithmic phase, when most of the α-amylase is secreted, is virtually the same irrespective of the carbon source used and this clearly cannot be described as inducible.

In summary, the results show that there is a low but definite synthesis of α-amylase from the moment the cells start to grow until the end of the logarithmic phase. The maximum secretion of enzyme occurs after the end of the logarithmic phase when the cell mass is increasing at a reduced rate. The results further demonstrate that the major part of the α-amylase formation is not an inducible process—there being no proof that the remainder is inducible.

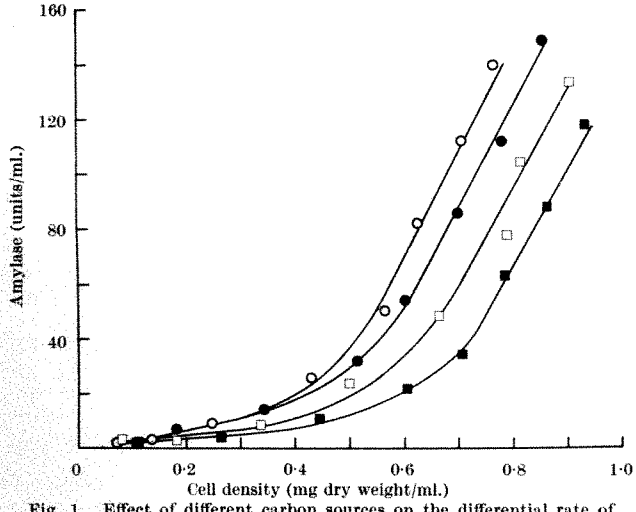

Fig. 1. Effect of different carbon sources on the differential rate of α-amylase formation. A series of T-tubes each containing 40 ml. of a defined medium was inoculated from a suspension of washed *B. subtilis* (Takamine) spores in distilled water and incubated as described by Coleman and Elliott (ref. 1). Tubes were taken in duplicate at 2-h intervals over a period of 14 h, commencing early in the logarithmic phase. On each occasion the cell mass and the α-amylase content of the supernatant fraction of the culture were determined as described by Coleman and Elliott (ref. 1). The composition of the defined medium was as follows: ammonium monohydrogen phosphate, 34 mM; potassium chloride, 5 mM; magnesium sulphate, 1 mM; calcium chloride, 0·125 mM; zinc sulphate, 0·0125 mM; sodium citrate, 2·125 mM; ferric chloride, 0·5 mM; 'trace metal ion' solution, as described by Coleman and Elliott (ref. 5), 0·25 ml./l.; vitamin solution, 50 ml./l., and a mixture of equal amounts (by weight) of nineteen naturally-occurring L-amino-acids (cyst(e)ine omitted) to give a total amino-acid concentration of 0·5 per cent. The medium was adjusted to *p*H 7·2 with 10 per cent (v/v) phosphoric acid and supplemented with either starch (●), maltose (○), glucose (■) or glycerol (□), each at a concentration of 1 per cent. The vitamin solution consisted of riboflavin, 0·1 mg, and 1·0 mg each of inositol, biotin, choline chloride, folic acid, nicotinamide, calcium pantothenate, pyridoxal-5-phosphate and thiamine (aneurin) in 1 l. of water

Rate-determining Step in the Action of L-Amino-acid Oxidase

ALTHOUGH detailed information concerning the substrate specificity[1,2], co-factor requirement and physico-chemical properties[2] of L-amino-acid oxidase is available, our knowledge of the mechanisms of the reactions catalysed by this enzyme leaves much to be desired. Radda[3] has recently proposed a mechanism for the oxidation of phenylglycines by L-amino-acid oxidase which involves the elimination of the α-hydrogen as a hydride ion (or radical) followed by hydrolysis of the imine and dissociation of the enzyme-product complex.

Electron-withdrawing substituents in the phenyl ring of phenylglycine increased, within limits, the rate of the overall reaction and it was concluded that the initial loss of the α-hydrogen, as a hydride ion, was not rate-determining[3]. Furthermore, a Hammett plot gave a value for ρ of 1·8 which is similar to that observed for base-catalysed ester hydrolyses. Radda suggested that hydrolysis of the α-amino-acid is the rate-determining step. However, the Hammett plot showed a break to a line of negative slope with strongly electron-withdrawing substituents and it was suggested that this might represent a change in the rate-determining step of the reaction with the loss of the α-hydrogen becoming energetically significant.

Several lines of evidence led us to question the proposed mechanism. Previous work with flavoproteins (sarcosine oxidase[4], glucose oxidase[5], and possibly monoamine oxidase[6]) has demonstrated that removal of the α-hydrogen (probably as a proton) constitutes the rate-determining step. Furthermore, hydrolysis of α-imino-acids is better compared to the hydrolysis of Schiff's bases than to base-catalysed ester hydrolysis. In this connexion, Cordes and Jencks[7] have shown that the mechanism of hydrolysis of Schiff's bases from substituted benzaldehydes and aliphatic amines is *p*H-dependent. At neutral *p*H (6·5–7·5) the principal reaction is an attack by hydroxyl ions on the protonated Schiff's base. In this region (*p*H optimum of L-amino-acid oxidase, 7·2–7·5) (ref. 2) the effects of substituents are minimal as they exert opposing influences on the attack by hydroxyl ions and the protonation of the Schiff's base—ρ is approximately zero. Hence, the ρ value of 1·8 for the oxidation of phenylglycines appears inconsistent with a mechanism in which the hydrolysis of the α-imino-acid is rate-determining. The positive value of ρ simply indicates that negative charge is being developed in the transition state and is consistent with the removal of the α-hydrogen as a proton in the rate-controlling step.

The present investigation is based on the use of kinetic isotope effects, a technique which has been a powerful tool in the elucidation of reaction mechanisms[8–9]. α-Deuteriotyrosine and α-deuteriophenylglycine were prepared by standard synthetic procedures[10–12] under

Table 1. RATES OF OXIDATION OF AMINO-ACIDS BY L-AMINO-ACID OXIDASE (*Crotaleus adamanteus*)

	Rate in μl. Oxygen/min/mg*	k_H/k_D
D,L-Phenylglycine	2·1	1·41
D,L-α-Deuteriophenylglycine	1·5	
D,L-Tyrosine	11·8	1·41
D,L-α-Deuteriotyrosine	8·4	

* Average of three separate experiments which agreed within 5 per cent. Flask contained 30 μmoles substrate in 3 ml. of *tris* buffer (0·2 M, *p*H 7·2). With phenylglycine, 1 mg of L-amino-acid oxidase (σ, type IV) was used, and with tyrosine, 0·5 mg of a crude venom preparation obtained from Calbiochem.

conditions which give 95 per cent deuterium labelling in the desired positions. The purity of the products was determined by paper and thin-layer chromatography. The rates of oxidation were followed manometrically and comparison of the rates of oxidation of tyrosine with its α-deuterated analogue showed an isotope effect, $k_H/k_D = 1{\cdot}41$. Under conditions identical to those described by Radda, a similar isotope effect was found for the oxidation of phenylglycine (Table 1).

These isotope effects clearly indicate that the removal of an α-hydrogen is rate-determining in the oxidation of tyrosine and phenylglycine.

It is of great interest to note that the isotope effect observed ($k_H/k_D = 1{\cdot}41$) is substantially below the theoretical maximum value ($k_H/k_D = 7$) and is, in fact, approximately equal to the value calculated from simple considerations of the mass difference between hydrogen and deuterium ($k_H/k_D = \sqrt{2} = 1{\cdot}42$) (ref. 13). Wiberg[13] has pointed out that the magnitude of the isotope effect depends on the extent to which zero point energy is conserved in the transition state. The low values observed in this investigation indicate that stretching of the carbon–hydrogen (or carbon–deuterium) bond has proceeded only to a small extent in the transition state. Aebi[14] has arrived at similar conclusions for the peroxidatic formate oxidation by catalase.

These findings do not provide any explanation for the break in the Hammett plot observed by Radda[3], since it would be anticipated that increased electron-withdrawal would facilitate the removal of an α-hydrogen as a proton. As previously suggested[3], this anomaly could represent a change in the rate-determining step or steric factors hindering Michaelis-complex formation. We are at present extending these investigations to substituted phenylglycines in order to differentiate between these possibilities.

Note added in proof. Since acceptance of this communication, Coffey *et al.* (*J. Biol. Chem.*, **240**, 4058; 1965) have suggested, in the case of D-amino-acid oxidase, that the reaction proceeds through a mechanism involving proton abstraction; and Neims *et al.* (*Biochemistry*, **5**, 203; 1966) have demonstrated a biphasic Hammett plot in the case of D-amino-acid oxidase and have suggested the use of deuterium isotope effects to clarify this anomaly.

Metabolic End-products of Anaerobic Spermatozoan Metabolism

DURING anaerobic fructolysis by mammalian spermatozoa, fructose is reportedly metabolized by way of glycolysis to lactic acid[1,2]. Results from many anaerobic metabolic investigations in our laboratory, however, in which bovine spermatozoa were incubated for 4 h at 37° C have consistently yielded low lactic acid values in relation to the fructose utilized. This failure to account for all the metabolized fructose as lactic acid led us to investigate the possibility that other metabolic acids were being formed and, if so, to determine if the level of carbon dioxide in the gaseous phase, previously reported to influence spermatozoan metabolism[3], affected the formation of these acids.

In order to eliminate the substrates present in the seminal plasma, exogenous substrate-free epididymal-like spermatozoa (ELC) were used. The detailed method for the collection and preparation of ELC has been reported[4]. They are collected directly into 100 ml. of an inhibitory diluent, washed once, and finally resuspended in saline. A total of 18×10^9 cells from pooled ejaculates were used for six gas treatments as follows: 100 per cent nitrogen or nitrogen containing 5, 25, 50, 75 or 100 per cent carbon dioxide. The 3×10^9 cells in each treatment were placed in four separate flasks each containing 750×10^6 cells for the 4-h incubation at 37° C in a citrate–bicarbonate medium[5] containing 0·5 per cent fructose. After incubation the contents of the four flasks in each gas phase were combined, deproteinized with barium hydroxide and zinc sulphate, and filtered. The filtrate was reduced to near dryness by evaporation under vacuum at 55° C and absorbed on a small quantity of silicic acid. The acids present were then separated by column chromatography[6]. Chloroform containing increasing amounts of *t*-butyl-alcohol was used to elute the acids present, which were then titrated against 0·005 normal potassium hydroxide. They were identified by the use of known acids both by paper and column chromatography techniques. The organic acids present in the spermatozoa and incubation diluent before and after incubation are reported as the micro-equivalents of each acid per 10^8 cells.

The carbon dioxide evolution was determined manometrically[7], and the fructose disappearance was measured colorimetrically[8]. The carbon dioxide evolved from the bicarbonate of the diluent in response to the acids produced is shown in line 1, Table 1, with the fructose utilized by the cells during the 4-h incubation period showing directly below the carbon dioxide data. As was expected, the highest utilization of fructose and evolution of carbon dioxide occurred under the 5 per cent carbon dioxide–95 per cent nitrogen[9].

The acids, accompanied by the standard error (*S.E.*) for the two replicates, are listed in the order of their elution from the silicic acid column. The presence of these acids in the incubation medium indicates that all these metabolic acids were produced at least in detectable levels under all anaerobic gaseous régimes. Low levels of each acid present in the initial portions taken before incubation were apparently in the sperm cells.

All the acids listed in Table 1, with the exception of fumaric and oxalic, have previously been reported to be present in semen immediately after collection[10–12]. The absence of seminal plasma in the incubation diluent, however, eliminates it as a source of any of these acids. After anaerobic metabolism in the presence of fructose, only acetic[13] and lactic[1,2] have previously been detected. The production by spermatozoa of other acids during the 4-h incubation period shows that metabolic pathways, in addition to the Embden–Meyerhof one, function in spermatozoa under anaerobic conditions and probably serve as as source of energy for both motility and biosynthetic purposes.

Table 1. UTILIZATION OF FRUCTOSE, EVOLUTION OF CARBON DIOXIDE, AND ORGANIC ACIDS PRODUCED BY BOVINE SPERMATOZOA (ELC) FROM FRUCTOSE DURING 4-H ANAEROBIC INCUBATION AT 37° C IN WARBURG RESPIROMETER (PER 10^8 CELLS) (n = 2)

Malic	0·58 ± 0·15	0·33 ± 0·05	0·25 ± 0·12	0·77 ± 0·08	0·87 ± 0·25	0·24 ± 0·03	1·00 ± 0·70

Of the acids shown in Table 1, only lactic acid accumulation is highly correlated with the overall metabolic rate as measured by the evolution of carbon dioxide or utilization of fructose for each level of carbon dioxide in the gaseous phase. Fumaric acid accumulation shows the opposite trend, however, and increases as the level of carbon dioxide in the gas phase is increased. As evidenced by the *S.E.*, considerable variation between replicates was present in the levels of some of the acids produced.

The accumulation of fumaric, succinic, malonic and malic during anaerobic metabolism is evidence for the activity of the tricarboxylic acid (TCA) cycle even in the absence of oxygen. The increase in the concentration of fumaric, malonic and malic acids during incubation of the spermatozoa under the higher levels of carbon dioxide suggests that this may be the result of the uptake of carbon dioxide which occurs under anaerobic conditions[9].

The accumulation of these acids by spermatozoa during anaerobic metabolic studies would definitely explain the frequently reported failure to account for all the fructose utilized as resulting in lactic acid. The production of these acids as by-products of anaerobic spermatozoan metabolism would also explain some of the differences cited by Rothschild[14] between the values of anaerobic heat production and the disappearance of fructose in bovine sperm samples.

Electron Spin Resonance Examination of Charge Transfer Complexes of Polycyclic Carcinogens and Nucleic Acid Bases

THE extensive discussions in the literature on the ability of polycyclic hydrocarbons to form charge-transfer complexes with various molecules[1], for example, iodine, and the attempts which have been made to correlate this property with the carcinogenicity of the hydrocarbon[1,2], prompted us to examine the electron spin resonance spectra of the charge-transfer complexes known to be formed[3] by polycyclic hydrocarbons and the DNA and RNA bases.

Szent-Györgi *et al.*[2] reported that certain carcinogenic hydrocarbon-iodine complexes involved complete transfer of an electron, detectable by electron spin resonance, and we wished to ascertain whether or not this could be observed for the corresponding purine and pyrimidine complexes. For the purposes of comparison, the electron spin resonance spectra of the iodine complexes were also recorded.

The iodine complexes were prepared in chloroform solution in a quartz tube of 8 mm outside diameter from 3–5 mg of the carcinogen and a 1–2 mole equivalent excess of iodine. The solutions were evaporated to dryness before examination by electron spin resonance. The DNA- and RNA-base hydrocarbon mixtures were obtained similarly by evaporation of a suspension of both compounds in benzene-95 per cent ethanol. In each case blanks containing each component alone were subjected to the evaporation procedure and the electron spin resonance spectra examined. In no case was a signal detected for the starting compounds alone.

The results obtained are summarized in Table 1.

Table 1

Compound	Iodine: Colour of complex	Iodine: Electron spin resonance signal* (spins/mole)	Adenine, guanine, cytosine, uracil
3,4-benzpyrene	Black	$1·8 \times 10^{21}$ ($2·5 \times 10^{20}$)	All mixtures colourless
20-methylcholanthrene	Red-black	$1·4 \times 10^{20}$ ($8·0 \times 10^{20}$)	No electron spin resonance signal detectable for any charge-transfer complex
1,2-benzanthracene	Light-brown	—	
1,2 : 5,6-dibenzanthracene	Brown	—	
2-aminofluorene	Black	$3·4 \times 10^{21}$ ($1·8 \times 10^{20}$)	
2-acetylaminofluorene	Red-brown	—	
5,7-dimethyl-1,2-benzacridine	Dark-brown	—	
Oestrone	Brown	—	
17β-oestradiol	Brown	—	
Stilboestrol	Dark-brown	—	

* Numbers in parentheses give values reported in ref. 2.

The carcinogenic oestrogens, oestrone, oestradiol, and stilboestrol were also examined in the hope that some correlation with the carcinogenic polycyclic hydrocarbons might become apparent, since steroids also form charge-transfer complexes with purines and pyrimidines[4].

The negative results obtained suggest that the complete transfer of an electron by carcinogens to give free radicals does not occur in carcinogen-DNA or carcinogen-RNA interactions, and the data provide additional circumstantial evidence in support of the conclusion drawn by Epstein *et al.* that charge-transfer tests are unreliable as criteria for evaluating the carcinogenicity of polycyclic compounds.

The electron spin resonance spectra were recorded on a 'Varian *V*-9500' X-band spectrometer. As shown in Table 1, the quantitative data obtained for the iodine complexes with a positive electron spin resonance signal are in good agreement with the values quoted by Szent-Györgi *et al.*[2].

MICROBIOLOGY

Preparation of Pure Blue-Green Algae

IN the course of measuring the resistance of blue-green algae to γ-radiation from a cobalt-60 source, initially contaminated blue-green algae were found to be free from bacteria after irradiation. Since difficulties are encountered in the purification of Cyanophyta[1] (less than 30 per cent of the organisms in the Indiana University Collection are bacteria-free[2]), γ-radiation may afford an easy, reliable method for purifying algae from bacteria and be of advantage in physiological and biochemical investigations of these organisms. Practical conditions for the purification of a group of typical Cyanophyceae were, therefore, determined.

Filamentous algae were grown in 10 ml. of supernatant Chu[3] medium in 20-ml. loosely capped vials so that the sides and bottom of the vial were covered with a thin filamentous mat. Unicellular algae were inoculated into similar media to form lightly coloured suspensions. Irradiation was provided by a 'Gammacell 220' (Atomic Energy of Canada, Ltd.) furnishing $6{\cdot}48 \times 10^4$ rads/h at the irradiation site. At the end of the irradiation period (Table 1), a sample of algae from each vial was streaked out on trypticase soy agar to test for bacterial growth while another sample was sub-cultured into fresh medium to observe algal growth. The results given in Table 1 show that 4 h irradiation (about 260,000 rads) is capable of producing bacteria-free cultures with no observable algal damage. The only observable change appeared to be an increase in the size of pseudovacuoles which returned to normal with ensuing growth.

The purified algae were sub-cultured three times at 1-week intervals and observed regularly for 6 weeks, during which time they remained pure and in healthy condition. Cultural behaviour and microscopic structure remained characteristic; in the case of some filamentous forms, a slight stimulation of growth was apparent. Tests for anaerobes were negative. Fungi were not observed.

The work was carried out in the Water Resources Laboratories of the Department of Civil Engineering, University of Delaware. I thank Mrs. Cara Fries, who ran the anaerobe tests.

Copulation of Ultra-violet-irradiated and Unirradiated *Saccharomyces* Cells of Different Ploidy

THE inactivation of *Saccharomyces* strains of different ploidy induced by radiation has been investigated in detail by various authors[1]. For X-rays, 'recessive'- and 'dominant'-acting damages have been separated[2]. 'Dominant' lethal damage renders a zygote formed by fusion of an irradiated and an unirradiated cell unable to develop into a visible colony. Stein and Laskowski[3] took this type of damage into consideration when building a mathematical model to interpret the inactivation of *Saccharomyces*. Part of their theory was that ultra-violet light of wave-length 254 nm also causes this type of dominant damage. This communication presents results which show that this damage can indeed be observed after ultra-violet irradiation.

Key: + Growth occurred. − Growth did not occur.
+ + / + − } Growth in some cultures, but at least one bacteria-free isolate could be obtained.

A diploid (266) and a tetraploid strain (407) of *Saccharomyces* were used for the irradiation experiments. These strains are more or less isogenic and homozygous, of mating type constitution $\alpha\alpha$ and $\alpha\alpha\alpha\alpha$ respectively, and serine prototrophic[4]. The unirradiated copulation partner was a haploid strain (211-1*bN*) of mating type *a*, which was serine auxotrophic. Ultra-violet irradiation was produced using a low-pressure mercury lamp (*HNS* 12, Osram) with a dose rate of $3{\cdot}1 \times 10^3$ erg/cm²/min with 10 per cent variation. The diploid and the tetraploid strain were incubated before irradiation for 40 h on a solid yeast extract medium (YP: 2 per cent agar, 0·5 per cent peptone, 1 per cent yeast extract (Difco), and 2 per cent glucose). The haploid strain was taken from a 20 h old shaker culture (liquid YP medium). Both were incubated at 30° C.

Before irradiation the strains were washed three times, and the suspended cells were centrifuged at low speed. This procedure gave about 98 per cent single cells in the supernatant and these were brought to a concentration of about 10^6 cells/ml. After irradiation the cells were mixed with the unirradiated haploid cells in a ratio of 1 : 5 and incubated on a solid YP medium for about 3 h at 30° C. From the resulting mixture of zygotes and cells, zygotes were extracted with a 'Fonbrune' micromanipulator. Zygote formation decreased with increasing dose of ultra-violet irradiation. In the control experiments without ultra-violet irradiation, the frequency of zygote formation was about 40 per cent. To avoid selection in the process of isolation, all the zygotes in one visual field of the microscope were taken.

After incubation at 30° C for 48 h the zygotes were inspected microscopically on the solid YP medium. Two types were observed: (1) zygotes that formed one or (very seldom) up to 200 descendants which were not able to grow up in liquid YP medium (lethal zygotes); (2) visible colonies with about 10^7 cells; these small colonies were transferred to fresh solid YP medium and checked for their mating type constitution by crossing with test strains by a technique described elsewhere[5]. Three different types were found. (*a*) Cultures giving no zygotes, either with the *a*- or with the α-test strain. (*b*) Cultures forming zygotes with the α-test strain. (*c*) Cultures forming zygotes with the *a*-test strain (these were very seldom noticed). Colonies of the first class were always serine prototrophic. This type included all cultures grown from real zygotes, while it is possible that types (*b*) and (*c*) resulted from incomplete formation of zygotes or, although this is very improbable, from the isolation of a haploid or diploid cell. Results of the copulation experiments are shown in Table 1.

Table 1. COMPARISON OF SURVIVAL FREQUENCY OF ULTRA-VIOLET-IRRADIATED DIPLOID AND TETRAPLOID *Saccharomyces* STRAINS AND THE COLONY-FORMING ABILITY OF ZYGOTES, FORMED BY IRRADIATED DIPLOID AND TETRAPLOID AND UNIRRADIATED HAPLOID CELLS

Irradiated strain	Ultra-violet dose (min)	Survival frequency	No. of isolated zygotes	Results of the examination of the cultures grown up from the isolated zygotes: Bogus zygotes, Irradiated strain	Bogus zygotes, Haplont	Real zygotes vital *v*	Lethal zygotes *l*	Frequency of lethal zygotes $\frac{l}{l+v}$
266	0·0	1·00	40	1	1	38	0	0·00
	6·5	0·23	47	0	5	25	17	0·41
	7·5	0·13	53	1	9	11	32	0·74
407	0·0	1·00	40	0	2	36	2	0·05
	5·0	0·51	50	2	1	27	20	0·42
	7·5	0·14	90	0	12	30	48	0·62
	8·0	0·07	50	0	6	11	33	0·75
	8·5	0·04	20	0	4	5	11	0·69

The frequency of lethal zygotes increases with the dose of ultra-violet radiation (last column in Table 1). The high rate of isolated zygotes, which later gave rise to parental haploid cells (column 6 in Table 1), showed that some processes may be involved after ultra-violet irradiation which 'save' most of the unirradiated part of the 'semizygotes'.

First observations, using the phase-contrast microscope with a special technique[6], made clear that the membrane between both copulating cells is dissolved in almost all the zygotes inspected after ultra-violet irradiation, although it was impossible to be sure about the fusion of the nuclei. It seems possible that 'dominant' ultra-violet damage will act only in real zygotes with fused nuclei, and that without fusion the unirradiated partner has a chance of survival. This means that 'dominant' lethality does not operate like a poison, but consists of damage within the nucleus or the mitotic apparatus as has been supposed for X-ray-induced 'dominant' damage in *Saccharomyces*. This suggestion is supported by the observation that most of the lethal zygotes begin to form one, and only one, daughter cell after ultra-violet irradiation.

When the results of ultra-violet irradiation are compared with those observed for X-rays[1,2], it seems that both types of irradiation act similarly in producing 'dominant' lethality. A comparison of the inactivation rate (l-s) with the frequency of lethal zygotes $l/l+v$ (see third and last column in Table 1) shows that in diploid and tetraploid strains the whole ultra-violet inactivation is larger than the 'dominant' damage. Although the main part of the inactivation can be explained in this way, the assumption of Stein and Laskowski[3], that 100 per cent of the ultra-violet inactivation of a tetraploid strain is caused by this 'dominant lethality', needs to be modified.

Antibiotic Production in the Dacrymycetaceae

UP to the present time only four species of Dacrymycetaceae have been tested for antibiotic activity against bacteria[1,2]. Using sporophore extracts, Wilkens and Harris found no activity against *Bacterium* (*Escherichia*) *coli* or *Staphylococcus aureus* by *Femsjonia luteoalba* Fr., *Calocera cornea* (Batch.) Fr., *Calocera viscosa* (Pers.) Fr. or *Dacrymyces deliquescens* (Bull.) Duby. The present investigation was undertaken after a zone of inhibition produced by a culture of *Dacrymyces palmatus* (Schw.) Bres. was pointed out to me by Dr. R. H. Petersen.

Cultures were grown on a complete medium of malt extract, yeast extract and dextrose and a defined medium of glucose, asparagine, minerals and vitamins. One species, *Dacryopinax spathularia* Martin, was tested for antibiotic activity against various bacteria and fungi. Assay of antibiotic activity was made by the following techniques: (1) A filtrate of a culture of *D. spathularia* was placed in holes bored in agar medium seeded with selected test organisms. The zone of inhibition was measured after 24 h. (2) Photometric measurements were made at 400 mμ of turbidity increases of liquid cultures after 24-h exposure to medium in which *D. spathularia* had grown for 3 weeks. The *D. spathularia* was removed by membrane filtration. The second method proved to be the more consistent of the two. The addition of fresh nutrients did not change the results, which are shown in Table 1.

The antibiotic was active against all ten species of bacteria and four species of fungi tested by the photometric method. In several tests, however, *Saccharomyces cerevisiae* and *Candida albicans*, after initial inhibition,

Femsjonia luteoalba Fr.	+

Activity was tested by placing plugs of test cultures on seeded agar plates.

showed growth after several hours exposure, presumably by the selection of resistant mutants, or the formation of adaptive enzyme.

To test the cause of the lack of response of Gram-negative bacteria to the plate method, *E. coli* and *Bacillus subtilis* were grown in media with varying concentrations of antibiotic and the activity tested by photometric assay of growth. No significant differences were found in the response of the two species. In a further experiment, these two species and *S. cereviseae* were exposed to the antibiotic for 24 h. The cells were centrifuged, washed with fresh media and plated. All three species grew. Because no resistant forms had ever been found previously among the bacteria, it would seem that the antibiotic is inhibitory and not lethal, at least at 24-h exposure.

A number of other species of Dacrymycetaceae were tested for activity by removing plugs from agar cultures and placing them on plates seeded with *B. subtilis*. The results shown in Table 2 and Fig. 1 indicate that antibiotic production is widespread in the Dacrymycetaceae. The lack of activity in the original screening[1,2] was probably owing to a dilution effect caused by the large quantity of "jelly" present, or lack of production of the antibiotic in fruit bodies. The absence of activity in the genus *Calocera* (Table 2) may be of taxonomic importance.

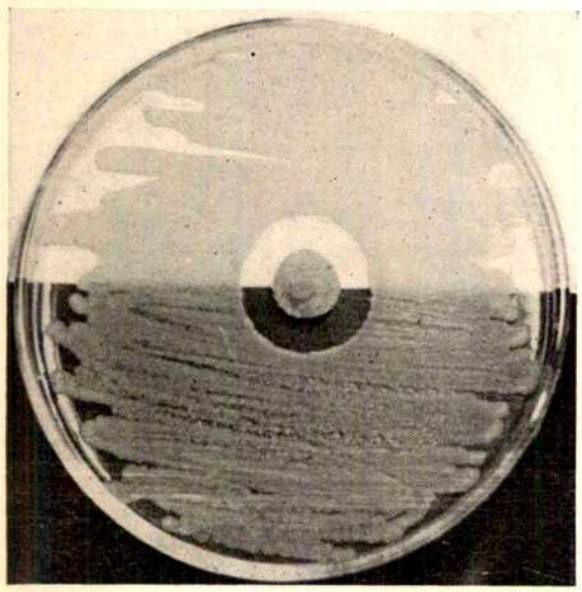

Fig. 1. Activity of a plug from a culture of *Dacrymyces palmatus* against *Bacillus subtilis*

The antibiotic, which can be produced on a simple chemically defined medium, is heat resistant (120° C for 1 h) and is stable to storage at room temperature (examined up to 6 months). The isolation of pure material has not been successful because of the difficulties imposed by the presence of a water-soluble polysaccharide which is produced by *D. spathularia*, and other members of the family that have been examined. Studies are at present under way to determine the mode of action of the antibiotic.

I thank Drs. P. G. Miles and R. H. Petersen for their help during the course of this work and Dr. W. H. Spencer for supplying many of the cultures of bacteria and fungi.

In vivo Transfer of Infectious Drug Resistance

INFECTIOUS drug resistance that can be transferred *in vitro* from a donor bacterium to a sensitive recipient bacterium can also be transferred *in vivo*. Transfer has been shown to occur in mice which have had their normal intestinal flora reduced by the preliminary feeding of antibiotics. In such mice the donor and recipient strains become well established and multiply in the intestine[1,2].

A much simpler method of investigating the transfer of infectious drug resistance *in vivo* has now been developed. The success of this new method depends on the administration of donor and recipient strains of bacteria to newly hatched chickens which have no alimentary bacterial flora. The choice of donor and recipient strains for the following experiments was based on the results of previous *in vitro* transfers. Two strains of *Escherichia coli*, *C*9 and *C*15, were used as donor strains and both were resistant to tetracycline and streptomycin. They were wild-type strains which had been isolated from normal fowls. Two recipient strains of *E. coli* were used which were ampicillin resistant mutants[3] of two pathogenic serotypes 02 and 078; they were both fully sensitive to tetracycline and streptomycin. The original strains were isolated from cases of fowl coli septicaemia. A strain of *Salmonella typhimurium* (N.C.T.C. 5710) was also used as a recipient and this also was fully sensitive to tetracycline and streptomycin.

Chickens were collected from the incubator as soon as possible after hatching and often when they were still partly in their shells. They were infected by mouth with ten drops of an overnight broth culture of the donor bacterium and 6 h later received by mouth ten drops of an overnight broth culture of the recipient bacterium. Food and water were then made available and no special precautions were taken to provide sterile conditions. Tap water was used for drinking and the food was a proprietary chick mixture without antibiotics. The chickens were kept on wire mesh floors to prevent contact with faeces. They were observed for 10 days after being fed the bacterial strains, and faecal samples were cultured each day after the second day and examined for the presence of converted recipients.

Three experiments were carried out, and Table 1 shows the strains used in each experiment. It also shows that

Table 1

Experiment	Donor strain	Recipient strain	No. of chicks used	No. of chicks in which transfer occurred
(1)	*E. coli* C15	*E. coli* (078)	8	8/8
(2)	*E. coli* C15	*E. coli* (02)	16	16/16
(3)	*E. coli* C9	*S. typhimurium*	30	12/12*

* This figure represents a random sample at one particular time.

transfer of drug resistance occurred in all the chickens tested.

In these experiments there was only an occasional death among the groups of chickens after being fed both donor and recipient strains. In preliminary experiments, however, it was found that when the recipient strain *E. coli* 078 was fed without the donor strain many more deaths, about 25 per cent, occurred. These deaths were shown by bacteriological examination to result from coli septicaemia and were probably due to lack of bacterial competition in the alimentary tract.

In the first two experiments where both the donor and recipient were strains of *E. coli*, selection of the converted recipients was achieved by making use of their non-transferable ampicillin resistance. Daily samples of faeces from individual chickens were suspended in nutrient broth containing 20 μg ampicillin/ml. and incubated with gentle agitation at 37° C for 2 h. The samples were then plated on MacConkey agar containing 20 μg ampicillin/ml. and the lactose fermenting colonies which developed were identified by slide agglutination with specific antisera. Transfer of drug resistance could be detected as early as 24 h after feeding the two strains and the converted recipients could be isolated throughout the 10-day observation period. At first the converted recipients isolated from the faecal specimens formed a large proportion of the total faecal coliform count, but as the experiments progressed the proportion declined considerably.

In the third experiment, in which the recipient was *S. typhimurium* and the donor *E. coli C9*, the faecal specimens from individual birds were plated in an undiluted form and also after being diluted 10^{-2} in phosphate buffered saline. The selective medium used was brilliant green agar containing 25 μg oxytetracycline/ml. In addition, undiluted faecal samples, after being enriched with selenite broth, were plated on this medium. The converted recipients recovered were identified by slide agglutination with specific antiserum. Converted recipients were isolated as early as 24 h after feeding the two strains and their excretion continued for the 10 days of the experiment. During the first few days, the converted recipients were so numerous in the faeces that they could be isolated by direct plating on brilliant green agar containing oxytetracycline. Towards the end of the 10-day period their isolation could only be made from those samples enriched with selenite broth. However, by adding oxytetracycline to the drinking water at this stage the converted recipients could be isolated by direct plating of the faecal samples.

In both the transfer from coli to coli and from coli to salmonella, oxytetracycline resistance was transferred to the same level as that of the donor strain. In contrast, streptomycin resistance was transferred either at the same level or at a much lower level than the donor.

The results of these experiments show that transfer of drug resistance occurs as readily in the intestine of the chicken as it does when the two bacterial strains are mixed in a broth culture. Preliminary experiments have also shown that infectious drug resistance can be transferred in the chicken from resistant donor *E. coli* derived from pigs and calves to a sensitive recipient strain of *E. coli* (026) derived from man. It is, therefore, possible to obtain drug transfer *in vivo*, using chickens, even when the donor and recipient strains used are derived from different species.

This work was carried out during the tenure of a Wellcome fellowship of the Animal Health Trust.

VIROLOGY

Absence of Serological Evidence of Myxoma Virus Infection in Humans exposed during an Outbreak of Myxomatosis

MYXOMATOSIS is a viral disease of rabbits regarded by some investigators as a neoplastic disease[1,2]. Epizootics have been observed in domestic rabbits (*Oryctolagus* spp.) in several areas of the Americas since 1898 when the disease was first reported by Sanarelli in Uruguay[3]. In California, myxomatosis outbreaks have been reported in domestic rabbit colonies along the coast from San Diego County to San Mateo County[4,5]. The disease in the *Oryctolagus* spp. is acute and highly fatal. The native wild rabbits (*Sylvilagus* spp.) are more resistant, and some develop benign fibromatous tumours[1]. In California, the brush rabbit (*Sylvilagus bachmani*) has been shown to be a reservoir host of the virus[5]. The virus has been shown to be transmitted naturally by a mosquito vector[6].

The host range of the virus disease appears to be very narrow. In his early work, Sanarelli[3] found that most animals were refractory to the disease. In attempting to infect several dogs he reported that one developed myxomatous neoplastic changes in the cutis. Two human subjects injected with infected rabbit serum developed a transient conjunctivitis. The animal work later was repeated by Bull and Dickinson[7]. They tested sixteen varieties of native Australian animals; none of the animals developed the disease. While there is considerable evidence of a narrow host range, the absence of observable signs of disease does not preclude the occurrence of inapparent infections nor of chronic effects after prolonged incubation.

With the increased interest in the possible viral aetiology of human cancer, evidence of transmission to man of viruses such as myxoma is of value. An opportunity to investigate for possible natural transmission of myxoma virus to man was presented in the summer of 1963 when myxomatosis occurred in a colony of domestic rabbits at a boys' camp in Santa Barbara County, California. An investigation was undertaken, and this report describes the outbreak and the results of a survey for serological evidence of myxoma infection in the boys and camp supervisor.

The outbreak began in June 1963 and resulted in daily losses of rabbits during the summer. Almost all the 600 rabbits in the colony died by the end of September when the epizootic ended. A similar epizootic had occurred in the same colony the preceding year.

The diseased rabbits demonstrated typical oedematous swellings of the head and vent. Histological examination of the lesions revealed myxomatous changes. Mosquitoes were observed feeding on the rabbits. Because of their role in the transmission of myxomatosis, adult mosquitoes from the rabbitry and larvae from nearby water sources were collected for identification. The adults proved to be *Anopheles freeborni* and *Culex tarsalis*, and the larvae *Anopheles franciscanus*, *Culex tarsalis*, *C. peus*, *C. bohardi* and *C. apicalis*. No viral isolations were attempted, but Marshall[5] demonstrated myxoma virus in pooled specimens of *A. freeborni* collected at the site of a myxomatosis outbreak in San Mateo County, California, in 1959.

That myxoma virus was the causative agent of the Santa Barbara outbreak was confirmed in the following manner. Portions of the inflamed eyelids and spleen were removed from an infected rabbit soon after death. Equal amounts of these tissues were pooled, ground, and saline was added to make a 10 per cent suspension. A rabbit, shown by serum neutralization (SN) testing to be devoid of myxoma antibody, was inoculated intradermally with 0·5 ml. of the suspension. A second rabbit, which had been immunized with myxoma vaccine 10 months previously, was inoculated in the same manner[6]. The susceptible rabbit died 9 days after inoculation with typical symptoms of myxomatosis. The temperature of the immune rabbit became elevated on the fourth day, but the animal remained clinically normal.

Blood specimens were taken from twelve boys, ranging in age from 12 to 15 years, and from one adult staff member. None of the persons tested reported any unusual or acute illnesses during this period. Mosquito bites were occasionally reported among the boys during the epizootic. In addition they all worked daily in or around the rabbit colony. All the boys lived within 300 yards of the colony during the 4 months of the outbreak, with the exception of two boys who left the camp after 3 months' exposure. The first sera were taken on August 8, 1963, approximately 2 months after the outbreak began, and second specimens were collected 7 weeks later. Six control specimens were taken from adults living in Berkeley, California; two of these were obtained from persons known to have antibodies against vaccinia virus. In addition, the serum of one of us (J. K. S.), who had worked with the myxoma virus in the laboratory for more than 14 years, was also tested.

The presence of myxoma antibody was determined by means of the SN test conducted in roller tube cultures of a rabbit kidney cell line as described by Saito and McKercher[8]. The antigen used was the *MSA* strain of myxoma virus which has a cytopathogenic effect on rabbit kidney cells. Myxoma reference serum was obtained from a vaccinated rabbit that was subsequently challenged with virulent virus. All sera used in the test were inactivated at 56° C for 30 min.

In the test procedure the virus was diluted in cell culture medium containing 3 per cent lamb serum in ten-fold steps, beginning with the 1 : 5 dilution. The sera were diluted 1 : 2·5 and mixed with an equal volume of the appropriate dilution of virus to give a final dilution of 1 : 5 of serum in the presence of decimal dilutions of virus. The serum–virus mixture was held at room temperature for 90 min and then added in a volume of 0·2 ml. per tube to cell cultures from which the medium had just been withdrawn. Five tubes were used for each serum–virus mixture. Ninety min at room temperature were allowed for adsorption to take place, and then 1·0 ml. of medium containing 3 per cent lamb serum was added to each tube of cell culture. Controls were included, and the cultures were incubated in stationary racks in an incubator set at 33·6° C. The final reading was made on the seventh day. The neutralizing capacity of the serum was expressed as the neutralizing index derived from the method of Reed and Muench[9].

None of the human sera had demonstrable antibodies against myxoma virus as tested by the SN technique, and there was no cross-neutralization observed in the two sera with vaccinia antibodies. Inactivation of human sera at 56° C for 30 min was necessary to eliminate non-specific neutralizing activity. Inactivation at this temperature had no effect on the antibody titre of the immune reference serum.

It cannot be concluded from this survey that inapparent human infection with myxoma virus never occurs. However, these persons had ample opportunity to become infected in an area where rabbits were dying daily with myxomatosis and where mosquitoes were present to perpetuate the epidemic. The lack of serological evidence of human infection suggests that under such conditions myxoma infection in humans is probably an unusual event, if it occurs at all. The negative SN test in the subject with years of varied laboratory exposure reinforces this view. Whether other circumstances, such as a vector with different feeding preferences or a more dense vector population, would result in human infections can only await opportunities for further investigation.

This work was supported in part by a research grant from the National Cancer Institute, U.S. Public Health Service. We thank Dr. Dee Taylor for the histopathological diagnosis and Mr. Gail Grodhaus for the mosquito identifications.

Comparative Cytopathology of Rinderpest and Bovine Parainfluenza 3 Viruses in Cell Cultures

BECAUSE cytopathology may be useful in the detailed classification of viruses, we explored the comparative cytopathic changes induced by bovine parainfluenza 3 and rinderpest viruses in *MS* and dog kidney cell cultures.

Attenuated rinderpest virus was obtained from W. Plowright[1]. The virus had been serially passed a hundred times in bovine kidney cells and titred to $10^{4.5}$ $TCID_{50}$/ml. before it was grown in *MS* and dog kidney cells. Parainfluenza 3 virus was isolated[2] from sick cattle and was serially grown fifteen times in calf kidney tissue cultures and titred to 10^6 P.F.U./ml.

MS and dog kidney cells were grown in a medium consisting of 0·5 per cent lactalbumin hydrolysate in Hanks's balanced salt solution on 7 × 22 mm glass coverslips. The amount of inoculum per culture tube was 0·2 ml. of an undiluted seed virus. At intervals, infected coverslips together with uninfected controls were removed and stained with haematoxylin and eosin, using the modified technique of Reissig *et al.*[3].

Rinderpest virus failed to elicit any visible cytopathic effects but produced eosinophilic cytoplasmic inclusions and giant cells in *MS* cells (Fig. 1). About 90 per cent of the cells showed these inclusions 7 days after the inoculation of the culture. The inclusions were generally surrounded by a halo and some had a granular structure. A few cells showed intranuclear eosinophilic inclusions on the ninth day. Giant cells often contained the first inclusion. Acidophilic cytoplasmic inclusions and few giant cells were produced by rinderpest virus in dog kidney cells. Giant cells often contained the first, and at times the only, inclusions that appeared in a culture.

Bovine parainfluenza 3 virus showed distinct cytoplasmic inclusions and giant cells on the third day after inoculation in *MS* cells. About 83 per cent of the cells showed cytoplasmic as well as intranuclear inclusions. On the eighth day almost all the cells showed intracyto-

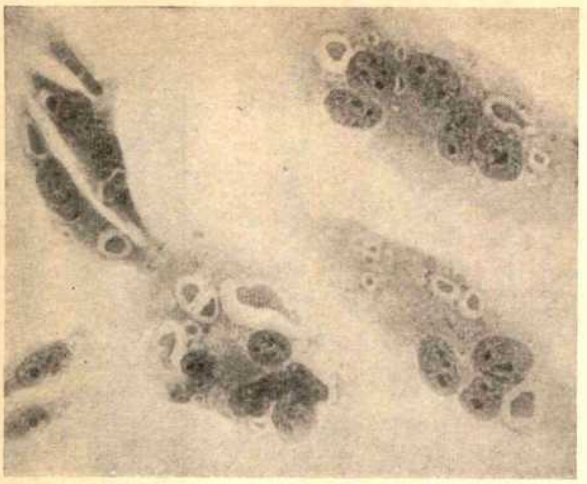

Fig. 1. *MS* cells 7 days after inoculation with rinderpest virus. Giant cells and eosinophilic inclusion bodies are present. Zenker's haematoxylin and eosin (×*c.* 500)

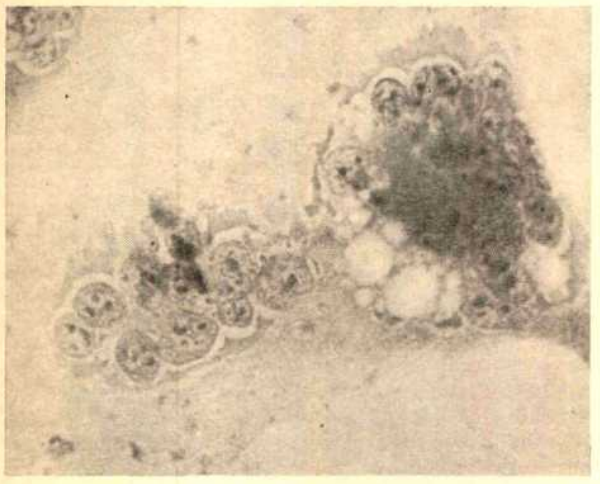

Fig. 2. *MS* cells 8 days after inoculation with bovine parainfluenza 3 virus. Giant cells and eosinophilic intranuclear and intracytoplasmic inclusions are present. Zenker's haematoxylin and eosin (×*c.* 500)

plasmic and intranuclear inclusions (Fig. 2). Few cytoplasmic inclusions and giant cells were seen in dog kidney cultures. No visible cytopathic effects were observed in the infected cultures.

These observations suggest that bovine parainfluenza 3 virus, a member of the myxovirus family[4], and rinderpest virus produce distinct and similar cytopathology in *MS* and dog kidney cells. Such findings support the decision taken in Montreal in August 1962 by the Viral Subcommittee of the International Nomenclature Committee[5] to accept that rinderpest, measles, dog distemper and respiratory syncytial virus are all members of the myxovirus group.

Serological Properties of Coxsackie *A7* Virus

DURING epidemiological work on enteroviruses, four strains of Coxsackie *A7* virus were isolated from faecal specimens of healthy children cultured in cynomolgus monkey kidney tissue. Experiments carried out with these isolates and other representative strains of Coxsackie *A7* virus revealed that differences in antigenicity exist among strains of Coxsackie *A7* virus and emphasized the importance of the selection of working sera to identify isolates.

Virus strains: The prototype strain of Coxsackie *A7* virus, strain Parker, was obtained from two laboratories. One was sent in 1961 from Dr. H. Gelfand, Communicable Disease Center, Atlanta, as a suckling mouse torso suspension designated as 'Parker *M*34': this virus is here referred to as 'Parker (CDC)'. The other prototype strain was received in 1961 from Dr. M. K. Voroshilova, Institute of Poliomyelitis and Viral Encephalitides, Moscow, as a 10 per cent suspension of muscles of suckling mice. This virus had originally been sent by Dr. S. Gard, Stockholm, to Dr. Voroshilova in 1957, and had since undergone four passages through suckling mice. This strain is referred to as 'Parker (Moscow)'.

AB IV strain was first isolated by Dr. Voroshilova in 1952[1], and was then adapted to rhesus monkey kidney tissue cultures and identified as Coxsackie *A7* virus in 1957 by Dr. K. Habel, National Institutes of Health, Bethesda[2]. We received the strain from Dr. Voroshilova in 1961, as *AB* IV-*K.H.* No. 2435 culture fluid. The strain 119 (368) was isolated by Dr. Voroshilova in 1961 from a case of paralytic poliomyelitis in Moscow and sent to us in 1964 as culture fluid. The strain *NYS*-58182 was a tissue-culture adapted virus derived from a suckling mouse isolate from a poliomyelitis case in 1958 and sent to us as *TC*2-3 pool in 1964 from Dr. H. A. Wenner, University of Kansas. The strain Kyoto-435 was isolated in 1963 by Dr. Ashihara[3] by the inoculation of faecal extract of a clinical poliomyelitis case into a suckling mouse and was received in 1964 as the second passage.

Antisera: Monkeys and rabbits were immunized against representative strains. Undiluted tissue culture lysate after one freeze-thawing and a light centrifugation or a 10 per cent homogenate of infected suckling mouse torsos after a light centrifugation served as antigen for immunization. In most cases the antigen was subjected to a fluorocarbon treatment and was stored at −25° C. Rabbits and monkeys were, as a rule, immunized by subcutaneous and intravenous routes. Serum was inactivated at 56° C for 30 min before use. Anti-*AB* IV horse serum H–419 was supplied by Dr. Voroshilova in 1964.

Neutralization test: For tissue culture neutralization tests primary cynomolgus monkey kidney tube cultures were used. On the day before the test, the growth medium was replaced with serum-free maintenance medium (Earl's balanced salt solution containing 0·5 per cent lactalbumin hydrolysate and 0·11 per cent sodium bicarbonate, 100 U. of penicillin and 100 μg of streptomycin per ml.) and this was replaced with serum-free maintenance medium before inoculation. An equal amount of virus containing about 100 $T.C.I.D._{50}$/0·1 ml. and serial four-fold dilutions of serum was mixed and kept standing at 36° C for 3 h followed by standing at 5° C overnight. 0·2 ml. of the mixture was inoculated into each tube, containing 1 ml. of maintenance medium. Observation was carried out for 7 days and 50 per cent neutralizing end-point was calculated. Four tubes were used per dilution of the test serum. For suckling mouse neutralization tests, new-born mice from several litters were randomized and re-distributed to minimize variance in susceptibility. An equal amount of virus containing about 200 $L.D._{50}$/0·03 ml. and serial four-fold dilutions of serum were mixed and incubated at 36° C for 2 h. 0·03 ml. of the mixture was inoculated subcutaneously into each mouse, using one litter, in some cases only half the litter, per

dilution of the test serum. Daily observations were made for 14 days and 50 per cent neutralizing end-points were also calculated.

Experimental results:

(1) Isolation and identification of four strains of tissue culture isolates. Table 1 shows the data on the isolation of these strains. Three of them were isolated in our laboratory and the fourth strain, Natori-32, was isolated by Dr. H. Ujiie, Miyagi Institute of Public Health, and sent to us for identification. Attempts to identify these isolates by our routine procedures, using antisera against poliovirus 1, 2, 3, Coxsackie *A*9, *B*1-6, Echovirus 1–7, 9, 11–27 and Reovirus 1, failed to indicate to which class these agents belonged. Further investigations revealed that all these isolates are neutralized by the antiserum against *AB* IV strain of Coxsackie *A*7 virus. Three of these strains are also pathogenic to new-born mice by subcutaneous inoculation, manifesting generalized myositis and degeneration of the striated muscle.

Table 1. ISOLATION OF COXSACKIE *A*7 VIRUS IN MONKEY KIDNEY TISSUE CULTURES

Strain name	Collection of specimen			First appearance of CPE	Suckling mouse pathogenicity
	Year	Area	Source		
Z–C–61–7	1961	Nagaoka	Faeces (healthy child)	1st passage (9th day)	+(3)*
Z–C–52–7	1961	Nagaoka	Faeces (healthy child)	1st passage (11th day)	−(4)
63–*G*–35–4	1963	Takatsu	Faeces (healthy child)	2nd† passage (4th day)	+(2)
Natori-32	1963	Miyagi	Faeces (healthy child)	1st passage (9th day)	+(5)

* Numbers in parentheses indicate the tissue culture passage level of each strain, at which suckling mouse pathogenicity was examined.
† The first passage showed no cytopathogenic effect (CPE) up to the sixth day after inoculation.

(2) Cross-neutralization tests. The cross-neutralization test was carried out using antisera against various strains of Coxsackie *A*7 virus and some representative results are summarized in Table 2. These indicate that all the tissue culture adapted strains were equally neutralized by anti-*AB* IV, -63–*G*–35–4 or -Natori-32 immune sera. These sera also neutralized the Parker (Moscow) strain according to suckling mouse neutralization tests, but scarcely so in the case of Parker (CDC) and Kyoto-435 strains. Antiserum against Parker (Moscow) strain also neutralized tissue culture adapted strains in the same manner as the homologous strain, but less strongly so against Parker (CDC) and Kyoto-435 strains. On the contrary, immune sera against the prototype Parker (CDC) of Kyoto-435 strain neutralized tissue culture adapted strains to a lesser extent than the homologous strains. As a rule, immune sera against the strain Parker (CDC) neutralized Kyoto-435 strain as well as the homologous strain, and vice versa. Two immune sera, that is, *M*–5807–2 (monkey immune serum against Parker (CDC) strain) and *SR*–9–2 (rabbit immune serum against Kyoto-435 strain), were rather exceptional, heterologous neutralization titres between these two strains being quite low compared with the homologous titres.

The reason why the two lines of the prototype Parker strain of Coxsackie *A*7 virus show a shift in antigenicity has yet to be explained. It is interesting, however, that all the tissue culture adapted strains of Coxsackie *A*7 virus examined so far seem to be closely related to the prototype Parker (Moscow) strain, whereas one suckling mouse isolate, Kyoto-435, is closely related to the other line of the prototype strain, Parker (CDC). The findings demonstrate that monkeys or rabbits will respond in some cases, though not so frequently, to an agent more or less specifically, producing rather strain-specific antibody, as was observed with the sera *M*–5807–2 and *SR*–9–2. Extensive investigations using numerous strains of Coxsackie *A*7 virus, both tissue culture and suckling mouse adapted strains, are now under way. Complement-fixation and haemagglutination inhibition tests will also be included in further investigations. The data reported here would thus seem to indicate the importance of the selection of an adequate number of working sera for the identification of Coxsackie *A*7 isolates.

Herpes Simplex Virus Particles in the Nerves of Rabbit Corneas after Epithelial Inoculation

THIS article demonstrates, for the first time, infection of deep ocular structures by herpes simplex virus as revealed by the presence of herpes particles in the cells of the stromal nerves.

Inoculation of the corneal epithelium of rabbits with herpes simplex virus produces an experimental disease that closely resembles naturally occurring human herpes simplex corneal infection (dendritic keratitis) in several ways: in both man and rabbit the epithelial lesions have a branching form, there is anaesthesia of the cornea, and the superficial ulcers respond to treatment with anti-herpetic drugs[1]. A certain number of human herpes simplex corneal infections are followed by inflammation of the deep layers (disciform keratitis)[2]; in such deep lesions, herpes virus is demonstrated much less frequently than in dendritic keratitis[1,3]. Under proper conditions, similar deep keratitis can be produced in the rabbit by certain strains of herpes simplex virus, despite the fact that herpes virus and antigens appear to be limited to the corneal epithelium or endothelium[1,4,5].

We have investigated rabbit eye tissues by light and electron microscopy after infecting the corneal epithelium with a strain of herpes simplex virus which regularly produces lesions in the stroma[6]. At intervals after in-

Antibody titres are expressed as reciprocals of $\log_4$ serum dilution, showing 50 per cent neutralization end-point against 34–300 $T.C.I.D._{50}$ or $L.D._{50}$ of the challenge virus.
* 1,000 $T.C.I.D._{50}$ was used as challenge virus.

fection, specimens were taken from the central cornea and corneoscleral junction (limbus). Small blocks of tissue were fixed in 3 per cent glutaraldehyde buffered with 0·067 M cacodylate, and then washed in a 0·1 M cacodylate solution containing 0·25 M sucrose. The tissues were post-fixed with 1 per cent osmium tetroxide in phosphate buffer, dehydrated in graded alcohols, and embedded in 'Epon' resin. Thin sections of this material were contrast-stained with uranyl acetate and lead acetate, and examined in an RCA 3*E* electron microscope; after the thin sectioning, thick sections (1–2 μ) for light microscopy were cut from each block and stained with toluidine blue.

Particles with the characteristic morphology of herpes simplex virus[7,8] were found in the corneal epithelial cells and in the nerves at the limbus. A herpes-infected corneal nerve in the limbal plexus, as described by Whitear[9], is shown in Fig. 1. Within the nucleus of one Schwann cell in this nerve there are characteristic herpes particles bounded by a single membrane ("naked virus particles") about 75–100 mμ in diameter and containing a dense central nucleoid (Fig. 2). Other virus particles are present at the cell membrane (Fig. 2); these are similar in structure to the nuclear virus particles, but possess a second limiting membrane or envelope. The cell was identified as a Schwann cell by the nerve axon in the cytoplasm and by the typical amorphous basement membrane just outside the cell membrane. The extracellular virus particles are lying between the plasmalemma and this basement membrane (Fig. 2).

Since herpes simplex virus acquires its outer envelope from the cell membrane by a process of budding[8], the position of these extracellular virus particles makes it probable that they have budded out from the cell membrane and have not penetrated the thick basement membrane surrounding the cell. The presence of single-membrane particles in the nucleus, and of double-membrane particles between the plasmalemma and basement membrane, indicates that this Schwann cell has been the site of formation of both naked and enveloped virus particles.

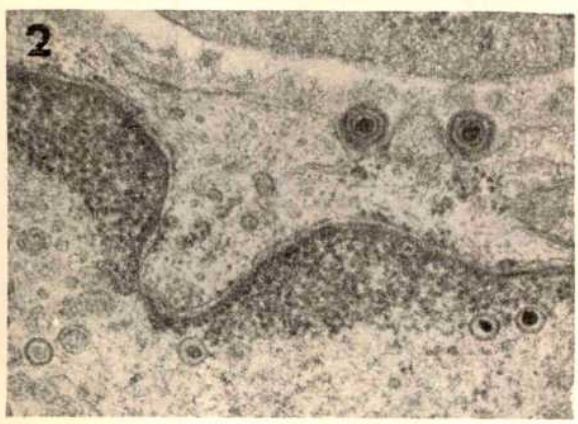

Fig. 1. Light photomicrograph of a section from the limba region of a rabbit eye infected with herpes simplex virus 48 h previously. Much of the superficial epithelium is missing; the infected peripheral nerve (arrow) lies in the anterior layers of the stroma. Toluidine blue stain. (× 480)

Fig. 2. An electron photomicrograph of the same Schwann cell in subsequent serial section. In the nucleus (bottom) there are three dense centred virus particles bounded by a single-membrane. At the cell surface there are two virus particles with two limiting membranes (upper right). The position of these virus particles between the cell membrane and the basement membrane would suggest that they had acquired an outer envelope from the cell membrane, but had not yet passed through the basement membrane. (× 43,000)

Infection of the limbal nerves has been detected 48 h and 72 h after inoculation; further investigations are now in progress to determine the duration and extent of this deep ocular infection. Typical particles have been found regularly in the corneal epithelial cells, but none of the other stromal cells (keratocytes) of the cornea or limbus show similar evidence of infection despite the marked inflammatory response of these tissues.

The presence of virus particles in these Schwann cells is the first direct morphological evidence that herpes simplex virus proliferates in the deep stroma of the cornea and sclera. It has been known for many years that herpes virus infection of the cornea, or other peripheral sites in the rabbit, often produces encephalitis and that the virus can reach the central nervous system through the peripheral nerves[10]. A recent re-evaluation of the pathogenesis of herpes encephalitis in mice by means of an immunofluorescent technique has shown that the virus reaches the central nervous system in blood-borne macrophages (in young animals) or by an ascending infection of the peripheral nerves[11]. Although the strain of herpes simplex used in these experiments rarely caused encephalitis in rabbits, the agent did infect the Schwann cells of nerves beneath the corneal epithelium. If such a local dissemination of virus occurs in dendritic keratitis in man, this involvement of stromal nerves would offer an explanation for the corneal anaesthesia and involvement of deeper structures of the anterior segment of the eye found so regularly in human cases of herpes simplex keratitis.

This work was part of a project on viral keratoconjunctivitis carried out in the Francis I. Proctor Foundation and the Department of Microbiology, University of California Medical Center, San Francisco. We thank Dr. E. Jawetz and Miss V. R. Coleman for their help in this investigation, which was supported in part by the U.S. Public Health Service.

ENTOMOLOGY

Micro-determination of Insect Blood Volume

Methods of estimating insect blood volume depend either on haemocyte counts before and after an injection of a measured volume of saline or on the dilution of amaranth dye by the haemolymph[1]. The latter method

has been recommended for repeatable and consistent results with locusts[2]. Neither method, however, is likely to be practical for experiments with small insects, for example, the housefly, because the volume of liquid used for dilution (0·1–0·2 μl.) is too small to be administered with accuracy.

The following method, which is being used in our investigations of altering the ionic ratios in insect blood, has proved satisfactory in determining small blood volumes, and is based on the exchange of a cation which exists in abundance in the blood with ion-exchange resin. Sodium in both housefly and blowfly exists largely in the haemolymph.

Cation exchange resin '*IR*-120' sieved to a uniform mesh of 36 is thoroughly activated to the (H^+) form and tested for complete absence of sodium by ashing a sample and testing with a flame photometer. This resin is strongly acidic and has an exchange capacity of about 16 μg Na^+/10 beads at 20° C.

Weighed houseflies are held by suction on their dorsal or ventral side. An incision is made with a sharp hypodermic needle in the last abdominal segment, or inter-muscularly in the thorax, or even in the head capsule. Ten beads for flies weighing up to 20 mg are inoculated with watchmakers' forceps. After 10 min when the entire haemolymph has circulated the resin and the exchange reached equilibrium, the beads are carefully removed and with a little experience should be secured clean. They are washed with de-ionized water, ashed, and their sodium content determined with a flame photometer. This represents the total blood sodium in equilibrium with the resin.

A random sample of 1 or 2 μl. of blood drawn into a micro-pipette is mixed on a watch glass with the same number of beads for a few minutes. The resin is washed with de-ionized water and the amount of Na^+ exchanged/μl. is determined. The volume of blood =

$$\frac{\text{total blood } (Na)^+ \text{ exchanged}}{(Na)^+ \text{ exchanged}/\mu l.}$$

The ion exchange equilibrium constant $(Na)^+$ solution/$(Na)^+$ resin, for up to 5 μl. of housefly blood using ten beads, is 0·3 at room temperature and it remains constant within the range 15°–25° C. It is therefore necessary that both experiments are carried out within that range.

Four- to six-day-old houseflies fed on milk and kept at 25° C and in 50 per cent relative humidity showed a blood volume of 0·17 ± 0·02 μl./mg wet body-weight. A similar result was obtained for the blowfly (*Phormia terraenovae*), where again ten beads/20 mg body-weight were used. The blood volume of both species varied according to age and diet.

The advantages offered by this method include: (1) it takes into account any blood which exudes from puncturing the insect, because the resin will exchange ions with it through the process of inoculation; (2) it can be applied to insects much smaller than the housefly using beads of suitable mesh; (3) it yields results very rapidly.

I thank Dr. C. T. Lewis for valuable discussions and the Tropical Pesticide Research Committee of the Department of Technical Co-operation for financial support.

HAEMATOLOGY

Gm(g)—A "New" Gamma-globulin Factor

THE four antigenetically different heavy polypeptide chain sub-types[1–3] of γG-globulin* are probably determined by genes at different genetic loci[4–7]. Two of these, the 'We' and 'Vi' loci, are closely linked and related to the Gm system[4–7]. Gm^1 and Gm^4 are alleles belonging to the 'We' locus. Myeloma proteins or isolated γG-antibodies of the We sub-group are Gm(1) or Gm(4) (refs. 4 and 8). Gm^5 belongs to the 'Vi' locus where various partly identical genes are present[9]. Isolated γG-antibodies of the Vi sub-group are either Gm(5) or lack any known Gm factor[4–6]. It has been suggested that Gm(–5) antibodies of the Vi sub-group are determined by a hypothetical unidentified gene Gm^-, which is the true allele of Gm^5 (refs. 4 and 6).

This communication reports a new γG-globulin factor, called Gm(g), determined by a gene, Gm^g, behaving as an allele of Gm^5 at the 'Vi' locus. Gm(g) can be identified by a haemagglutination-inhibition test[10] using anti-Gm(g) 3978 and red cells coated with incomplete Gm(g) anti-D 4752.

Incomplete anti-D 4752 from a Gm(1,–2,4,5,g), Inv(–1, –2) donor was characterized as a γG-antibody by preparative ultracentrifugation and various tests with specific rabbit antibodies to γG-, γA- and γM-globulin respectively[11]. Red cells (O,R_1R_2) coated by anti-D 4752 in excess were strongly agglutinated by antiglobulin sera but not by several anti-Gm((1),(2),(4), (5),(6),(8),(9),(10), (11),(12)) or anti-Inv ((1),(2)) reference reagents. Red cells coated with pepsin-digested (Fab) anti-D 4752 were tested with anti-γ-globulin factors detected by Fab γG-globulin. For convenience, such anti-γ-globulin factors are called 'pepsin-agglutinators' and they show specificity for heavy chain sub-group determinants[11,12]. Similarly, reference anti-D antibodies were also tested with at least two anti-Gm factors and four 'pepsin-agglutinators' of each specificity (Table 1). All the Gm(1) and Gm(4) anti-D antibodies belonged to the We sub-group and Gm(5) anti-D to the Vi sub-group. Anti-D 4752 was a Gm(–5) antibody of Vi sub-group.

Table 1. HEAVY CHAIN SUB-GROUP AND Gm SPECIFICITY OF VARIOUS ANTI-D ANTIBODIES

Anti-D	Gm-type of donor	Specificity of anti-D antibody: Heavy chain sub-group	Gm-type
3091	1,2,–4,–5,g	We	1,2,–4,–5,–g
3311	1,–2,4,5,g	We	1,–2,–4,–5,–g
3083	–1,–2,4,5,–g	We	–1,–2,4,–5,–g
3358	–1,–2,4,5,–g	We	–1,–2,4,–5,–g
3109	–1,–2,4,5,–g	Vi	–1,–2,–4,5,–g
3500	–1,–2,4,5,–g	Vi	–1,–2,–4,5,–g
4752	1,–2,4,5,g	Vi	–1,–2,–4,–5,g

By using red cells coated with whole anti-D 4752 a corresponding haemagglutinating substance in serum 3978 was found (titre 128). Activity was also detected by anti-CD Ripley. No reaction was obtained with red cells coated by each of thirty-six other strong incomplete anti-D antibodies specific for at least one of the factors, Gm(1),(2),(4),(5),(6),(7),(8),(9),(10),(11),(12) or Inv (1),(2). Another serum (3765) showed a weak reaction with anti-D 4752 and a strong reaction with reference Gm(1) anti-D. Activity detected by anti-D 4752 was only absorbed by red cells coated by anti-D 4752 but not by using Gm(1) anti-D. On the other hand, the anti-Gm(1) activity of serum 3765 was only removed by Gm(1) anti-D and not by using anti-D 4752. Sera 3978 and 3765, both Gm(–1,–2, 4,5,–g) were from patients with rheumatoid arthritis. There was no prozone in the agglutination of red cells coated by anti-D 4752 or anti-CD Ripley.

The haemagglutinating substances of sera 3978 and 3765 were inhibited by native pooled γG-globulin and by γG-globulin of serum 4752, as characteristic for anti-Gm

* The nomenclature used in this paper is that drafted in *Bull. Wld. Hlth. Org.*, **33**, 721 (1965).

factors. No inhibition was obtained with Fab γG-globulin, which indicated that the reactive site was part of the Fc fragment. Results of density gradient ultracentrifugation and tests with specific rabbit antisera[11], and of mercaptoethanol-treatment[11], indicated that the anti-Gm(g) factors were γM-globulins.

Fifteen Gm(1,–4,–5) Caucasian sera which were Gm(2) positive or negative and fifteen Gm(–1,–2,4,5) sera were tested in dilutions 1/4, 1/6 and 1/8 for inhibition of 2,4 and 8 agglutinating units[10] of anti-Gm(g) 3978. All the Gm(1) sera inhibited the agglutination while the Gm(–1) sera did not. Similar results were obtained when isolated γG-globulin[12] (2 mg/ml.) of the same sera was used. Gm typing[10] of sera from a hundred unrelated Caucasian blood donors (Table 2) showed the following frequencies : Gm(1), 52 per cent; Gm(2), 25 per cent; Gm(4), 91 per cent; Gm(5), 91 per cent; Gm(g), 49 per cent. All the Gm(2) sera were also Gm(1). Except for two sera which gave intermediate reaction in Gm(g) typing, all but one serum showed concordance between Gm(1) and Gm(g) types. Four agammaglobulinaemia sera were Gm(–g). Each of five isolated Gm(1) myeloma proteins kindly provided by Dr. M. Harboe were all Gm(1,–g). In a two-dimensional haemagglutination-inhibition test[10] the Gm(g) inhibiting capacity was weaker than that of Gm(1) in a given serum positive for both factors.

Of thirteen American and twenty West Indian Negro sera, kindly provided by Dr. K. Kano and Dr. E. R. Gold, respectively, twenty-five were Gm(1,–4,5,–g), five Gm(1,4,5,–g), one Gm(1,–4,5,g), one Gm(1,–4,–5,g) and one Gm(–1,4,5,–g). One West African Negro serum was Gm(1,–4,5,–g).

Results of the serological tests indicated that Gm(g) anti-D 4752 and anti-Gm(g) 3978 determined a γG-globulin factor distinct from previously known factors[6,9,13,14]. The Gm(g) anti-D 4752 did not contain other Gm factors. According to the 'one gene–one polypeptide chain' concept (see ref. 6), Gm(g) is determined by a separate gene.

Various findings indicated that *Gmg* is the true allele of *Gm*[5]:

(i) Anti-D 4752 was a Gm(–5) γG-antibody of the Vi sub-group.

(ii) Anti-Gm(g) was found in Caucasian Gm(–1,–2,4.5,–g) sera, in one case coexisting with anti-Gm(1).

(iii) All sera tested were either Gm(5,–g), Gm(–5,g) or Gm(5,g). In Caucasians, Gm(g) and Gm(1) were usually inherited together, just as Gm(4) and Gm(5). Only one Caucasian serum was Gm(1,4,5,–g). Although the genes at the 'We' and 'Vi' loci are closely linked, 'crossing-over' occurs[6], which would explain this phenotype. The intermediate reactions are probably due to the very small amounts (0·25–1·1 mg/ml.) of Vi γG-globulin in normal sera[1]. In Negroes Gm(1) and Gm(5) are inherited together, and Gm(4) is very rare in a Negro population without Caucasian genes[14]. Accordingly, phenotype Gm(1,–4,5,–g) was most frequent in American and West Indian Negroes and was also found in the single West African Negro. The other phenotypes were explained by Caucasian ancestry in American and West Indian Negro populations.

(iv) Gm(g) antibodies were uncommon. Two-dimensional haemagglutination inhibition experiments further indicated that only a small proportion of the γG-molecules in a Gm(g) serum carries the Gm(g) specificity. *Gmg* thus takes part in the synthesis of a relatively small amount of γG-molecules, just as *Gm*[5].

Since *Gmg* is probably equivalent to the unidentified gene *Gm*– at the 'Vi' locus[4,6] (Fig. 1), the common gene complexes in Caucasians are *Gm*[1]*Gmg*, *Gm*[1,2]*Gmg* and *Gm*[4]*Gm*[5]. Further investigations of Gm(g) are at present being carried out.

Table 2. Gm-TYPES OF 100 NON-RELATED CAUCASIAN SERA

	Gm(g)	Gm(–g)	Intermediate
Gm(1,–4,–5)	9	0	0
Gm(–1,4,5)	0	48	0
Gm(1,4,5)	40	1	2

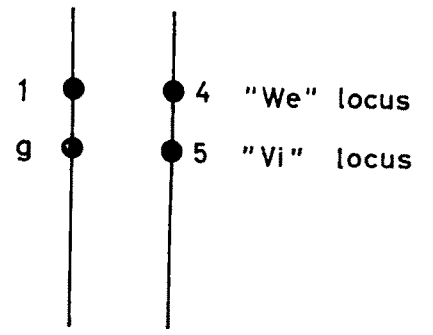

Fig. 1. *Gm* genes at the 'We' and 'Vi' loci in Caucasian Gm(1,4,5,g) individuals. Probable localization of *Gmg*

I thank Drs. H. Fudenberg, E. R. Gold, K. Halvorsen, M. Harboe, K. Kano, E. van Loghem, L. Mårtensson, C. Ropartz, A. G. Steinberg and M. Waller for generous provision of reagents which made this work possible. This study was aided in part by a grant from L. Meltzers Hoyskolefond, Bergen, Norway.

Note added in proof. Twenty-two African Negro sera kindly provided by Drs. T. E. Cleghorn and F. Lothe were all Gm(1,–4,5,–g). Gm(g) has been given the designation Gm(21) by the WHO International Reference Centre for Genetic Factors of Human Immunoglobulins.

PATHOLOGY

Polyarteritis Nodosa-like Disease in Outbred Mice

Helyer and Howie[1] described a disease of *NZB/BL* × *NZY/BL* and *NZB/BL* × *NZW/BL* F_1 hybrid mice closely resembling human systemic lupus erythematosus (SLE) in renal histology. A breeding nucleus of these mice was provided by Drs. F. and M. Bielschowsky and Dr. Howie, to allow confirmation of their histological findings. Similar lesions were found in *NZB/BL* mice, although the age of onset is later than in the *B* × *W* hybrids. Outbred albino Palmerston North (*PN*) mice, initially intended as controls, showed renal and arterial lesions more closely resembling human polyarteritis nodosa than SLE. A comparison of the two types of lesion is summarized in Table 1. Spontaneous arteritic lesions have been described in rats by Skold[2] and in mink by Leader[3]. Deringer[4] has described arteritis of the ovarian and small bowel arteries in *BL/De* mice, but generalized spontaneous arteritis in mice does not appear to have been described previously.

The *PN* mice were bred in a small colony at the Palmerston North Hospital for 10 years, then used to

Table 1. COMPARISON OF RENAL CHANGES IN MICE OF *PN* AND *NZB/BL* STRAINS

		Arterial fibrinoid	Perivascular cells	Tubular dilatation and/or casts	Glomerular change
All renal lesions	*PN*	17	21	16	18
	NZB/BL	1	16	11	22
Minimal lesions excluded	*PN*	11	15	14	13
	NZB/BL	1	4	7	20

Twenty-two *PN* and twenty-two *NZB/BL* mice of comparable age and sex were used. All show either glomerular change or arterial fibrinoid.

establish a specific pathogen-free colony by Glaxo Laboratories, Ltd. We are indebted to this firm for providing mice retired from intensive breeding at approximately 6 months of age. Of 169 mice under investigation, 90 mice have been examined *post-mortem*, and 28 of these show lesions. Three of the latter were found dead and three were killed prematurely. The remainder were killed when they became ill. The group is not homogeneous in that there were only 45 males and some were selected for albuminuria from a larger group at 6 months of age.

Seventeen animals showed renal changes of moderate or marked degree, and five showed minimal changes. The renal tubules were dilated and in most cases contain casts. The glomerular affection was less severe than in the *NZB/BL* mice, wire loop lesions being clearly shown in only three *PN* mice but in the majority of *NZB/BL* mice. Marked perivascular cuffing with lymphocytes and plasma cells occurred in both groups of mice. Arterial fibrinoid necrosis, often localized to a segment of the artery, was seen in most of the affected *PN* kidneys. Eleven of these, and three additional mice, showed arteritis of other vessels often of a more acute type with polymorphonuclear and eosinophil infiltration. Coronary arteritis with myocardial scarring occurred in three mice. The splenic arterioles were involved in five cases, and the carotid, femoral, salivary, lymph node, and small bowel arteries were affected in two cases each. Fibrinoid change with loss of elastic tissue and localized aneurysm formation was seen in the ascending aorta in three animals and another died of a ruptured aneurysm of the abdominal aorta. This lesion was seen in only one *NZB/BL* mouse, which was not one of the comparison sample. Arteritis of medium-sized vessels was rarely encountered in *NZB/BL* and *B* × *W* hybrids. The fibrinoid in arterial lesions and glomeruli resembled that of human periarteritis and Aleutian disease of mink[3] in that it stained red with picro-Mallory, pink with periodic acid–Schiff and green with fluorescent antiglobulin. Pyronine staining was weak except in the glomerular loop lesions. Staining with the Feulgen reagent was negative. The arterial lesion stained faintly with alcian blue. Thioflavine *T* did not stain, except in two animals with amyloidosis as well as arteritis. Five of forty-eight animals without arteritic lesions showed amyloidosis. No lesions were seen in mice killed at 6–12 months after neonatal injection with a cell-free saline extract of kidney from *NZB/BL* mice affected by SLE-like disease. One *PN* mouse developed lesions at 9 months, but the majority developed lesions later, nine of forty-one at 9–12 months, and six of twenty-nine at 12–15 months. Adequate sections of the thymus were available in forty mice. Germinal centres[5] were clearly discernible in four out of ten with arteritic lesions, and in one of thirty without. None of the eleven mice with lymphoma showed arteritis. This does not appear to be a result of earlier death from this lesion. The numbers are too small to comment on these findings or on the relationship to inter-current disease. Homogeneous antinuclear staining previously described in outbred mice by Norins and Holmes[6] and in an inbred strain by Friou and Teague[7] did not show a clear correlation with arteritis. Positive staining occurred in six of sixteen affected mice and in four of forty-four others. Two other mice with renal lesions showed transient nucleolar fluorescent staining. *LE* cells were not found in any of forty-four *PN* mice. One animal with leukaemia had the only positive Coombs test of sixty-one terminal sera examined.

The degree of the differences between the lesions of the *PN* mice and the *NZB/BL* mice makes it probable that they are separate but closely related conditions, one resembling polyarteritis nodosa and the other human systemic lupus erythematosus. This provides a further spontaneous animal model for the investigation of this group of diseases.

This work was supported by grants from the U.S. National Institutes of Health, the Arthritis and Rheumatism Council, Great Britain, and the Palmerston North Medical Research Foundation.

PHYSIOLOGY

Serum Cholesterol Levels in Alloxan Diabetic Rats after Loading with Various Alimentary Fats

IT has been shown[1] that large amounts of lard taken orally for several days raised the serum cholesterol levels of alloxan diabetic rats above 300 mg per cent, whereas those of normal rats after the same loading remained at about 100 mg per cent.

It is well known that dietary fats, especially those of vegetable origin, affect the serum cholesterol content. Russell *et al.*[2] demonstrated that 28 days of a diet containing 30 per cent lard produced a marked elevation of the serum cholesterol in alloxan diabetic rats. A 30 per cent corn oil diet, however, had no effect.

The purpose of the investigation reported here was to investigate the effect of a brief excessive load of vegetable fat on the serum cholesterol content of alloxan diabetic rats. We used coconut oil, which is rich in saturated fatty acids, and sunflower oil, known for its relatively high content of unsaturated fatty acids.

The experiment was carried out with male Wistar rats 8–12 weeks after a subcutaneous injection of alloxan. Only the rats with blood ketone body levels above 10 mg per cent 3 days after injection, and excreting more than 5 g glucose within 24 h 6 weeks later, were used as diabetics. The techniques and methods were as described previously[1]. The fat loading of the alloxan diabetic and the control normal rats was carried out as follows: on the first day the rats received five doses of coconut oil or sunflower oil (0·5 ml./100 g body-weight) through stomach tubes. On the second day they received the same oils in five doses each of 1 ml./100 g body-weight. 15 h after the last feeding they were bled and the serum cholesterol content was determined using the micro-

Table 1. SERUM CHOLESTEROL LEVELS IN NORMAL AND DIABETIC RATS (mg/100 ml.)

	Normal	Diabetic	*P* value*
No fat loading	99 ± 3·7 (12)†	97 ± 3·4 (16)	—
Coconut oil	150 ± 4·4 (5)	285 ± 20·0 (7)	< 0·01
Sunflower oil	95 ± 7·0 (7)	334 ± 37·0 (7)	< 0·01

* Results of Student's "*t*" test.
† Numbers in parentheses represent the number of animals in each group.

method of Rappaport and Eichhorn[3]. During the course of the investigation it was found that the normal rats did not tolerate loading with coconut oil; one third of them died. The average values and their standard deviations of the serum cholesterol levels for all groups of rats are given in Table 1.

Table 1 shows that only coconut oil elevated the serum cholesterol levels of normal rats. In the alloxan diabetic rats, however, both vegetable oils caused the same striking rise of serum cholesterol as had the lard in the previous investigation. These findings seem to be in accordance with the theory based on the work of Brady and Gurin[4] that the diabetic liver cannot convert acetate to long-chain fatty acids, but can synthesize cholesterol at the usual rate. On the other hand, impairment of cholesterin synthesis has recently been reported in alloxan diabetic animals[5,6].

The fact that we could produce a threefold increase of the serum cholesterol content of alloxan diabetic rats within 60 h with various alimentary fats shows that in the diabetic animals it is possible to metabolize the two-carbon fragments broken down from the alimentary fats through an elevated synthesis of cholesterol.

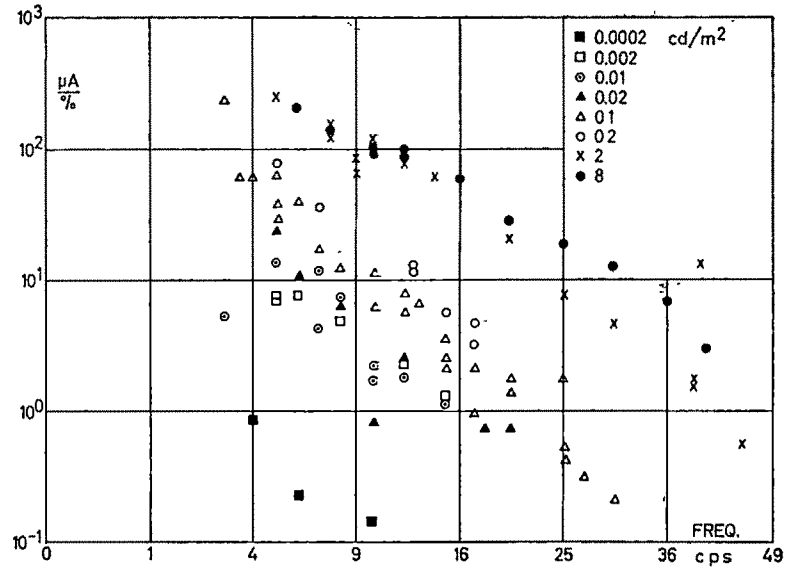

Fig. 2. Attenuation of foremost human visual mechanisms. Same conditions as Fig. 1. Ordinate shows current amplitude divided by corresponding modulation depth of light on a logarithmic scale. Frequency scale is parabolic

Electro-optical Interaction in the Retina

WE have advocated[1,2] the use of combined electrical and optical stimulation of the human eye as a research tool, and have discussed[3] some experimental results obtained by Brindley[4] with this method. This article amplifies some of our previous[2] experimental results.

In a series of experiments, we measured the angles $\varphi + \pi$ between modulated lights $L(t) = L_0(1 + M \sin \omega t)$ and currents $i(t) = i_0 \sin(\omega t - \varphi - \pi)$ applied to the eye simultaneously, which yield minimal total flicker perception. These angles were measured as a function of the frequency $\omega/2\pi$ over a wider range of brightnesses L_0 than before[2].

We checked once more[2] that the value φ obtained in this way does represent the phase angle by which L must lead i for maximal total flicker perception and thus probably is the phase shift applied to the light-signal by the foremost part, or parts[4], of the human visual system. It turns out that φ is independent of i_0 and M at fixed L_0. Experimental photopic and scotopic results are presented in Fig. 1.

It should be noted that, although in all runs the light stimulus was presented on a 40° test field, actual photopic measurements bear on a few degrees in the centre of the field. Scotopic phase shifts bear on the periphery of the test field, where the electrical phosphene is much more conspicuous at these levels of adaptation.

These data, which were obtained using only one subject and with pinkish light from a 1*B*59 tube, should illustrate, nevertheless, the general behaviour. An artificial pupil was not used.

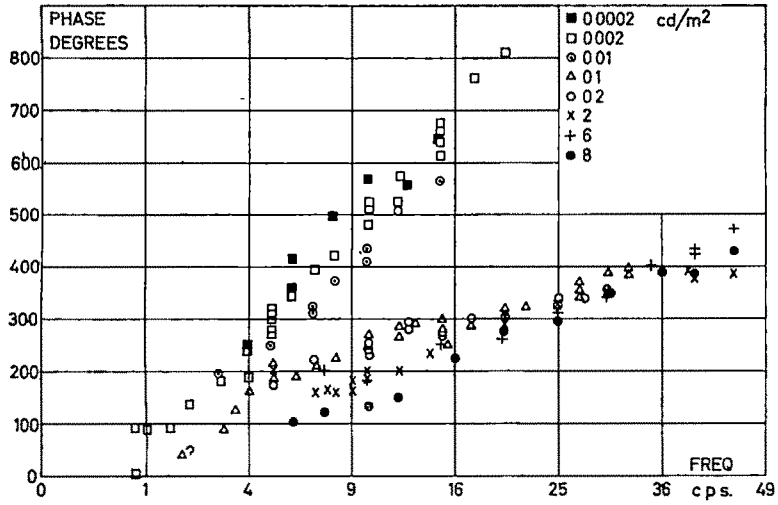

Fig. 1. Phase shift of foremost human visual mechanisms. Subject F.V., left (leading) eye; optical test field 40°, pinkish light from 1*B*59 glow modulator tube. No artificial pupil. Frequencies are plotted on a parabolic scale

In the same series of experiments, the current amplitudes were set for optimal cancelling of light-induced and current-induced flicker by means of a procedure which we described earlier[2]. Session-to-session variability of these settings prevented a definition of the curves shown in Fig. 2 better than about 0·3 log unit.

A considerable low pass behaviour of the amplitude-versus-frequency curves occurs at all levels of brightness, as would be expected from the phase measurements (but we prefer to postpone a detailed discussion of this property for the time being).

It is certain, however, that the amplitudes obtained are not nearly proportional to the prevailing brightness L_0. On the other hand, strict proportionality between i_0 and M at fixed L_0 exists; the proportionality constant, i_0/M, depends only slightly on the brightness; it fluctuates from one half-hour session to the next. In the experimental series described here, at least 10 min of adaptation elapsed before any measurements

were made. This was necessary because of the slow adaptational changes exhibited by the threshold for the electrical phosphene[5,6].

The 1*B*59 light source was used in a feedback circuit described earlier. As no mydriasis or artificial pupil was used, our data at low frequencies and medium brightnesses may be slightly influenced by pupillary movements.

A current source of at least 120,000Ω internal impedance injected current up to 0·5 m.amp root mean square by way of a 10 cm² ring-electrode placed over the upper and lower left eyelids of the subject. A large electrode on the right arm was connected to earth. The right eye was tightly closed. Zero phase angle in the foregoing means that maximum light flux and positiveness of the eye-electrode occur at the same time.

The family of photopic curves probably represents some average activity of the three kinds of cone receptors recently[7] demonstrated. Whether or not this curve can be split up by using differently coloured or monochromatic light, to show the relative phase shifts demonstrated by de Lange[8] and Walraven[9] in flickerphotometry, will have to be examined later.

Interference of Injected Tetra-*n*-Propylammonium Bromide with Outward Sodium Ion Current in Squid Giant Axons

IT was demonstrated recently[1] that tetraethylammonium (TEA^+) chloride affects the potassium permeability of a squid giant axon in a very interesting way. After TEA^+ is injected into the axon to an axoplasmic concentration of about 40 mM, membrane resistance to outward K^+ current is unusually high, while resistance to inward current remains about normal; that is, after injection the K^+ permeable membrane has the property of "anomalous rectification". This was interpreted to mean that TEA^+ ions enter the membrane from the axoplasm and stop up the K^+ channels unless the channels are swept clear of TEA^+ by inrushing K^+ ions. While testing other quaternary ammonium salts for this property, it was found that tetra-*n*-propylammonium ($Tn\text{-}PA^+$) bromide affected in this way not only the K^+ current but also the Na^+ current.

The experiments reported here were performed on giant axons of the Chilean squid *Dosidicus gigas*, and the techniques and artificial sea-water used were similar to those previously described[1].

In Fig. 1 are plotted current-voltage curves of the membrane, taken during the period of high Na^+ permeability by the method indicated in the inset: the membrane was depolarized to 10 mV to increase the Na^+ permeability, and a second voltage step was applied at the peak of the Na^+ current transient so obtained. Current was measured immediately after the second step. $Tn\text{-}PA^+$ at an axoplasmic concentration of 8 mM causes marked rectification of the current, while TEA^+ at the same concentration does not affect it (Fig. 1). Control curves similar to that shown (preceding which nothing was injected) were recorded after injection of both potassium chloride and potassium bromide in sufficient quantity to raise the axoplasmic K^+ concentration by 10 mM or more. Fig. 2*a* shows the currents produced by longer depolarizing steps, at an axoplasmic $Tn\text{-}PA^+$ concentration of 10 mM. The first peak in the curves is the Na^+ current, while later current is K^+. In the depolarization to 90 mV, which is beyond the Na^+ equilibrium potential, changes can be seen in both the Na^+ and the K^+ current. When the trace first reappears, the current (Na^+) is decreasing in magnitude rather than increasing as it does in the control curve (Fig. 2*b*). This implies that the rectification of Na^+ current after a voltage step is not established instantaneously, and that we observe here its time course. The K^+ current displays a hump resembling that produced by 2·4 mM TEA^+ (Fig. 2*b*): the K^+ current increases, decreases, then increases slowly.

These results raise two questions: what properties of these quaternary ammonium ions cause them to compete with Na^+ and K^+ for the current channels, and why do they stop up the channels instead of simply passing through? The most obvious answer to the first question is that these two ions, in solution, may be similar in size

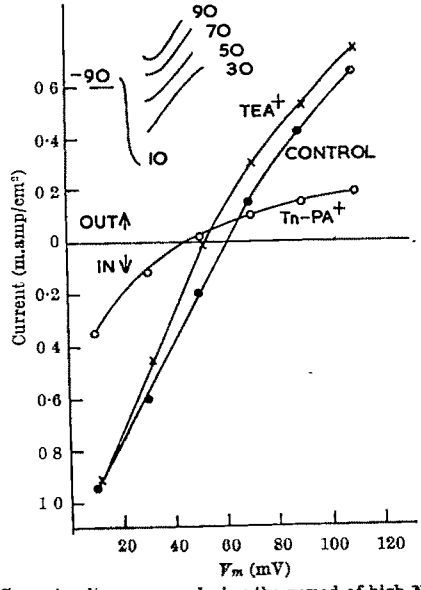

Fig. 1 Current-voltage curves during the period of high Na^+ permeability, taken by the method shown in the inset. Numbers in the inset give membrane potential (V_m). $Tn\text{-}PA^+$ had this effect only when injected into the axon

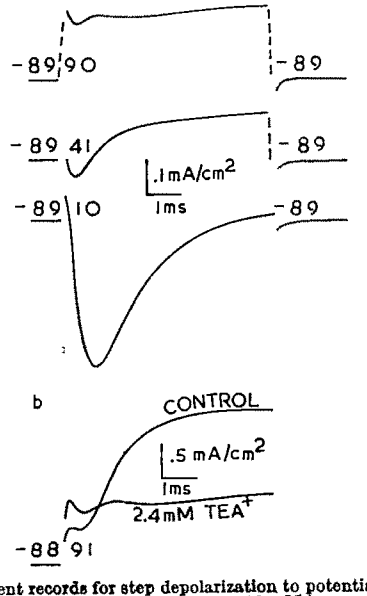

Fig. 2. Current records for step depolarization to potential given (mV). Axoplasmic $Tn\text{-}PA^+$ was 10 mM in *a*

to hydrated Na^+ or K^+ as the case may be. In crystals, at least, the sizes of the ions can be compared easily. In $KAl(SO_4)_2.12H_2O$ the K^+ ion is surrounded by six water molecules at a distance from K^+ to oxygen of 2·94 Å (ref. 2) (all distances will be centre-to-centre distances). The distance to the centre of the entire water molecule is perhaps 3 Å. Adding to this 1·45 Å, which is half the distance between water molecules in pure water, the maximum radius of the K^+ ion with one hydration shell is about 4·45 Å. This is similar to the maximum radius of TEA^+ in crystalline tetraethylammonium iodide[3], which is 4·6 Å if the radius of the terminal $—CH_3$ group is taken as the van der Waals radius of 2 Å (ref. 4). TEA^+ (and also Tn-PA^+) probably does not have a hydration shell in solution[5], so nothing more need be added to the 4·6 Å. The fact that the larger Tn-PA^+ ion (5·9 Å by the same calculation, with arms fully extended[6]) interferes with the Na^+ current suggests that in solution Na^+ may be more hydrated than K^+. In $NaAl(SO_4)_2.12H_2O$ the Na^+ ion is surrounded by six water molecules at a distance of about 2·5 Å (ref. 2). In solution, the first hydration shell may be more complete, since it is sterically possible to fit in more than six water molecules. A second layer added to a closely packed first layer (that is, with water molecules 2·9 Å apart) would be at a distance of about 4·2 Å from the Na^+, making the maximum radius about 5·65 Å. These radii must not be taken too seriously, but they do suggest that in solution the hydrated K^+ ion is similar in size to TEA^+, and the hydrated Na^+ similar to Tn-PA^+. Tn-PA^+ perhaps competes with K^+ when its hydrocarbon arms are not fully extended. The reason why TEA^+ and Tn-PA^+ stop up the channels is less apparent. These ions are less radially symmetrical than Na^+ and K^+, and this may allow them to approach more closely and thus bind more tightly to a (hypothetical) negatively charged group in the membrane. The fact that both TEA^+ and Tn-PA^+ are effective only when inside the axon indicates a difference between the inside and the outside of the membrane.

Fortified with this evidence that the K^+ ion in solution has one hydration shell while the Na^+ ion has two (a view that is widespread but not conclusive), it is easy to proceed to a simple theory of the cation selectivity of the membrane. In Fig. 3 the large circle represents a site selective for Na^+. The site has a negative charge, but its precise character is unimportant so long as it is a good fit for a hydrated Na^+ ion and its circumference is rigidly fixed. Entry of a hydrated K^+ ion (medium size circle) would only partially fill the site, leaving an appreciable space. Water molecules, the smallest available molecules, could not fit, and the space would remain empty, even though its total volume was equal to that of a number of water molecules. Creation of such a space would require a great deal of energy, for to make a hole the size of a single water molecule in an aqueous solution requires as much energy as the transport of a water molecule from the aqueous to the vapour phase. Still more energy would be required to lower the dielectric constant of the space[7]. The large energy barrier resulting from these two factors would prevent the entry of the K^+ ion. The hydrated Na^+, on the other hand, would be too large to enter a K^+ selective site, which would be similar to the Na^+ site but smaller. This selectivity hypothesis does not depend on the exact value of the radii used here, which are not likely to be absolutely correct.

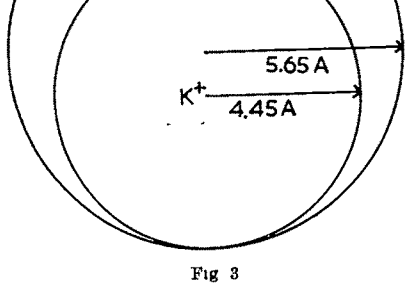

Fig 3

I thank my wife for dissecting the axons used, all members of the Biophysics Laboratory for help and discussion, and the Estación de Biologia Marina for facilities.

PSYCHOLOGY

A Two-hour Reading Course

IT seems likely that the improvements brought about by reading efficiency courses are largely due to such factors as increased concentration rather than the training of eye movements or 'perceptual skills'[1,2]. It has been suggested[3,4] that increasing one's concentration while reading, or 'reading more actively' (a term frequently used by instructors), results in an increasing use of the redundancy of the passage being read, making the immediate stimulus more easy to recognize and process further.

To test the practical implications of such a hypothesis a single session reading course was designed to include the following features:

(1) An initial 450-word passage followed by a comprehension test consisting of ten simple open-ended questions.

(2) Short lectures on bad reading habits: (*a*) inadequate concentration; (*b*) vocalization or sub-vocalization; (*c*) unnecessary regressions.

(3) Reading a short selection of statistical approximations to English (first, third and sixth orders) to illustrate the existence of constraint in the language without reference to meaning.

(4) An illustration of the effects of context on word recognition. This was accomplished by flashing several words on a screen, initially in isolation then with a context sentence which predicted it to a small degree, finally with a context sentence which predicted the word to a high degree. The exposure time and contrast were chosen so that about a third of the students saw the word on the first exposure, a further third on the second exposure and nearly all when the word was briefly exposed with a strong context.

(5) Illustrations of the notion of backwards redundancy on the level of both words and ideas, indicating to what extent regressions may be unnecessary.

(6) Five 3-min sessions of silent reading of a 'Pelican' or similar non-fiction volume, during which students were expected to keep in mind what they had just been told.

(7) A final passage for reading with a comprehension test.

The whole procedure lasted just less than 2 h, and there were interspersed frequent statements of the type "You *can* all improve your reading efficiency" and similar exhortations and encouragements.

Table 1

	Sub-group 1 ($n=36$)		Sub-group 2 ($n=26$)	
	Initial test—*A*	Final test—*B*	Initial test—*B*	Final test—*A*
Mean efficiency	211	243	161	242
Mean efficiency	211	252	158	252
Mean improvement	33 per cent		80 per cent	
Median improvement	19 per cent		45 per cent	
Wilcoxon T	140		11	
	($P<0.002$)		($P<0.0001$)	

Note: The word 'efficiency' is defined as the product of speed of reading in words per minute and the fractional comprehension.

The students were personnel on a U.S. Air Force base; three lectures have been given, with a total of sixty-two students. Two passages, *A* and *B*, were used, some of the students reading *A* initially and *B* finally and the rest vice versa. The time for reading was taken by the students to the nearest 5 sec and the reading efficiency was calculated as the product of the speed of reading in words per min and the fractional comprehension score. The results are shown in Table 1.

It is clear that the group as a whole improved its reading efficiency in the 2 h. The best estimate of the average improvement is about 30 per cent, one student improving by 500 per cent and fifteen students performing less well on the final test than on the initial test. The mean group improvement found on commercial courses, which take from 15 to 27 h, is about 50 per cent.

Three points must be made about the present course. First, the course was held in the evening following a full day's work for the students, and the course itself was reportedly exhausting. Accordingly, the final scores might be artificially low. Secondly, as opposed to this, the only real test of a course of this kind is the long-term effect. It is likely that many of the students in the absence of further encouragement will not maintain their improved performance. Thirdly, the course makes no direct attempt to extend the students' capacity, merely to show them what kinds of relevant knowledge they already have. For some of the people, for example, an extensive vocabulary training would be necessary. This was pointed out to the classes, as were a few fairly obvious "reading techniques" such as the advantages of reading the summary of a book before tackling the main body, and the different strategies which one might use when reading material for specific purposes; but for some people more detail of this kind would be necessary. It was clear, however, that many of the students had never realized that language was redundant, nor that they need not read every word of a text. In some cases a short course of this kind could be as effective as a longer one.

When Recognition is No Better than Recall

RECENT findings have thrown doubt on the validity of the generalization that it is easier to recognize than to recall. Davis *et al.*[1], using a list of fifteen two-digit numbers as stimuli, found that if all ninety possible numbers are presented in a recognition test, performance is no better than recall when both are tested immediately after the presentation.

I have made a similar comparison of recognition and recall using a list of English counties as stimuli. (This research was carried out before the recent boundary changes.) Counties preserve the advantage numbers have of being a clearly defined, limited, and enumerable category, but whereas all subjects can generate all ninety two-digit numbers at will, they are not able to list all the counties.

Table 1. MEAN RECALL AND RECOGNITION SCORES FOR COUNTIES

Stimuli	Recall	Recognition
Commonly named	5·45	5·27
Rarely named	3·86	5·27
Average	4·65	5 27

The experiment was carried out in two stages. In the first, response availability was examined. Eighty-six young newly-enlisted men, tested in groups of 10–20, were asked to write down the names of all the English counties. Ten minutes were allowed, by which time all had stopped writing. A mean number of 19·99 out of a possible 40 were listed (*S.D.*, 5·45). The frequency with which any particular name was listed ranged from 93 per cent of subjects (Hampshire) to 9 per cent (Huntingdonshire).

In the second stage, two lists of counties were selected as stimuli for memory experiments in which free-recall and recognition measures were compared. One list consisted of the six most frequently named counties. The other consisted of the six least frequently named ones. To lengthen the lists of stimuli sufficiently to exceed the memory span and thus induce some errors, six additional counties from the middle of the response-availability range were added, three at the beginning and three at the end. The same six buffer items were used with both lists and they were not counted when assessing performance.

The stimuli were printed on large cards and were presented one at a time with a 5-sec exposure and a 1-sec interval between items. Memory was tested immediately after presentation. Alternate members of each group were required to recognize the stimuli from a list of all forty counties typed in random order, while the remainder had a blank sheet of paper on which they had to write out the twelve they had seen in any order. Three minutes were allowed for this test. Three groups of fresh subjects were tested with each list, the order of presentation of the critical stimuli being varied each time. Altogether, twenty-two subjects were tested under each condition.

The mean performance on the critical stimuli is shown in Table 1. It can be seen that although recognition is markedly better than recall for the rarely named counties and is better overall, with the commonly named counties recall is slightly superior.

Similar tests have been carried out with a 40-min delay between presentation and test, during which time the subjects were kept busy with other, unrelated, experimental tasks. With the commonly named counties the mean performance on recognition was 5·07 (fifteen subjects), while that on recall was 4·31 (sixteen subjects). The superiority of recognition under this condition was statistically significant ($P < 0.02$). With two-digit numbers, however, introduction of the delay did not lead to significant advantage for recognition. The relevant scores were: recognition, 8·07 (forty subjects); recall, 7·85 (forty subjects) $P > 0.25$.

The picture is thus rather complex, but it would appear that on immediate test recognition is no better than recall for readily available responses. A fuller account of these experiments and their implications will appear elsewhere.

Vertical Sinusoidal Vibration as a Psychological Stress

MOST modern vehicles move, by design or accident, to some extent in all six theoretical axes (movement along and rotation around the three orthogonal axes, fore-aft, side-side, and up-down). Whole-body vibration is likely to be applied to human occupants most frequently and with greatest power in the vertical (seat to head) direction,

however[1]. Investigations of major physiological and psychological effects of vertical vibration have, in addition, usually used sine-wave forcing functions as a necessary research convenience[2].

Reviews of vertical sinusoidal vibration effects[1-4] related to psychomotor performance generally report two areas of impairment; fine motor control and vision. Both effects derive from body resonance phenomena, which are primarily dependent on frequency. For example, vertical oscillation at about 5 c/s produces a marked resonance of shoulder-girdle and abdominal contents, which in turn means that manual dexterity is degraded, and unpredictable relative motions obtain between the eye and the visual target. These are examples of the specific effects of vibration stress.

Non-specific stressor action, resulting in experimentally demonstrable impairment of mental function, has only rarely been reported for vibration. Theoretically[5,6] man has a finite capacity for handling information, and if some of this is devoted to persistent anxiety about his organic integrity it should be possible to show that a limited capacity remains for carrying out tasks. Two experiments are reported which set out to test this hypothesis[7].

The psychological task chosen combines mental arithmetic and immediate memory. Subjects have a list of digits read out to them, and are required to give the sum of the last two digits presented. As an example, the series 5 . . 7 . . 3 . . 11 . . 8 has solutions 12 . . 10 . . 14 . . 19. The task thus involves storing one item from an operation while performing that operation. Interpolated items of this type are known to accelerate the normal decay of immediate memory[8].

In the first experiment, five adult male subjects were exposed to vertical sinusoidal vibration at 4·8 and 6·7 c/s, at an acceleration-amplitude of 0·5 *g* applied to the seat, for two 15-min exposures at each frequency. Two sets of digit lists were prepared, using the numbers 1–5 (four problems) and 4–20 (sixteen problems) in random order. Possible learning or adaptation effects were reduced by arranging the vibration conditions and digit lists in a different random combination for each subject. The presentation of and response to the tasks were tape-recorded, and two measures of performance derived. The first, the time taken to complete a list, included the total time the subject used in computation; the time which the experimenter spent in reading out digits was subtracted. The second measure was the total number of addition errors made. A final index of performance, indicating the time spent achieving each correct addition, was derived from these two measures. An analysis of variance of these results demonstrated that performance on the sixteen-problem lists was adversely affected by vibration at either frequency, compared with performance when stationary. There was no difference between the conditions at 4·8 and 6·7 c/s, even though the former is by general agreement the more uncomfortable in terms of body transmissibility. The four-problem list is considered to have been too easy to be sensitive to stress effects.

In the second experiment, eight adult males who were then military jet pilots were experimented on. They were exposed to the same vibration conditions, but for two 10-min exposures only at each frequency. Two new sets of digit lists were constructed, using the numbers 1–10 (nine problems) and 5–30 (twenty-five problems). Eight subjects allowed possible order effects to be balanced out over the total experimental design, a procedure which has some advantages over randomization. Identical measures of performance were used to derive the metric time utilized per correct response. Analysis of variance showed that vibration had impaired performance of the nine-problem list, but not of the twenty-five-problem list, which was judged to have been too difficult relative to the learning opportunity available. Again, the conditions at 4·8 and 6·7 c/s did not give rise to significantly different impairments.

Table 1

Time spent on each correct solution (secs)		Hypothetically increasing stress level → Static	0·5*g* at 6·7 c/s	0·5*g* at 4·8 c/s
Hypothetically increasing task difficulty ↑	Digits 5–30	2·7	2·7	2·7
	Digits 4–20	2·1	2·3	2·4
	Digits 1–10	1·3	1·4	1·5
	Digits 1–5	1·2	1·4	1·6

Table 1 presents means for these data. Although these cannot be tested statistically (because of different subject populations and experimental treatments) this table does lend support to the theory, partially confirmed elsewhere[5,6], that stress level and task difficulty operate synergistically to diminish human information processing ability at higher levels.

AGRICULTURE

Bract Pigmentation in Bananas

SIMMONDS[1] investigated the pigmentation of the bracts of wild banana species and edible cultivars. Of the two wild species from which the Eumusa series of edible bananas are derived[2] *Musa acuminata* was found to contain a mixture of delphinidin, petunidin, malvidin, cyanidin, and peonidin, that is, both cyanidin, delphinidin and their methylated derivatives, whereas *Musa balbisiana* contained only a mixture of delphinidin and cyanidin. Methylated anthocyanidins were absent. The bracts of edible bananas were found to have "broadly, the pigments expected on taxonomic and genetic grounds but show an (unexplained) tendency towards a generally lower level of methylation of the anthocyanidins"[1]. That is to say, some cultivars clearly derived from *M. acuminata* nevertheless only contained non-methylated anthocyanidins. At the time of the 1954 investigation the various geographical subspecies of *Musca acuminata*[3] were not yet clearly defined and little material from Melanesia was available. We now have available in Honduras a much larger *Musa* collection[4] of which 526 accessions of *Musa acuminata*, *Musa balbisiana*, and their cultivars having bracts pigmented with anthocyanin have been examined.

The methods of extraction, hydrolysis, and paper chromatographic separation were as described by Simmonds[1].

The results with the wild species are summarized in Table 1.

Clones in which the anthocyanidins are not methylated are found not only in *M. balbisiana*, but also in the *banksii* (New Guinea) and *errans* (Philippine) geographical subspecies of *M. acuminata*. The lack of methylation is not, therefore, confined to *M. balbisiana* as Simmonds believed.

Table 1. ANTHOCYANIDINS IN *Musa acuminata* AND *Musa balbisiana*

Species or sub-species	No. of accessions tested	No. containing only cyanidin-delphinidin	No. also containing methylated anthocyanidins
M. acuminata burmanica	3	0	3
M. acuminata siamea	6	0	6
M. acuminata truncata	6	0	6
M. acuminata zebrina	6	0	6
M. acuminata microcarpa	7	0	7
M. acuminata malaccensis	19	0	19
M. acuminata errans	4	1	3
M. acuminata banksii	15	9	6
M. balbisiana	14	14	0
Totals	80	24	56

Table 2. ANTHOCYANIDINS IN THE BRACTS OF *M. acuminata* EDIBLE CULTIVARS (353 ACCESSIONS)

Presumed derivation of cultivars*	Diploid		Triploid		Total	
	U†	*M*†	*U*	*M*	*U*	*M*
siamea	0	1	0	11	0	12
zebrina	0	16	6	29	6	45
microcarpa	31	37	0	5	31	42
malaccensis	1	15	51	53	52	68
errans	1	8	11	0	12	8
banksii	22	22	6	27	28	49
Totals	55	99	74	125	129	224

* D. L. Richardson (unpublished work)
† *U*, Number of accessions with only cyanidin and delphinidin. *M*, Number of accessions also containing methylated anthocyanidins.

This makes it less surprising to find cultivars derived from *M. acuminata* cultivars lacking in methylated anthocyanidins which, as Table 2 shows, are relatively common.

Half of the diploid cultivars derived from *banksii* have bracts which contain only non-methylated anthocyanidins. This is not unexpected, as a similar distribution is found in the wild sub-species. It is, however, unexpected to find so many cultivars of microcarpa derivation which do not contain methylated anthocyanidins. These include such common edible bananas as 'Eda-an' and 'Pisang jari buaya'.

Triploid acuminata cultivars lacking methylated anthocyanidins are also common. These are not confined only to the Cavendish group as believed by Simmonds[1], but also include 'Pisang susu' in the *malaccensis* group and the Philippine Lacatans among others.

In agreement with Simmonds[1] it was found that among these accessions derived from both *M. acuminata* (*AA*) and *M. balbisiana* (*BB*) the *AB* diploids (three tested) contained methylated anthocyanidins, the *AAB* triploids were mixed (thirty-one *U*, sixteen *M*), and the *ABB* triploids (thirty-seven tested) contained only unmethylated pigments.

Of the naturally occurring tetraploids[4], Atan (*AAAB*, two accessions) and Kalamagol (*AABB*, two accessions) contain methylated anthocyanidins, whereas Klue Teparod (*ABBB*, two accessions) contains only unmethylated pigments. A high proportion of genic contribution from *Musa balbisiana* obviously results in bracts lacking in methylated pigments as with *Musa balbisiana* itself.

Of greater importance to a banana breeding programme is hybridization within the acuminatas and bract pigmentation may be a convenient genetic marker. Accordingly, the inheritance of pigment type within *Musa acuminata* is being investigated.

Mode of Action of L-Threo-β-phenylserine as a Chemotherapeutant of Cucumber Scab

CERTAIN amino-acids, such as L-threo-β-phenylserine, have been shown to reverse the action of indoleacetic acid on root growth of cucumbers, bud development of beans and epinasty of tomatoes. It was thought that a relation might exist between the activity of such compounds as auxin antagonists and their chemotherapeutic activity against certain fungal diseases including cucumber scab[1].

Competitive inhibition of auxin action by these compounds seems less probable than an indirect effect. I have shown that after application of 0·02–0·005 M L-threo-β-phenylserine to the roots of cucumber seedlings, crude extracts of the hypocotyls and cotyledons possess higher IAA oxidase activity than extracts of untreated plants. This might explain the antiauxin activity of L-threo-β-phenylserine.

If there is a relation between the increase in IAA oxidase activity and the decrease in the IAA content of the plants on the one hand and the increase in resistance against *Cladosporium cucumerinum*[1,2] on the other hand, other substances influencing IAA oxidase activity may be expected to influence the susceptibility as well. Thus *B* 995 (*N*-dimethylamino succinamic acid) and CCC ((2-chloroethyl)trimethylammonium chloride), which produce an increase in IAA oxidase and peroxidase activity in cucumbers[3], should increase the resistance. Gibberellic acid should have an opposite effect[3,4].

The influence of these substances on the susceptibility of cucumbers for *C. cucumerinum* was investigated by applying the compounds to the roots of 7-day-old cucumber seedlings var. 'Lange Gele Tros', or by spraying twice on the green parts. The seedlings were inoculated with a suspension of spores of *C. cucumerinum* after treatment. The severity of the disease was assessed according to the rate of infection of the hypocotyls after incubation for 3–6 days at 20° C in a moist atmosphere. The disease indices given in Tables 1 and 2 have been calculated using a scale from 0 (healthy) to 4 (severely diseased).

Table 1 shows that both *B* 995 and CCC (obtained by courtesy of G. Ligtermoet and Zn.) have a protective effect. Higher concentrations caused injury, particularly to the roots. The protective effect of *B* 995 and CCC and, to a lesser extent, that of L-threo-β-phenylserine (S.A.F. Hoffmann La Roche and Co.) was reversed by simultaneously administering gibberellic acid (potassium salt, Nutritional Biochemicals Corporation). The effect of gibberellic acid alone was investigated by applying it to the roots in various concentrations and determining the disease index 3, 4 and 5 days after inoculation. Untreated plants showed the maximum index, 4, at the fifth day after inoculation, but plants treated with gibberellic acid 450, 90 and 18 p.p.m. reached this stage already after 3, respectively 4 days. Even treatment with 3·6 p.p.m. seemed to result in a somewhat faster development of disease symptoms. The increase in susceptibility caused by gibberellic acid could also be demonstrated by inoculation with a spore suspension of a concentration that would not cause maximum infection in untreated plants, but would do so in plants treated with gibberellic acid. Moreover, under our experimental conditions only seedlings inoculated 7–9 days after sowing show the typical symptoms of a heavily diseased hypocotyl, whereas in older plants the first leaf is attacked instead. After treatment with gibberellic acid, however, the hypocotyl appeared to remain susceptible for a longer time. The fact that disease symptoms appear particularly in the younger growing parts of the plant may be important in itself in this connexion, since these usually contain more IAA.

Table 2 shows that spraying with IAA also increased the susceptibility of the seedlings. This result points to a direct relation between the IAA content of the plants

Table 1. PROTECTION OF CUCUMBER SEEDLINGS AGAINST *C. cucumerinum* BY TREATMENT WITH VARIOUS SUBSTANCES AND REVERSAL OF THE EFFECT BY GIBBERELLIC ACID

	Concentration (p.p.m)	Disease index—gibberellic acid 0	Disease index—gibberellic acid 50 p.p.m
L-threo-β-phenylserine	905	0·9	1·7
"	452·5	2·4	3·8
B 995	250	0·8	3·9
"	125	2·9	4·0
CCC	250	1·8	3·8
"	125	2·7	4·0
Water		3·7	4·0

Disease index determined 5 days after inoculation.

Table 2. INCREASE IN SUSCEPTIBILITY OF CUCUMBER SEEDLINGS FOR *C. cucumerinum* CAUSED BY SPRAYING WITH INDOLEACETIC ACID AS DEMONSTRATED BY COMPARING DISEASE INDICES AT DIFFERENT TIMES AFTER INOCULATION

Concentration of indoleacetic acid (M)	Days after inoculation 4	5	6
0·001	2·9	3·6	4·0
0·0002	2·7	3·3	4·0
0·00004	2·3	3·4	3·7
0·000008	2·1	3·4	3·6
Water	1·9	2·8	3·4

and their susceptibility to *C. cucumerinum*. Thus it may be considered to support the hypothesis that the chemotherapeutic action of phenylserine is mediated through its influence on IAA oxidase activity. The activity of the enzyme *in vitro* was not influenced by adding phenylserine. This means that the increase in activity in treated plants must be effected in an indirect way. Elema[4] found that gibberellic acid in peas inhibits formation of *p*-coumaric acid, a co-factor for enzymatic IAA oxidation: addition of the compound to extracts of plants treated with gibberellic acid restored IAA oxidase activity.

It is tempting to explain the effect of phenylserine by assuming increased production of *p*-coumaric acid or other compounds acting as co-factors for IAA oxidase in treated plants.

Only preliminary experiments have so far been carried out on the mechanism of action of other chemotherapeutically active amino-acids. It seems probable that other mechanisms than interference with IAA oxidase activity may also be involved.

SOIL SCIENCE

Seleniferous Soils in Parts of England and Wales

GEOCHEMICAL reconnaissance by stream sediment sampling of 3,000 square miles in the Midlands, North Wales and South-west England disclosed extensive areas characterized by abnormally high molybdenum contents of 5–60 p.p.m. compared with normal background of < 2 p.p.m. The technique used was similar to that applied in Eire[1], and in view of the association of selenium and molybdenum in that country, a selection of the British samples was also analysed for selenium. The results showed selenium to be present in stream sediments in each of the anomalous molybdenum areas, with maximum values ranging from 3·8 to 9·0 p.p.m. selenium compared with the normal background of < 0·2 p.p.m. (Table 1).

Following up the stream sediment indications, preliminary soil samples have been collected from selected anomalous catchment areas. Sample sites were chosen on low-lying poorly drained organic soils, which Irish experience[1,4] has shown to be favourable for the accumulation of selenium and molybdenum. The analyses show that the stream sediment values are related to soils that contain moderately anomalous concentrations of these two elements rising to 7·0 p.p.m. selenium and 45 p.p.m. molybdenum (Table 2).

Table 1. RANGE AND MEAN CONTENT OF SELENIUM AND MOLYBDENUM IN STREAM SEDIMENT

Area	No. of samples	Se (p.p.m.)	Mo (p.p.m.)
North Staffordshire and Derbyshire	22	0·2–9·0	5–40
		2·8	19
Caernarvon	16	< 0·2–4·0	1–25
		1·3	13
Devon	23	0·2–3·8	5–10
		1·9	6
Normal background		< 0·2	< 2

Data refer to minus 80-mesh fraction; selenium was determined colorimetrically (ref. 2) and molybdenum spectrographically (ref. 3).

Table 2. RANGE AND MEAN CONTENT OF SELENIUM AND MOLYBDENUM IN POORLY DRAINED SOILS IN ANOMALOUS CATCHMENT AREAS

Area	No. of samples	Sample depth (in.)	Se (p.p.m.)	Mo (p.p.m.)
North Staffordshire and Derbyshire	8	12	1·5–7·0	8–45
			4·0	20
Caernarvon	4	0–6	1·7–5·0	5–20
			3·0	10
Devon	4	12	0·2–4·0	10–20
			1·5	13
Normal background			< 0·2	< 5

Data refer to minus 80-mesh fraction.

Table 3. SELENIUM AND MOLYBDENUM CONTENT OF SELECTED ROCKS FROM THE ANOMALOUS AREAS

Area	Rock-type	Se (p.p.m.)	Mo (p.p.m.)
North Staffordshire and Derbyshire	Lower Carboniferous		
	Marine shales	2–24	10–30
	Sandstone	2	15
	Limestone	0·2–1·0	< 2
Caernarvon	Ordovician		
	Dark grey slates	0·7	4
	Black pyritic slates—upper bed	4·5–6·5	9–60
	Tuff	1·3	3
	Black pyritic slates—lower bed	0·2–1·8	13–17
Devon	Culm Measures		
	Grey-black marine shales	< 0·2–3·5	< 2–15
	Pyritic shales	2·5–6·0	15–30

The principal bedrock source of the selenium and molybdenum seems to be certain marine shale facies of the Lower Carboniferous in both Staffordshire and Devon, and of the Ordovician in North Wales (Table 2).

Herbage studies have not yet been completed, as much of the work was carried out in the late autumn. Analysis of several samples of mixed grasses from the anomalous regions indicates both selenium and molybdenum contents to be well above those considered normal, and more detailed investigations will be undertaken during the present growing season.

Hypocuprosis is recognized in cattle grazing pasture in part of the molybdenum anomalous region in North Staffordshire, but has not been reported from the Devon and Caernarvon areas. Two suspected cases of chronic selenosis have been reported from Derbyshire, but not from the specific area described in this communication[5]. No animal selenium studies have been made in Devon or North Wales. Nevertheless, the geochemical data indicate the possibility of animal disorders, probably at the sub-clinical level, associated with both selenium and molybdenum in all three areas examined.

More detailed studies are being undertaken, but the preliminary results reported here are of immediate interest in that they provide the first evidence of the existence of seleniferous soils in Britain and lend support to the view that geochemical drainage surveys have potential value in detecting and delineating suspect areas where trace element imbalances may constitute an agricultural problem.

This work was supported by a special research grant from the Natural Environment Research Council and a research contract awarded through the Geological Survey and Museum.

VETERINARY SCIENCE

Transition of Developmental Stages of *Theileria parva in vitro* at High Temperature

Theileria parva is responsible for East Coast fever of cattle—a disease which is usually fatal and which is characterized by an acute thermal reaction, a lymphoid hyperplasia followed by exhaustion of the lymphoid tissues and leucopenia.

T. parva has been cultivated in its 'macroschizontal'[1] stage over several months in tissue cultures of bovine lymphocytes associated with baby hamster kidney cells[1,2]. The mode of multiplication has been investigated in these cultures and it has been shown that the parasite does not destroy its host cell, but propagates within the multiplying lymphoid cells. In established cultures the nuclear particles of *Theileria* divide at about the same rate as the host cells—the mean number of parasite particles and the percentage of infected cells remain constant. During division of the host cell, the theilerial body closely associates with the mitotic apparatus and is pulled apart and distributed to both daughter cells in late mitosis.

A similar mechanism of multiplication has been assumed for the intralymphoid stage of the disease in the animal. The lymphoid hyperplasia largely arises from mitotic division of lymphoid cells, many of which are infected with *T. parva*. Proof that this is the only way by which the number of the cells infected with *Theileria* increases in the bovine animal is still lacking. There is, however, no evidence for a new infection of lymphoid cells by disintegrated single theilerial particles. It is possible that in cattle an ideal host–parasite relationship is not established, but that the parasite finally destroys the host cell.

In the animal, in the later stages of the disease, another form of the parasite appears in some of the lymphoid cells, which consists of a large number (100 or more) of single particles—the so-called 'gamont' or 'microschizont'[1]. These particles have been assumed to infect erythrocytes. The tick host, *Rhipicephalus appendiculatus*, mainly feeds on blood and the intra-erythrocytic forms are presumed to give rise to the life-cycle in the tick.

The first form (often called the agamont or macroschizont) was cultivated for several months *in vitro* at 37° C without showing any of the microschizontal forms. When incubated at 40° C, however, occasional microschizonts appeared in most cultures.

Two strains of *T. parva* were cultivated according to Hulliger's method[2] for 122 and 233 days, respectively; these were then transferred to a waterbath adjusted to 41°–42° C. Maximum temperatures were read once a day with a clinical thermometer; these were found to range from 41·3° to 42·4° C in the first and from 40·2° to 42·2° C in the second experiment. The cells were initially incubated for 1–2 h in 100 per cent bovine serum, then transferred to normal medium which consisted of 80 per cent Eagle's medium[3], 10 per cent tryptose broth and 10 per cent serum. Normal calf serum and serum from animals in the late stages of East Coast fever were used. Supernatant fluid was taken off and smears made at intervals of 2–3 days. New medium was added on these occasions.

Cell growth. There was very little cell multiplication. A few mitoses could occasionally be seen, but multiplication was so limited that no expansion was necessary.

Appearance of microschizonts. The first microschizonts appeared on the sixth day in the first experiment and on the ninth day in the second. In both experiments, irrespective of the type of serum used, large numbers (28–36 per cent) of the parasitized cells contained microschizonts and their precursors. The cell numbers in the cultures decreased in the next few days and the numbers of macroschizonts diminished. A few microschizonts and macroschizonts could be seen over 2–4 days more, but the cells then gradually degenerated if left at the high temperature.

Morphological changes. The following sequence of events was reconstructed from the chronological appearance of the stages in these two experiments and also on rare occasions in other cultures at 40° C: (*a*) Macroschizonts with very large particle numbers (thirty or more) appeared in some of the parasitized cells (Fig. 1) while the average particle number in untreated cultures is fifteen. (*b*) After one or two days, the large macroschizonts had increased in number and, in many, the chromatin particles had become bulky (2–3μ in diameter) and densely staining. The host cells were often disrupted in smears. (*c*) Bodies morphologically similar to microschizont particles and about 1μ in diameter appeared; these were associated with the large chromatin particles of the macroschizonts. These were seen at the edge of the large particles, often in clusters. (*d*) Large agglomerations of these microschizont-like particles were evident, filling the cytoplasm of the host cells. In many, it was not possible to discern the host cell membrane. Portions of some of the bulky chromatin particles remained within most of the microschizont masses (Fig. 2).

It proved possible to produce the microschizontal stage of *T. parva* in cultures of macroschizonts. The process seemed to be associated with slower or arrested mitosis of the host cells while the theilerial particles continued to multiply without inhibition. This resulted in large parasites containing many nuclear particles which then

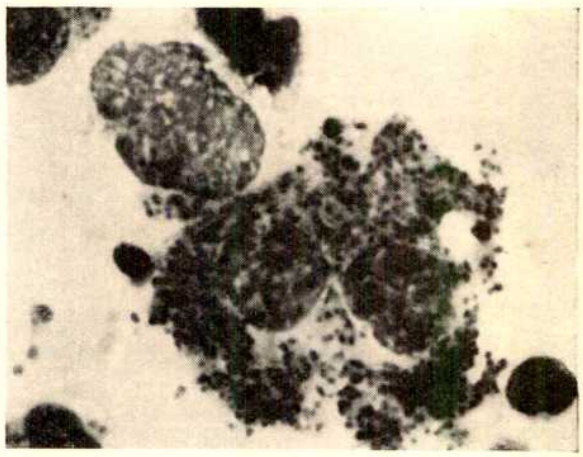

Fig. 1. Macroschizont of *T. parva* with a large number of particles. (Giemsa staining. × *c.* 1,200)

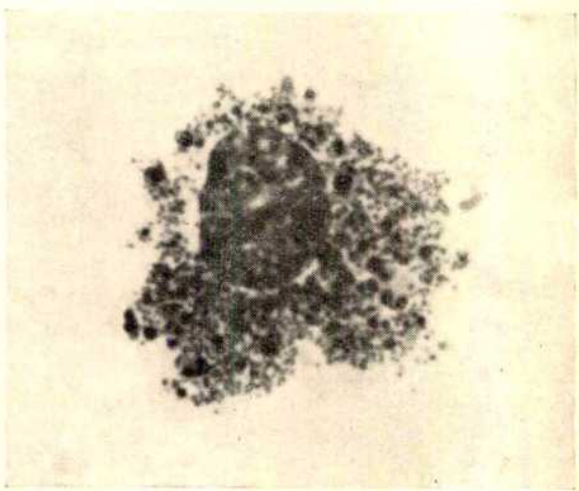

Fig. 2. Microschizont with a few large chromatin particles left. (Giemsa staining. × *c.* 1,500)

increased in size. The single microschizontal forms were produced from these large particles. Some of the large nuclear bodies often remained.

A similar process occurs in cattle, but, more often than not, nuclear division of the microschizont precursor is more complete than in cultures—less of the residual chromatin being seen.

Macroschizonts multiply by a complex process: the single nuclear particles divide by binary fission within one cytoplasmic body. The resultant multinucleated body divides into two during the mitosis of its host cell, one part going to each daughter cell. The production of microschizonts would seem to be by a process of multiple division, or by rapid successive binary divisions of nuclei and cytoplasm leading to parasites each consisting of one nuclear particle in a separate cytoplasmic envelope. The host cells then disrupt and the parasites are freed.

The part played by the high temperature is not clear. It definitely slows down multiplication of the host cell, but not of the parasite. As yet, microschizont formation has not been achieved in cultures by means other than high-temperature incubation. Partially deficient medium, varying oxygen tension and low temperature, while they slow down the rate of cellular multiplication, have failed to bring about microschizont production. The high temperature seems to be essential for the development of this stage. The disease caused by *T. parva* is characterized by high temperatures up to 42·4° C during the period of microschizont development. A reciprocal adaptation of the disease in the host and development of the parasite might therefore be considered. Temperature changes have also been suggested as a factor in the development of other protozoa[4].

The infectivity of these tissue culture microschizonts for the tick vector is at present under investigation.

We thank Miss K. Cowl, D. Mugo and K. Mugo for their technical assistance.

GENERAL

Hypothesis-testing in Classification

A RECENT paper by Williams and Lance[1] considers the place of probability in classification, and regards the concept as inapplicable where the population classified is finite. In limiting themselves to probabilities associated with sampling, however, they seem to ignore an important part which probabilistic considerations can and should play in classification.

Taxonomy is always concerned with decisions between 'splitting' and lumping'. Should two groups of individuals be placed in different classes or the same class? This is not the problem of discrimination, where classes have already been distinguished and defined; the question is whether the classes should be separated in the first instance.

The usual principles of hypothesis-testing call for a null hypothesis leading to a well-defined distribution of observational statistics. In classification problems, the most useful type of null hypothesis is generally that the individuals studied form a single class. If it is shown that this hypothesis must be rejected, progressively more complex hypotheses (of two, three or more distinct classes) may take its place until the simplest hypothesis which can be accepted at the selected significance level is found.

If the attributes on which the classification is to be based are metric, then their values in the individuals observed may be regarded as forming a sample from a continuous multivariate distribution which will usually be unimodal if the null hypothesis of a single class is true. It may often be considered appropriate to include in the null hypothesis an assumption that (possibly after transformation in some cases) the joint distribution of attribute values is multivariate normal. The parameters of this distribution can then be estimated from the observations and the hypothesis tested. Rejection will most often indicate multimodality. The distinct modes must then be identified and boundaries between them delineated in the zones of minimum frequency, in order to enable each individual to be allotted to one of the classes (modes) thus distinguished.

If the attributes are qualitative, a significance test of this sort cannot be based on a single attribute only. A suitable null hypothesis is then independence of the various attributes, which may readily be tested by contingency tables or otherwise. If the different attributes occurring in each individual are independent of one another, the whole set of individuals may be regarded as a single class in which the different attribute values are assorted at random. If, on the other hand, certain combinations of attribute values occur in preference to others, the individuals with these combinations may be regarded as constituting distinct classes.

If both quantitative and qualitative attributes occur, the foregoing tests may be applied separately to each of the two types of attribute; if the null hypothesis of a single class is still tenable, the evidence in respect of the two types can in principle be combined by comparing the multivariate distribution of values for the quantitative attributes in each cell of the contingency table representing the qualitative attributes.

The approach outlined in the preceding three paragraphs is perhaps a counsel of perfection. But approximate tests may readily be envisaged—involving, perhaps, step-by-step procedures and order statistics—and should be developed for routine application.

It may be noted that these tests of the null hypothesis are as applicable when the sets of individuals and attributes studied are completely known as when either or both are samples from an infinite set. The problem is comparable with that of testing contingency tables. The figures in a table may be complete, and not a sample of a larger population, yet nevertheless the question of independence still has meaning and a significance test is appropriate. Likewise it has meaning to ask whether attributes in a set of individuals occur independently of one another, irrespective of whether the set is or is not a sample.

Williams and Dale[2] argue that significance tests in classification are pointless because they will normally be disregarded. If the set under consideration is large, the classifier will want to divide it, whatever the results of a significance test. Whether this is a correct description of the behaviour of classifiers in most fields is questionable. In any event, the fact that a significance test may be ignored is scarcely a reason for not having one.

Significance tests of the type proposed here can serve as statistical guidance for the classifier confronted with the usual dilemma of 'splitting' versus 'lumping'. For most purposes, he will be content to accept the simplest hypothesis in accord with the facts, and the simplest hypothesis is usually one involving fewest classes. He splits only where splitting seems unavoidable. Such decisions are not served by most techniques for numerical taxonomy. They show 'how' observations may be classified, not 'whether' they should be classified. It is for this latter purpose that the similarity and deviant indices already proposed[3–6] have been designed, and for

which a complete technique of cluster analysis is in preparation.

Rapid Method for determining Numerical Indexes for Time-course Curves

IN reporting experiments with biological processes such as abscission, germination, and dormancy, where results are observed and recorded periodically, most investigators have found it convenient to present the data as time-course curves. While time-course curves such as those shown for abscission in Fig. 1 are useful in indicating the initiation and the total amount of abscission, as well as the slope of the response curves (rate), they cannot readily be compared numerically. For comparison of the results of large numbers of treatments in individual experiments, or of groups of experiments, and for statistical analyses, numerical designations are necessary. The time required for 50 or 100 per cent abscission and the percentage abscission at an arbitrary time after treatment are designations commonly used. Neither of these methods allows a satisfactory comparison of data frequently encountered in research. For example, comparison of the data represented by curves 1, 2, and 3 in Fig. 1 on the basis of the time to 50 or 100 per cent abscission is impossible as not all the curves reach either of these levels by the end of the experiment. This problem is intensified when treatments retard or inhibit abscission. Furthermore, the relationship of the curves changes with time, and thus comparison of the percentage abscission at an arbitrary time represents only a small part of the information in the curve.

The 'abscission index' described here incorporates all the attributes of a time-course curve into a single number. The data are first plotted as time-course curves on graph paper, ruled 12 by 20 units to the inch (K. and E. No. 358–21). Each side of the graph is 5 in. and the area is

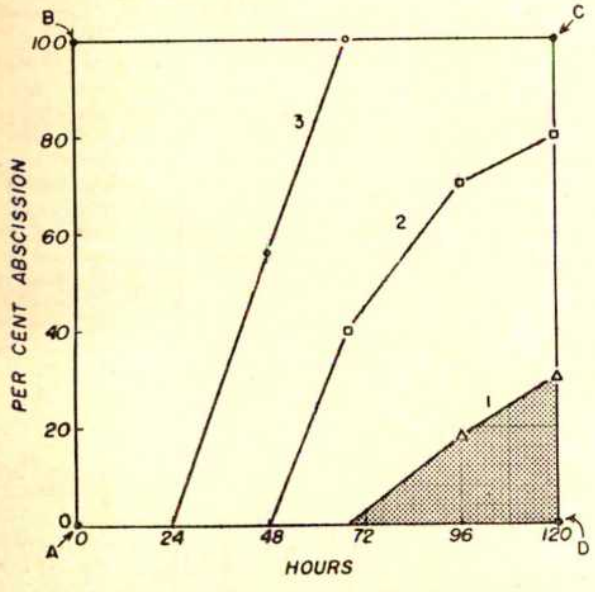

Fig. 1. Time-course curves representing abscission data

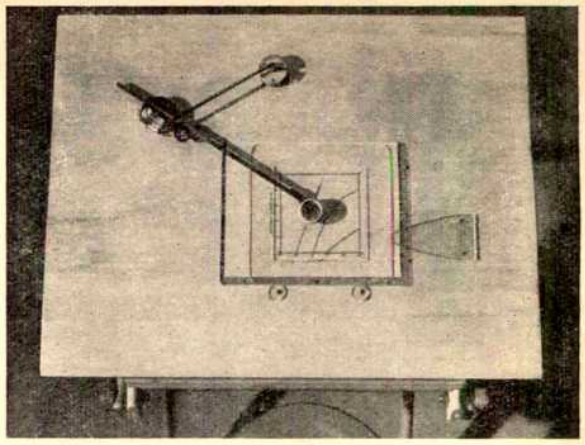

Fig. 2. Apparatus used for the precision measurement of time-course curves

25 in.^{2} (in Fig. 1, the area of the rectangle connecting points A, B, C, and D). To obtain the index, the area under each curve (for example the shaded area under line 1) is measured with an optical planimeter (Filotecnica Salmoiraghi model 236A). The tracer arm has been modified and adjusted to a position allowing the vernier scale reading to be exactly 100 when the area enclosed by lines connecting $ABCD$ is traced. Consequently, when any curve is traced, the vernier reading is the area under that curve expressed as per cent of the total area of $ABCD$. As the instrument is calibrated so that 25 in.^{2} reads 100, the areas determined can readily be converted to any other desired units. Adjustment of the length of the planimeter tracer arm enables indexes to be obtained from various sizes and shapes of graphs; such indexes can be directly compared.

Fig. 2 is a photograph of the planimeter set up on a drawing board that has been modified to make the index determinations rapid and accurate. A section $8 \times 11{\cdot}25$ in. has been removed from the centre of the board and replaced by clear 'Plexiglas' positioned over a light box. Grooves in the 'Plexiglas' allow the graph to be held in position by a vacuum produced by a small blower mounted under the board. The graph paper is positioned so that the axes are in conjunction with lines engraved on the top surface of the 'Plexiglas' inlay. An accurately machined plastic template resting against three stops serves as a guide for the lens on the end of the tracer arm. When the circumferential surface of the lens is held firmly against the inner edge of the template, the hardstone centre of the lens exactly follows the boundaries of the graph. Use of this template contributes greatly to both the speed and accuracy of the determinations.

The abscission index described is the area under a time-course curve expressed as a percentage of the area of a rectangle of which one dimension represents 100 per cent abscission and the other dimension represents the time-duration of the experiment. This index is similar in concept to that recently described by Finlay[1], but the method described here has the advantages of versatility and speed, as well as simplicity of operation. This method and the resulting indexes are adaptable to many types of biological investigations and should prove to be a valuable research tool.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, July 18—Friday, July 22

ROYAL MICROSCOPICAL SOCIETY (at Imperial College, London, S.W.7), at 10 a.m. daily—Conference on "The Role of the Microscope in Scientific Investigation".

Thursday, July 21

UNIVERSITY OF LONDON (at the Westminster Medical School, Horseferry Road, London, S.W.1), at 5.15 p.m.—Prof. J. H. Wilkinson (Pennsylvania): "Iso-Enzymes—Their Biological and Clinical Significance".*

Friday, July 22

UNIVERSITY OF LONDON (at the Royal Veterinary College, Royal College Street, London, N.W.1), at 5 p.m.—Dr. Howard A. Schneider (Chicago): "Some Nutritional Parameters in the Ecology of Infectious Disease".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

ASSISTANT (honours graduate) IN THE DEPARTMENT OF GEOGRAPHY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (July 20).

ASSISTANT LECTURER IN ZOOLOGY IN THE BIOLOGY DEPARTMENT—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (July 20).

LECTURER OR ASSISTANT LECTURER IN THE PHYSIOLOGY DEPARTMENT—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (July 20).

TUTORIAL RESEARCH FELLOW OR STUDENT IN GEOGRAPHY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (July 24).

ASSISTANT LECTURER IN SOCIAL ANTHROPOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (July 25).

HOSPITAL PHYSICIST (Senior Grade) IN THE DEPARTMENT OF PATHOLOGY, Queen Elizabeth Hospital for Children, Hackney Road, London, E.2—Group Secretary, Hackney and Queen Elizabeth Group H.M.C., Hackney Hospital, London, E.9 (July 27).

LECTURER/ASSISTANT LECTURER (with a special interest in social/urban geography) IN THE DEPARTMENT OF GEOGRAPHY—The Secretary, The University, Aberdeen (July 30).

LECTURER IN BIOCHEMISTRY—The Secretary, Royal Free Hospital School of Medicine (University of London), 8 Hunter Street, London, W.C.1 (July 30).

LECTURER/ASSISTANT LECTURER (with a good honours degree or equivalent and special qualifications in any of the following fields: (i) biogeography; (ii) meteorology; (iii) surveying and photogrammetry; (iv) cartography) IN THE DEPARTMENT OF GEOGRAPHY, University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, July 31).

LECTURER OR ASSISTANT LECTURER (with a keen research interest in control engineering) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING, to join a team, directed by Prof. J. M. Nightingale, working on the application of modern control theory to practical problems in a variety of fields including electrical machine control, process control, bio-medical engineering, and digital systems—The Deputy Secretary, The University, Southampton (July 31).

LECTURERS OR ASSISTANT LECTURERS (2) IN EXPERIMENTAL PSYCHOLOGY—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (July 31).

SENIOR LECTURERS/LECTURERS IN THE DEPARTMENT OF BOTANY; and SENIOR LECTURERS/LECTURERS, SENIOR TEACHING FELLOWS/TEACHING FELLOWS IN THE DEPARTMENT OF PHYSICS, Monash University, Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar of the University (July 31).

POSTDOCTORAL FELLOW (biochemist with some experience in plant biochemistry and enzymology) IN THE CHEMICAL LABORATORY, to study the biosynthesis of alkaloids in higher plants—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (August 1).

SENIOR LECTURER (Psychology) (with an honours degree in psychology and preferably specialized in psychometrics and measurement in education) IN THE SCHOOL OF EDUCATION, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 1).

SENIOR LECTURER or LECTURER (with a postgraduate degree or requisite research experience in any of the following: (*a*) animal nutrition with interest in either mono-gastric or ruminant animals; (*b*) meat technology; (*c*) dairy technology; (*d*) animal genetics and breeding with an interest in poultry) IN THE DEPARTMENT OF AGRICULTURE, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 6).

LECTURER or ASSISTANT LECTURER IN INORGANIC OR PHYSICAL CHEMISTRY (preferably inorganic) IN THE DEPARTMENT OF CHEMISTRY, University of the West Indies, Jamaica—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 8).

PROJECT SCIENTIST (with a higher degree in electrical engineering or physics and extensive experience in electronic instrumentation or data processing systems) IN THE DEPARTMENT OF CONTROL ENGINEERING, School of Electrical Engineering, University of New South Wales, Australia, to work initially on a project aimed at achieving the optimal control of a steam generating plant by means of a digital control computer—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 8).

ARTS or SCIENCE GRADUATE (interested in engineering, and prepared to be trained by the Science Librarian) with a view to taking charge of the Engineering Sciences Library in twelve months' time—The Librarian, University College, Gower Street, London, W.C.1 (August 10).

CHAIR OF ELECTRICAL ENGINEERING at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, August 12).

CHAIR OF MECHANICAL ENGINEERING at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, August 12).

READER OR SENIOR LECTURER IN SOCIOLOGY in the Faculty of Arts and Social Sciences, Ahmadu Bello University, Northern Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 14).

ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, King's College (University of London), Strand, London, W.C.2 (August 15).

LECTURER (specially qualified in animal ecology or behaviour), ON THE STAFF OF THE DEPARTMENT OF NATURAL HISTORY, but attached to Culterty Field Station, Newburgh—The Secretary, The University, Aberdeen (August 15).

SENIOR LECTURER (preferably with an interest in the application of sociological theory to the study of industrial societies) IN SOCIOLOGY—The Secretary and Registrar, Bristol College of Science and Technology, Ashley Down, Bristol, 7, quoting Ref. 66/74 (August 15).

SECOND CHAIR OF ELECTRICAL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 19).

READER OR SENIOR LECTURER IN ANATOMY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 22).

ASSISTANT LIBRARIAN (qualified librarian, with a good honours degree, preferably in some branch of the physical sciences)—The Registrar, Bradford Institute of Technology, Bradford 7 (August 27).

JUNIOR LECTURER, LECTURER OR SENIOR LECTURER IN DAIRY OR SHEEP HUSBANDRY at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or the Registrar of the University (New Zealand and London, August 31).

LECTURER (physicist with theoretical or experimental research interests) IN THE DEPARTMENT OF NATURAL PHILOSOPHY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1, quoting Ref. 44/66 (August 31).

SENIOR LECTURER/LECTURER IN PHARMACY at Rhodes University Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 31).

SENIOR LECTURER (with experience in the fields of industrial and applied sociology) IN SOCIOLOGY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 31).

CHAIR OF ARCHAEOLOGY OF THE ROMAN PROVINCES AT THE INSTITUTE OF ARCHAEOLOGY—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 2).

AGRICULTURAL STATISTICIAN, SCIENTIFIC OFFICER GRADE, in London, for duties which will be concerned with the collation of technical data from scientific experiments—The Establishment Officer, Potato Marketing Board, 50 Hans Crescent, Knightsbridge, London, S.W.1.

ASSISTANT BIOCHEMIST (Basic Grade) (with a first- or second-class honours degree in chemistry or biochemistry) IN THE DEPARTMENT OF PATHOLOGY—The Hospital Administrator, Crumpsall Hospital, Manchester, 8, quoting Ref. 4884.

COMPUTER MANAGER (with experience of operating modern time-sharing computers) to have overall responsibility for the day-to-day operation of the computer and ancillary equipment—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex.

ENGLISH ELECTRIC RESEARCH FELLOW IN THE SCHOOL OF ENGINEERING SCIENCE for work in either of the following fields: automatic control, metal fatigue—The Registrar, The University of Warwick, Coventry, Warwickshire.

INSECT PATHOLOGIST (microbiologist, preferably with experience in bacteriology, mycology, virology or protozoology) to study insect diseases with their possible utilization in pest control—The Division of Entomology, University of California, Berkeley, California 74720, U.S.A.

MYCOLOGIST (with good taxonomic knowledge and physiological interests) for work on the production of ergot alkaloids and other biologically active substances of fungal origin by fermentation methods—The Secretary, Biochemistry Department, Imperial College, London, S.W.7.

ORGANIC CHEMIST OR BIOCHEMIST (with an interest in analytical techniques) to teach chemistry within the Department of Biological Sciences—The Registrar (RS), Portsmouth College of Technology, Hampshire Terrace, Portsmouth.

PHYSICS TECHNICIAN (with at least O.N.C. or City and Guilds Intermediate Certificate, but higher qualifications preferred) IN THE ISOTOPE LABORATORY—The Establishment Officer, Charing Cross Hospital, London, W.C.2.

PHYSIOLOGIST/BIOPHYSICIST to study physiological response to controlled changes in environmental conditions—D. C. Page, Head of Personnel Services, the Electricity Council, Research Centre, Capenhurst, Chester, quoting Ref. N/28.

RESEARCH ASSISTANT (preferably with experience of crystallography or electron microscopy/diffraction) IN THE DEPARTMENT OF PHYSICS to work on studies of epitaxial growth using low energy electron diffraction in a well-equipped established laboratory—The Registrar, University of York, Heslington, York.

RESEARCH ASSISTANTS (2) (honours graduates in pharmacy, physical chemistry, physics or mathematics) IN PHYSICAL PHARMACY—The Registrar (RS), Portsmouth College of Technology, Hampshire Terrace, Portsmouth.

RESEARCH FELLOW IN THE DEPARTMENT OF APPLIED MATHEMATICS to work on atomic and molecular processes—Prof. D R. Bates, F R.S , Department of Applied Mathematics, The Queen's University, Belfast, Northern Ireland.

RESEARCH FELLOW (preferably with research experience in plasma physics, optics, or spectroscopy) for a Science Research Council supported investigation into the coherence and ionizing properties of laser light—Prof. D. J. Bradley, Department of Physics, Queen's University of Belfast, Belfast 7, Northern Ireland.

SCIENTIFIC OFFICER (with an honours degree or equivalent and preferably some research experience) to undertake research on physiological problems arising from the adaptation of large animals to different conditions of environment and nutrition—The Secretary, Institute of Animal Physiology, A.R.C., Babraham, Cambridge.

TECHNICAL OFFICER (with a recognized degree or national diploma in agriculture) IN THE CEREALS SECTION OF THE TRIALS BRANCH—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

TRAINEE OFFICERS (2) (preferably between 20 to 25 years of age, with a degree in agriculture, agricultural botany or botany or the National Diploma in Agriculture with suitable experience)—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

VIROLOGIST, BASIC GRADE (preferably graduate in microbiology or bacteriology) to assist in the development of research into paediatric virological problems—The Group Secretary, Booth Hall Hospital, Manchester, 9, quoting Ref. 4901.

UNPUBLISHED LITERATURE

NEXT to downright villainy, misguided zeal is one of the most dangerous forces in society. At this stage, it is only proper that those who have designed the scheme known in the United States as PIE (for *Physics Information Exchange*) should be given the benefit of the doubt. There is nothing to show that they are villains, but their zeal is alarmingly apparent. What they propose is an experimental scheme for the rapid circulation of documents in high energy physics. The promise of rapidity, however unreal, cannot fail to be attractive. The risks are great, and deserve to be weighed thoroughly by the scientific community as a whole. *Physics Today*, the official journal of the American Institute of Physics, has done a public service by ventilating the issue and inviting comment. With luck, there is now a chance that the conduct of the experiment will be moderated by the weight of interested opinion. There is even sense in hoping that the experiment will never be mounted in the form originally proposed.

Physics Information Exchange is really a scheme for rationalizing the present practice of circulating what are called 'preprints'. In many fields of research it has become habitual for intending authors to circulate copies of their manuscripts to colleagues likely to be particularly interested. In one sense, the practice is in line with the way in which scholars have traditionally sought out the constructive criticism of their colleagues. It is a measure of the competitiveness of modern science that preprint circulation lists are often very large, and that some scientists seem to use the same lists of names for preprints and for Christmas cards. One immediate consequence of PIE would be to lighten the burden of circulating preprints. Those with something to show would send a single copy to an office at the U.S. Atomic Energy Commission in Washington, whence copies would be manufactured and sent to each of a number of chosen preprint libraries, which would in turn serve as secondary distribution centres. The supporters of PIE appear to have convinced themselves—though not their critics—that three hundred preprint libraries would cover the whole world, and that a modest bundle of documents each week would suck dry the literary talents of those who write on high-energy physics. Nobody would have to pay.

As with all closed communities, the most obvious question is how the membership of PIE would be decided. In principle, according to the sponsors of the scheme, everybody with a legitimate interest in theoretical high-energy physics should have a right to membership. But what kind of interest is legitimate? And who decides? With the best will in the world, these are not questions to be dismissed with the beguiling formula that "researchers in theoretical high energy physics throughout the world could qualify for membership". Dr. Michael Moravcsik of the Lawrence Radiation Laboratory, Berkeley, who has at least had the courage to let his name go forward as the chairman of the PIE planning group, cannot really expect this form of words to be sufficient. Either he and his collaborators must face up to the invidious task of defining what they mean by qualification, and thus perpetuate in their own system some of the clubbiness of which they complain in the present preprint networks, or they must throw their doors open to all who ask for membership and run the risk that administration will get the better of them.

Worse still, there is a danger that under the arrangements so far described, the confidence of the preprint authors will be betrayed. One illustration of this difficulty is that under the present informal arrangements for circulating preprints, plagiarists can be quickly struck off the lists. Under the much more impersonal arrangements for PIE, when authors will have no means of knowing where their preprints finish up, plagiarism will be hard to recognize, impossible to prove, and difficult to control. Will it, for example, be necessary for an act of plagiarism to be followed by the excommunication of the whole of a preprint library, or will central PIE insist that the library should excommunicate the offender? And who will act as arbitrator? It is hard to imagine that scientific authors, not renowned for their tolerance of imitators, will willingly trust their manuscripts to PIE unless it is a much more tightly-knit group than at present planned or, on the other hand, much more carefully controlled.

This is the essential contradiction in the proposals for PIE. The intention is to combine the speed and informality of personal communications with the wide dissemination of formal publication. It is disingenuous of Dr. Moravcsik to pretend that his plans for PIE are distinct from an act of publication simply because the documents to be circulated will be fragile, bulky, unscrutinized, un-edited and without indexes. It would be as sensible to exclude from the set of formal publications the great volume of the pulp literature to be found on some bookstalls simply because the grammar in it is defective, the printing inadequate and the words indelicate. The truth is that the essence of the act of publication is that of making literature publicly available. In the liberal interpretation of PIE, preprints would be made available to all and sundry, and that would constitute publication. One of the reasons why the planners of PIE have retained so much of their original optimism is that they have chosen to dodge the implications of this conclusion. For practical purposes, they are proposing to produce a new kind of scientific journal—one whose pages will be open to all who claim space in them, and which will lack the benefit of criticism by referees and constructive interchange between authors and editors. To meet the tedious need that scientists should be able to retrieve

what colleagues publish, or to refer to it, the organizers of PIE are hoping that established journals will undertake the chore of republishing material which has already done the rounds of the preprint libraries.

This, of course, is why the proposals for PIE are so offensive. The organizers are planning a scientific journal the outstanding quality of which will be the subordination of discrimination to speed. There is nothing much wrong with the present preprint system, and a little thought could enable participating scientists to gain more benefit from it. Equally, there is nothing wrong with proposals for new scientific journals, and of course there is everything to be said for using the techniques of modern communication to reduce the time-lag before publication to a few weeks or so. But there is no evidence at all to support the proposition implicit in the plans for PIE that what theoretical high energy physics needs most urgently is a bad scientific journal—one in which the safeguards on which contributors and readers have come to rely are gaily thrown overboard. It is, of course, entirely understandable that the editors of *The Physical Review* and of *Physical Review Letters* should feel most directly threatened by the proposals for PIE, but there is more than mere self-interest in the declaration of Dr. Simon Pasternack, the editor of *The Physical Review*, that the proposal for PIE is "a serious threat to physics communication and to the physics research community". The irony is that these two American journals have won their present place in modern physics by the sheer excellence of the discrimination to whose virtue and necessity the organizers of PIE are apparently indifferent. Thus the complaints that the proposals are probably unworkable, and that they are riddled with contradictions, although true, are not the most serious to be made against those who have invented PIE. It is much more serious that they are apparently insensitive to those qualities which distinguish good literature from bad. That is the most telling of many reasons for hoping that PIE will be stillborn.

NEW MATHEMATICS

THE educational system in Britain seems to be responding with accustomed confusion to the arrival of what is sometimes called the new mathematics. In secondary schools of various kinds, a number of experiments have been under way for several years. Though the School Mathematics Project under Professor Bryan Thwaites is the best known of them, it is by no means alone in the field. Other experiments have sought to turn the ingredients of the new mathematics to more practical account. Elsewhere, things have gone the other way, and experimental courses in mathematics are to be found which owe something to the axiomatic experiments in the United States, and which promise to cater most adequately for those schoolboys and schoolgirls who know in their bones that they are born mathematicians. In itself, this diversity has been a good thing. Many innovations have been tried, and teachers of different inclinations have been able to engage their enthusiasm where it seemed that there would be the greatest benefit. But diversity is now becoming an impediment to reform. For one thing, those teachers of mathematics wishing to renovate their syllabuses are at a loss to know which innovations to adopt. Worse still, those to whom change is abhorrent are more able to practise old ways without interference. And then the institutions which depend on the secondary schools for an education of some kind in mathematics—employers of all kinds, but particularly the universities—are puzzled to know what is going to happen. With all the confusion, there is a danger that the hard work of the last decade or so may nullify itself.

This prospect is particularly frustrating because a coherent development of mathematics in the schools is necessary if there is ever to be an improvement of the relationship between British schools and British universities on mathematics. At present, the means by which the universities recruit undergraduates in mathematics exerts an unreasonable—and a hostile—influence on mathematics teaching in the schools. Entry to most university departments of mathematics still requires that a pupil should spend roughly two-thirds of his time between sixteen and eighteen studying mathematics. Not merely is his education unbalanced, but he (or she) has to gamble on a career in mathematics at an age when very few pupils can be certain of their talents (and also correct in their estimation of them). It would be surprising if this strange practice were not a part of the reason why several university departments of mathematics have found recruitment difficult in recent years. The same system probably provides a great many young people who finish up as scientists with an education that is less rounded than it should be. The obvious solution is to design a system in which the departments of mathematics are restrained from asking intending entrants to specialize heavily in mathematics in the last two years at school. The ideal would be a system in which intending mathematicians and scientists alike were taught the same mathematics, which should be largely determined by the need—in the broadest sense—to provide a mathematical foundation for science teaching. The mathematicians should be enabled to select their bright young men and women not by seeing which of them can cover the most ground, but by more qualitative and more meaningful tests.

Though the heads of some departments of mathematics in the universities are sensitive to the need of a more liberal regimen in the schools, it is unlikely that the universities will abandon their entrenched position of their own accord. There is a kind of Gresham's Law which ensures that bad practice is more stable than the good. But the schools are unlikely to be able to force through a change until they know what they would like to see. Who, then, is to take this cause in hand? Of the British institutions likely to be influential, only the Schools Council is suitably independent yet free to advocate an opinion.

By all accounts, the council is hoping for great things from a conference in the autumn at which it hopes to win approval for a plan to make a synthesis of experiments in the schools. With luck, the universities may be persuaded to give the project something like a blessing. So far the strongest opposition seems to have come from pundits in the Department of Education and Science who argue that the diversity of current practice in the schools is a proof that the schools do not particularly wish to change their ways. In reality, of course, in teaching as elsewhere, diversity may be a sign of rapid evolution.

SUBMARINE RAILWAY

IT is not surprising that the Prime Ministers of France and Britain should have been grateful for a few crumbs of agreement to fill out the communiqué after their recent meeting in London. By all accounts, British membership of the European Economic Community was not a fruitful topic of conversation. It is therefore paradoxical that the two Prime Ministers should have considered this a suitable time for a decision in principle that the tunnel beneath the English Channel should in due course be built. It would have been easy to understand if their predecessors had come to such an agreement at any time in the last century. But now the case for a tunnel between France and Britain is wearing thin. Alternative ways of crossing what is, after all, a narrow strip of water have become more attractive, particularly in the last decade. At the same time, doubts have grown about the capacity of the proposed rail tunnel to cater adequately for the traffic between Britain and the mainland of Europe. It looks very much as if the two governments may be making the right decision at the wrong time.

The case for the tunnel is based on surveys of the traffic between Britain and the mainland of Europe which were carried out in the late fifties. Even when first published, it appeared that the demand for facilities to cross the English Channel had been underestimated. Experience has borne out that awkward suspicion, and one obvious result has been the rapid growth of cross-Channel ferry services in the sixties. Compared with the proposed tunnel, these surface and air routes have the advantage that they do not require that great volumes of traffic should be funnelled through two railheads. They are also increasingly cheap and quick. Meanwhile the chances are that the construction of a bridge across the Channel would not be relatively simpler (and cheaper) than seemed likely five years ago. In the circumstances it is to be hoped that the two governments will have another close look at the wisdom of the course to which they have committed themselves before the digging of a tunnel actually begins. If then they decide to go ahead, it is essential that the financing of the tunnel should not somehow confer an unfair commercial advantage on what promises to be an old-fashioned way of travelling from Britain to France.

NEWS AND VIEWS

Charter for Botanists

A PLAN to spend $1,500 millions during the next decade on the development of the plant sciences has been drawn up by a committee of the U.S. National Academy of Sciences (*The Plant Sciences, Now and in the Coming Decade*, Government Printing Office, Washington, $5.00). The starting point for the argument is frankly practical, and is based on the fact that applied botany is also the oldest of all industries and still the only way of converting solar energy into food. As part of its vision of the future, the committee makes much of the potential agricultural applications of plant growth regulators, propagation from fragments of plants and even single cells, the relationship between trace elements and fertility, ferrodoxin as a spur to the study of nitrogen fixation, and phytotrons as means of optimizing methods of cultivation.

Chambers for controlling the environment of plant growth would eat up half the capital expenditure the committee recommends. It would like to see 850 small chambers installed each year for the next decade at universities and other research establishments, and would also have the U.S. Government spend $9 millions on a new phytotron unit as well as half that sum on extensions to existing installations. Roughly $70 millions would be spent on electron microscopes in the same period, while botanical gardens would receive a total of $35.3 millions in the coming decade. The budget as a whole works out as follows, with amounts in millions of dollars:

	Research	Capital
Environment and nutrition	180	208·0
Biochemistry and biophysic	354	7·9
Growth and development	94	0 6
Plant structure	67	69 8
Genetics	77	—
Taxonomy	49	35·3
Plant pathology	60	12·5
Economic botany	—	57·5
Manpower	135	8·5
Computers	—	10·1
	1,016	410 2

The assumptions made by the committee about the cost of supporting individual researchers will be of particular interest outside the United States. At present the cost of a year's research in taxonomy is a mere $10,000, though the committee expects that this will rise to $16,000 by 1974. In biochemistry, by contrast, present costs amount to $35,000 a year, chiefly because of the costs of materials and laboratory assistance. By 1974, the committee supposes, it will cost $45,000 to keep a qualified plant biochemist working for a year. In other words, the committee paints a cheerful picture of the future of the plant sciences and their applications. It remains to be seen how many of its proposals will eventually be backed by hard cash, for this prospectus is only one of several now in circulation in Washington.

Universities in Clover

BRITISH universities are better off than they will admit, to judge from the statement of Mr. Anthony Crosland, Secretary of State for Education and Science, at the University of Birmingham last week. Commenting on the very rapid increase in the number of both

undergraduates and postgraduate students, nearly double that of nine years ago, Mr. Crosland said that "most of the credit for this quite remarkable achievement lies with the universities themselves". But the government was well aware of the high priority necessary for higher education and research and had backed this decision with increasing financial support. Mr. Crosland rejected the notion that the universities have been meanly treated by successive governments. Within the past five years the University Grants Committee has increased university expenditure from £80 million a year, about eight per cent of all educational spending, to £207 million, or 12½ per cent. In spite of the great expansion of students, the ratio of students to staff had remained constant at about seven-and-a-half. At the same time, resources devoted to university building over the last ten years had increased tenfold. In response to the Flowers Report, the Government had also allocated about £20 million to universities over the next six years for new computers and related costs. "This is a very substantial additional expenditure which perhaps has been too little noticed in the universities," Mr. Crosland added.

Both undergraduate and graduate studies are far ahead of the Robbins Report projections. The undergraduate enrolment for 1966–67 should be 189,000, or 2,000 more than originally estimated, while nearly a quarter of last year's graduates—13,500—stayed on for postgraduate work, thus more than doubling the estimated growth rate. This development, said Mr. Crosland, "has resulted from the cumulative decisions of all the universities in the country, and only incidentally from national policy in matters such as postgraduate awards." He concluded that the Government's role is to keep national issues in the forefront of academic discussion, and to create a climate of opinion in which close involvement with the social and economic needs of the nation is a respectable aspiration for a university.

Uranium in Europe

THE Euratom organization persists in taking what the stock exchanges would call a bullish view of the uranium market. In 1963, when uranium was something of a drug on the market and when the British Government was having to explain to the Canadians why the United Kingdom Atomic Energy Authority wished to stretch out its contracts to buy uranium from Canadian mines, Euratom published a report which drew attention to the likelihood of scarcity (EUR 414e—*The Problem of Uranium Resources and the Long-Term Supply Position*). Briefly, the estimates compiled in 1963 suggested that Europe as a whole would need something like 100,000 metric tons of uranium metal in the decade 1970–80, and that only some 15,000 tons of this would be supplied from within Europe at a reasonably competitive price of around $8 for a pound of U_3O_8. One immediate result, within the six countries of Euratom, was to stimulate uranium prospecting in Europe. Some of the results of this work are now described in the document *Les Ressources en Uranium dans la Communauté Européenne* published at Brussels.

The most remarkable change in the past three years has been a cheerful upward revision of the estimates of the potential uranium resources of Europe. It is true that the Benelux countries (Belgium, Luxembourg and the Netherlands) are written off as contributors, but it appears that France, West Germany and Italy are better off than has hitherto been thought. More detailed examination of uranium ore deposits known for some years has led to increases of estimates of their potential. Hunting for new kinds of uranium deposits has also turned out to be successful. The result is that the Working Party responsible for the survey considers that the proved reserves of uranium ore, known to be equivalent to 31,000 tonnes in 1964, could be increased by up to 40,000 tonnes by means of a sufficiently energetic programme of exploration. Some of this addition to present reserves would come from the discovery of new deposits, and some from the extension of deposits at present being worked. France is thought to contain half the uranium as yet undiscovered, while Italy and West Germany share the rest. The Working Party has a number of suggestions to make about the future exploration for uranium in Europe, not the least constructive of which is the suggestion that there should be better liaison between the geologists. But, for all its optimism about the future of uranium supplies, there remains an unhappy discordance between potential supply and likely demand. Even if prospecting turns out to be as successful "as it seems reasonable to hope, the reserves will, however, remain insufficient for the needs of the community as a whole in the decades ahead . . ."

Drilling Deep

IT should soon be known whether the National Science Foundation will have to buy its way out of the contracts signed for the equipment needed for drilling the *Mohole*, or whether the project will be allowed to limp along on a somewhat straitened budget. Earlier this year the appropriate committee of the United States House of Representatives declined to vote money for next year's operations, and thus put in jeopardy the construction of the *Mohole* drilling barge, estimated to cost $27 millions and due to start experimental drilling in the Pacific during 1967. Now it is up to the Independent Offices Appropriations Subcommittee of the United States Senate to decide whether there shall be some loosening of the public purse-strings. At this stage it is unlikely that the sponsors of the project will get the whole of the $127 millions now thought necessary to complete the *Mohole*, though it would be entirely sensible if the Senate decided to complete the barge on which work has begun, and to provide funds for a modest programme of experimental drilling in 1967 and 1968. After all, nobody questions the value of deep boreholes, but merely the wisdom and feasibility of going in one leap to the Mohorovicic discontinuity on a fixed budget, even if that budget is eight times the cost originally estimated.

Some of the artlessness of the *Mohole* project can be found in the record of the symposium on *Drilling for Scientific Purposes* held in Ottawa last year under the auspices of the International Upper Mantle Committee (Queen's Printer, Ottawa, 75 cents). At the symposium Professor H. H. Hess of Princeton described a meeting in Washington in March, 1957, at which eight people were gathered "to analyse projects submitted from earth scientists of the country. We had something like sixty projects to review in two days . . . we were rather tired, and Walter Munk mentioned that none of these proposals was really fundamental to an under-

standing of the Earth, although many of them were very good. If someone wanted to study the clay minerals of such and such a formation to find out about its diagenesis, well, this was a good thing to do. However, it would not solve a major problem about the Earth. If someone wanted to study the stability of anthophyllite, well yes, I would like to know about its stability too. But still, it is a relatively small point. We had gone through sixty of these proposals, most of which we rated as being very good projects. They should be supported." But then emerged the proposal that "we should have projects in earth science—geology, geochemistry, geophysics—which would arouse the imagination of the public and which would attract more young men into our science". That was the beginning of the *Mohole*.

The overall effect of the report of the symposium is, however, more a vindication than a condemnation of deep drilling. There is an impressive account of how a Canadian team has studied a basic intrusion in the Canadian Shield with three modest holes. The JOIDES programme, in which the three principal oceanographic institutions in the United States participate, has learned a great deal about ocean sediments since the Pliocene by drilling into the continental shelf off Florida. The Russians are looking hard, from the Baltic Shield to where Asia runs out into the Pacific, for profitable sites at which to drill holes of up to 7 or even 10 km. (One hole described at the symposium had then passed 3,800 metres, a third of it in granite.) The Swiss would drill into the Alps, the Japanese into the roots of their island arc and the Icelanders into the succession of lava flows which supports them and the Faroe Islands. Then there is great interest in the oceanic basalts above the Mohorovicic discontinuity whose magnetization may be responsible for magnetic anomalies recently measured. Obviously there will be plenty of work to keep a deep drilling barge busy even if *Mohole* itself is still a long way off.

specification of the site should help to thin out the field. It is laid down that the spot selected should be roughly 20 square kilometres in area, at least 3·5 kilometres across at its narrowest point, and flat to within 20 metres over the whole area. The ground must be stable to within 0·15 mm in 100 metres, and there must be a power supply capable of providing 100 MW by the time the accelerator is in operation, and with the possibility of 300 MW if storage rings are ever added. Something like 2 cubic metres of cooling water a second may be necessary, while access to the site by air and on the surface must be easy. Finally, the specification states, there must be towns nearby capable of absorbing the 15,000 people needed to run the accelerator. There is even a passage which refers to the way in which it will be easier to recruit staff in areas which are attractive to live in. It will be fascinating to see how the Council votes if it should ever be necessary to choose, on grounds of amenity, between a site in southern Europe—between Nice and Marseilles, for example—and one in the north.

Fossil Mammals

VERTEBRATE palaeontologists would do well to take note of four recent works on fossil mammals: Savage, Russell and Louis have made a painstaking reassessment of the European Eocene equids with special emphasis on some French material (*Univ. Calif. Publ. Geol. Sci.*, **56**: *European Eocene Equidae* (*Perissodactyla*); 1966). The equid faunas at any one time in the Eocene are seen to comprise several species, which differ mainly in size, and this may reflect diverse habitats. Recent living

(*Mus. Comp. Zool., Harvard Univ.*, **133**, No. 6: *The Fossil Elephant Shrews*; 1966). He supplies a diagnosis and achieves a neat rehousing of some African Tertiary mammals which had previously been misplaced among marsupials, mixtodectid insectivores and hyracoids. The order has only one family, the Macroscelididae; it is entirely African, and ranges from Lower Oligocene to Recent. The extinct sub-families were essentially herbivorous while the living members are more markedly omnivorous.

Reed and Turnbull have described the insectivore genera *Arctoryctes* and *Cryptoryctes* from the Oligocene and Miocene of North America (*Fieldiana: Geol.*, **15**, No. 2; 1966). They provide a detailed account of the functional anatomy of the bones of the forelimb and shoulder girdle of the fossil forms, and compare them with living talpid moles. The trends in the two groups are broadly parallel but differ in detail; the arctryctines are more specialized while the talpids have the lead in overall efficiency of the limb.

Domestic into General Science

QUEEN Elizabeth College of the University of London is taking another important step in the transition from its original role as King's College of Household and Social Science to a general science college. After 20 years as principal, Miss M. J. Sargeaunt is retiring in September and Dr. Kenneth G. Denbigh, professor of chemical engineering at Imperial College, London, since 1961, will be the new principal. Although he has [illegible] formal plans, Prof. Denbigh hopes the college [illegible] scientific centre. Because space [illegible] large and [illegible] than

Lister Institute—1966

THE London Lister Institute of Preventive Medicine has had another good year, as judged from the annual report for 1966. Although it gets no money from the University Grants Committee, the Institute is one of the recognized schools of the University of London for postgraduate research, and during 1965–66 there were sixteen postgraduate research workers at the Institute registered for higher degrees. Also embodied within the Lister are three units of the Medical Research Council—the Trachoma Research Unit, the Blood Group Research Unit and the Blood Group Reference Laboratory.

The research being undertaken involves the genetics, physiology and morphology of bacteria, trypanosomiasis, various aspects of virus diseases and bacterial infections, immunology, human blood group substances, biochemistry of lipids, macro-molecular components of blood, and human plasma proteins. In recent years, increasing emphasis has been placed on various aspects of virology and immunology. In virology, there have been considerable developments in studies of trachoma agents, and of special importance has been the success in passaging trachoma and inclusion conjunctivitis agents in the lungs of mice. The possibilities are being investigated of producing a potent vaccine free from those substances in nervous tissue which are responsible for the demyelinating accidents which sometimes occur during the treatment of rabies. New fields of research in immunology include investigations to test the possibility that generalized eczema may result from the incorporation of bacterial or fungal antigens into cells of the skin. There is also an investition of the possibility that nodular vasculitis may be caused by complexes of antigen and antibody.

Parliament in Britain

OPENING a debate in Committee on the Civil Estimates in the House of Commons on July 5, Sir Edward Boyle and other speakers strongly challenged the adequacy of the Government's allowance of £25 million for the university building programmes for 1965–69. In his defence the Secretary of State for Education and Science, Mr. A. Crosland, was content to emphasize the increase of numbers of students to 189,000 by October 1966, with a further 47,000 full-time students in technical colleges. In the course of his speech he announced that Professor B. H. Flowers had agreed to become chairman of the Computer Board; the Secretary of State also agreed that 44 university institutions might really be too many as compared with the same number of students in fewer but larger institutions. He, and other speakers, emphasized the importance of a balanced distribution of reserves between the universities and other educational institutions. The White Paper, *A Plan for Polytechnics and Other Colleges*, issued in May received favourable comment in the debate, but on both sides of the House it was urged that rigidity in higher education should be avoided. The geographical distribution of the proposed polytechnics was, however, criticized, particularly the absence of such institutions from eastern England.

There was some evidence of fresh thinking about public control of universities, and in replying on the debate, the Minister of State, Department of Education and Science, Mr. G. Roberts, said that there was no intention of creating a rigid pattern, irrespective of traditions and individual circumstances. The changes proposed in the White Paper were essentially flexible and evolutionary, and the Minister would not designate a college or group of colleges for status as a polytechnic until there had been full consultation with the Regional Advisory Councils and with the local education authorities concerned.

REPLYING for the Government in an adjournment debate in the House of Commons on colour television on July 6, the Postmaster General, Mr. E. Short, said that the decision to introduce colour television on the 625-line definition standard was determined by four main considerations which had led the Television Advisory Committees last December to reaffirm the earlier decision of 1962. First, given the decision to change the line standard from 405 to 625 lines, it would be a retrograde step to start colour on 405 lines. Secondly, dual standard colour sets would be more expensive to install and maintain, and might be so complex as to jeopardize the success of a colour service. Thirdly, sets designed to receive colour on both line standards would cost 7–10 per cent more than sets designed for 625-line colour only. Fourthly, it was questionable whether a 405-line colour transmission would permit an acceptable quality of colour reception for those with colour receivers, or of black-and-white reception for those without. The latter for years to come would constitute the great majority of viewers. By the end of 1967 it was estimated that 65 per cent, and by the end of 1968 about 75 per cent, of the population would be able to receive BBC 2. Mr. Short emphasized that, whether transmitted on u.h.f. or v.h.f., the 625-line standard provided a better picture than the 405-line standard. Uniformity, he said, was desirable.

University News:

Birmingham

DR. J. M. BISHOP has been appointed to the newly established second chair of medicine.

Bristol

DR. J. M. MARSTRAND has been appointed to a chair of pure mathematics; Dr. M. H. Rogers has been appointed to a chair in the Computer Unit.

London

PROF. J. N. MORRIS, director of the Social Medicine Research Unit of the Medical Research Council and professor of social medicine at the London Hospital Medical College, has been appointed to the chair of public health tenable at the London School of Hygiene and Tropical Medicine.

Loughborough

DR. G. W. KIRBY, at present lecturer in chemistry in the Imperial College of Science and Technology, has been appointed to a chair in organic chemistry at Loughborough University of Technology.

Reading

THE following professors have been appointed: Dr. J. C. Bowman (animal production); G. Williams (zoology).

Appointments

THE chairman of the Schools Council from October 1, 1966, will be Mr. Alan Bullock, Master of St. Catherine's College, Oxford. He will succeed Sir John Maud, who has been chairman of the Schools Council since its formation two years ago, and who is now to be chairman of the Royal Commission on Local Government.

It has also been announced that Mr. Geoffrey Caston, an assistant secretary at the Department of Education and Science, is to succeed Mr. Derek Morrell as one of the three joint secretaries of the Schools Council.

THE American Institute of Physics has appointed Dr. Ralph A. Sawyer as acting director in succession to Dr. Van Zandt Williams, who died suddenly on May 13, 1966. Dr. Sawyer acted as director of the Institute for a short period from October 1, 1964, to April 1, 1965, before Dr. Williams took up his appointment. He is a spectroscopist and has been closely associated with the University of Michigan.

MR. I. G. K. WILLIAMS, at present head of the Administrative Division in the Health and Safety Branch of the United Kingdom Atomic Energy Authority, has been appointed deputy director general of the European Nuclear Energy Agency.

Announcements

THE following have been elected full members of the Soviet Academy of Sciences: A. N. TIKHONOV (mathematics); N. G. BASOV, L. F. VERESHCHAGIN, S. V. VONSOVSKY, V. L. GINSBURG and A. M. PROKHOROV (general and applied physics); M. A. MARKOV and A. B. MIGDAL (nuclear physics); V. I. POPKOV (physical and technical problems of energetics); V. V. MENNER, M. A. SADOVSKY and A. V. SIDORENKO (sciences of the earth); V. P. BARMIN, P. D. GRUSHIN, V. P. MISHIN, V. V. NOVOZHILOV, N. A. PILYUGIN and M. K. YANGEL (mechanics and control processes); I. V. PETRYANOV-SOKOLOV, G. A. RAZUVAYEV and N. M. EMANUEL (general and technical chemistry); I. P. ALIMARIN, S. T. KISHKIN and A. M. SAMARIN (physico-chemistry and technology of inorganic materials); N. D. IERUSALIMSKY, J. W. PEIVE and G. M. FRANK (biochemistry, biophysics and the chemistry of physiologically active compounds); P. K. ANOKHIN, E. M. KREPS, V. V. PARIN and B. V. PETROVSKY (physiology); B. L. ASTAUROV and N. P. DUBININ (general

biology); A. A. GUBER (history); B. M. KEDROV (philosophy and law); A. M. RUMYANTSEV and T. S. KHACHATUROV (economics); V. M. ZHIRMUNSKY and M. B. KHRAPCHENKO (literature and language); G. K. BORESKOV, N. N. VOROZHTSOV, A. B. ZHUKOV, YU. A. KUZNETSOV, L. A. MELENTYEV, A. V. NIKOLAYEV and V. V. STRUMINSKY (Siberian branch). The following have been elected corresponding members: N. P. BUSLENKO, V. YA. KOZLOV, S. P. NOVIKOV, YU. V. PROKHOROV and A. A. SAMARSKY (mathematics); L. D. BAKHRAKH, A. F. BOGOMOLOV, V. S. BOROVIK-ROMANOV, L. A. VAINSHTEIN, L. P. GORKOV, E. M. LIFSHITS, R. V. KHOKHLOV and I. S. SHKLOVSKY (general and applied physics); V. P. DJELEPOV, L. B. OKUN, E. L. FEINBERG, L. P. FEOKTISTOV and A. E. CHUDAKOV (nuclear physics); N. S. LIDORENKO (physical and technical problems of energetics); YU. D. BULANZHE, P. N. KROPOTKIN, V. V. RZHEVSKY, A. B. RONOV, E. F. SAVARENSKY, E. M. SERGEYEV, A. I. TUGARINOV and V. E. KHAIN (sciences of the earth); G. S. BYUSHGENS, S. V. VALLANDER, S. S. LAVROV, N. N. MOISEYEV, I. F. OBRAZTSOV, G. S. POSPELOV, V. S. PUGACHOV, V. B. RAUSHENBAKH and G. P. SVISHCHEV (mechanics and control processes); N. S. YENIKOLOPOV, YA. M. KOLOTYRKIN, A. A. PETROV and A. S. SADYKOV (general and technical chemistry); R. S. AMBARTSUMYAN, V. V. KAFAROV, B. N. LASKORIN and E. M. SAVITSKY (physico-chemistry and technology of inorganic materials); M. V. VOLKENSHTEIN, M. N. KOLOSOV, M. A. PROKOFIEV, A. S. SPIRIN and A. A. SHLYK (biochemistry, biophysics and chemistry of physiologically active compounds); O. G. GAZENKO, P. G. KOSTYUK and A. M. UGOLEV (physiology); A. P. ANDRIYASHEV, M. S. GILYAROV, A. L. TAKHTADZHYAN and S. S. SHVARTS (general biology); YU. V. BROMLEI, YA. S. GROSUL, YU. A. POLYAKOV and V. L. YANIN (history); G. A. AKSENYONOK, D. A. KERIMOV and T. I. OIZERMAN (philosophy and law); V. A. VINOGRADOV, A. G. MILEIKOVSKY, T. V. RYABUSHKIN, V. G. SOLODOVNIKOV and T. T. TIMOFEYEV (economics); M. N. BOGOLYUBOV and D. F. MARKOV (literature and language); A. A. BOROVKOV, G. S. GORSHKOV, M. I. KARGAPOLOV, N. N. PUZYREV, M. G. SLINKO, V. P. SOLONENKO, L. V. TAUSON and N. N. YANENKO (Siberian branch).

THE U.S. National Academy of Sciences and the Czechoslovak Academy of Sciences have agreed on a programme of scientific exchanges lasting for the next 3 years. Visits of from one month to one year by individual scientists are included under the agreement, and it is expected that a total of 40 man-months of visiting a year in each direction will take place.

THE U.S. Naval Research Laboratory has agreed with the University of Maryland and with Cornell University to conduct joint programmes of research on plasma physics. The objective of the two bilateral agreements is that the laboratories concerned should plan their work in consultation with each other and that there should be frequent interchanges of students and scientists between the institutions. The Naval Research Laboratory's programme is being directed by Dr. Alan C. Kolb, now superintendent of the Plasma Physics Division in which he has worked for the past decade.

THE Council of the Royal Society of Edinburgh has announced that Dr. S. Evans, a member of the Scott Polar Research Institute, has been awarded the Dr. W. S. Bruce Memorial Prize for 1966, in recognition of his many applications of physics to scientific exploration in the Antarctic and particularly for his development of radio echo sounding of ice. The Council has also announced that the David Anderson-Berry Prize for 1966 has been awarded as follows: Dr. G. F. Whitmore, for his investigations into the effects of radiation on the underlying cellular and chemical events which occur at various stages during the growth and division of mammalian cells; *proxime* to Dr. L. A. Stocken and Dr. M. Ord, for their work on the effects of X-irradiation on the synthesis of deoxyribonucleic acid.

MR. D. WALLIS has been awarded the Miles Prize by the National Institute of Industrial Psychology, in recognition of his work on new training techniques at the Navy Department of the Ministry of Defence. He is the first recipient of this new Prize. Dr. D. McKie Kerslake has been awarded the Vernon Prize by the Institute.

THE one hundred and third meeting of the British Pharmaceutical Conference will be held in Manchester during September 5–9. Further information can be obtained from the Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, London, W.C.1.

THE third international Congress of Human Genetics will be held in the University of Chicago during September 5–10. Further information can be obtained from Dr. B. S. Strauss, University of Chicago, 1307 East 60th Street, Chicago, Illinois.

AN international symposium on "Selenium in Biomedicine" will be held at Oregon State University during September 6–8. Further information can be obtained from the chairman of the symposium, Dr. O. H. Muth, Nutrition Research Institute, Oregon State University, Corvallis, Oregon.

TECUITLATL; A GLIMPSE OF AZTEC FOOD TECHNOLOGY

By DR. W. V. FARRAR

University of Manchester Institute of Science and Technology

THE unicellular yellow-green alga *Chlorella* (Chlorophyta), and species related to it, has often been discussed in recent years as a possible source of cheap food. Its production, which needs only sunlight, water and inorganic salts, would be economical of labour and land; experimental work has been going on in many countries[1]. A great impediment to this project is the unpalatability of *Chlorella*, however prepared and disguised, to human beings[2], and no solution to this problem seems to be in sight. This article presents evidence that the pre-Conquest inhabitants of Tenochtitlán (the present Mexico City) ate considerable amounts of a *blue-green* alga (Cyanophyta) of unknown species, which both the natives and the Spaniards found palatable. While it was being written, a Belgian Saharan expedition reported[3] that Africans in the vicinity of Lake Chad were also in the habit of eating a blue-green alga, *Spirulina platensis*.

Tenochtitlán was built on an island in a lake of brackish undrinkable water (Lake Tezcoco), connected to the mainland by three causeways. The small part of the lake enclosed by the causeways contained fresh, but still undrinkable, water; it was always at a slightly higher level than the rest of the lake. Drinking-water came from several miles away, by means of an aqueduct. The size of the city astonished Cortés and his companions on their entry in 1521. Their estimates of its population have often been derided as exaggerations; but the report made by Cortés of 60,000 families agrees reasonably well with Humboldt's much later estimate that the old city must have been about three times as big as the one he visited, the population of which was about 137,000 (ref. 4). At a conservative estimate (say 250,000) it was much larger than the largest towns in Europe.

How was such a large urban population fed, in a country of primitive farming, where all land transport was on the human back? There were fish in the lake, but there were no large, edible domestic animals. The staple foodstuff was maize, but the varieties then cultivated were not high-yielding. From the descriptions by the *conquistadores* of the wares offered for sale in the great market of Tenochtitlán, it would seem that the people, though by no means starving, were pressing hard on their resources. Nothing edible was neglected, not even snakes, 'lice', or the usually despised dog. It was no doubt the pressure of necessity which led to human sacrifice on a vast scale, followed by cannibalism; and to the invention of "*chinampas*" or "floating gardens", though the latter either fell out of use[5], or never existed[6] except as an ingenious system of irrigation.

With this background of knowledge, it was interesting to find in Prescott's *Conquest of Mexico* two brief references[7] to a "slime" gathered from the lake and eaten by the people of Tenochtitlán*. Prescott's first authority was the eighteenth-century historian Clavigero[8]:

> "Not contented with feeding on living things, they ate also a certain muddy substance that floats on the water of the lake, which they dried in the sun and preserved, to make use of it as cheese, which it resembled in flavour and taste. They gave to this substance the name of Tecuitlatl, or excrement of stones."

Clavigero can only be considered as a secondary source; but the other reference is to Bernal Diaz, who was among the first Spaniards to enter Tenochtitlán. His memoirs, written in his old age in simple and vigorous language, are a classic of Spanish literature. In his wide-eyed account of the great market[9], he finds room for half a sentence about the "slime":

> ". . . then there were fishmongers, and others who used to sell little loaves which they make out of a sort of slime which they gather from the great lake, which they thicken and make loaves of it, having a flavour like cheese." (' . . . *pues pescaderos y otros que vendían unos panecillos que hacen de una como lama que cogen de aquella gran laguna, que se cuaja y hacen panes de ello que tienen un sabor a manera de queso.*")

A search among the other sixteenth-century chroniclers of the conquest of Mexico revealed a few more references. Cortés in his letters to the Spanish Court does not mention the "slime", unless his reference to the collection of "salt" from the lakeside[10] refers to tecuitlatl. But Cortés, returned from conquest, and in retirement in Spain, provided the material for a book written by his secretary, Gómara, who was himself never in Mexico. Gómara wrote[11]:

> "[they eat] a sort of earth, for with nets of very fine mesh they collect, at a certain time of year, a soft substance which breeds on the water of the lakes of Mexico, and they thicken it, though it is neither plant nor earth, but a sort of mud. It is plentiful, and they collect a lot of it; they empty it out on floors, as if they were making salt, and there it thickens and dries. They make it into cakes like bricks, which they sell, not only in the market [of Tenochtitlán] but carry it to others outside the city, and far off. They eat this as we eat cheese, and it has rather a salty taste, which is delicious with *chilmolli*†. They say that so many birds come to the lake for this food, that often in winter some parts are covered with them." (". . . *y aun tierra; porque con redes de malla muy menuda abarren en cierto tiempo del ano una cosa molida que se cria sobre la agua de las lagunas de Méjico, y se cuaja, que ni es yerba ni tierra, sino como cieno. Hay dello mucho y cogen mucho; y en eras, como quien hace sal, lo vacian, y allí se cuaja y seca. Hácenlo tortas como ladrillos, y no solo las venden en el mercado, mas llévanlas tambien á otros fuera de la ciudad y léjos. Comen esto como nosotros el queso, y así tiene un saborcillo de sal, que con chilmolli es sabroso. Y dicen que á este cebo vienen tantas aves á la laguna, que muchas veces por invierno la cubren por algunas partes.*")

The Franciscan friar Toribio (known as Motolinia, "the poor man") lived among the Mexicans for many years, speaking their language and sharing their food and way of life. His *Memoriales* (written about 1541) appear to be notes for, or a first draft of, his better-known *Historia*

* Ref. 7 has misleading footnotes (pp. 284 and 536) which equate the 'slime' with *ahuahutle*, the egg-masses of some water-insect, which are eaten as a sort of caviare. The two materials are quite different.

† A pungent sauce.

General, in which the following passage does not appear, though the relation between the two works is not very clear. His account[12] of the preparation of tecuitlatl is more detailed than that of Gómara:

"There breeds upon the water of the lake of Mexico a sort of very fine slime, and at a certain time of year when it is thickest, the Indians gather it with a very fine-meshed net until their *acales* (as they call their boats) are laden with it; on shore they make on the earth or on sand a very smooth plot, two or three *brazas*‡ wide and a little less in length, and they throw it down to dry, enough to make a cake two *dedos*‡ thick. In a few days it dries to the thickness of a worn ducat; and they cut this cake like broad bricks. The Indians eat a lot of it, and it keeps so well that they go with this merchandise to all the markets of the land, while those among us who share the tastes of the Indians find it very pleasant; it has a salty flavour." (*"Crianse sobre el agua de la laguna de México unos como limos muy molidos, y á cierto tempo del ano que están más cuajados, cógenlos los indios con unos redejoncillos de malla muy menuda, hasta que hinchen los acales ó barcos dellos, y á la ribera hacen sobre la tierra ó sobre arena unas eras muy llanas con su borde de dos ó tres brazas en largo y poco menos de ancho, y échanlos allí á secar; echan hasta que se hace una torta de gordor de dos dedos y en pocos dias se secar hasta quedar en gordor de un ducado escaso; y cortada aquella torta como ladrillos anchos, cómenlo mucho los indios y tiene se buenos anda esta mercaduria por todos los mercaderes de la tierra, como entre nosotros los que son de la salsa de los indios es bien sabroso, tiene un saborcillo de sal."*)

Another Franciscan friar, Bernardino de Sahagún, knew the natives so well that his *Universal History* (dealing mainly with religions and social customs) was first written in Náhuatl about 1550; he made a Spanish version thirty years later, although it was not published until 1830. His account[13] of tecuitlatl is brief but of particular interest:

"There is an *urrosas*§ which breeds upon the water, which is called Tecuitlatl; it is of a clear blue colour; after it is well thickened and coarse it is gathered, and spread on ashes on the ground, and afterwards they make cakes of it, and eat them cooked." (*"Hay unas Urrosas§ que se crian sobre el agua que se llaman Tecuitlate; son de color de azul claro; despues hacen unas tortas de ello, y tostadas las comen."*)

The most valuable authority would be the naturalist Francisco Hernandez, who was sent by the Council of the Indies to report on the flora, fauna, and minerals of New Spain and their possible economic exploitation. This report was compiled about 1550–60, but the manuscripts were scattered and lost, and there was no reasonably complete publication until 1790. This[14] does not mention tecuitlatl, but there is a summary of his unpublished notes[15] in which it is given as a chapter-heading under "minerals". (The notes presumably exist in manuscript in the Spanish archives.) The Spaniards were evidently confused about the proper classification of tecuitlatl; they could not (lacking the microscope) identify it as a plant, although it 'bred'; but the 'breeding' of minerals was still a common belief in the sixteenth century.

At some time unknown, but probably not long after 1550, the practice of making tecuitlatl must have ceased. The native population was decimated by repeated outbreaks of smallpox, and in the first confused years of Spanish occupation many traditions were lost. Cervantes de Salazar[16], writing about 1560, refers to it, but the passage is lifted entire from Gómara. Acosta[17], who was in Mexico during the years 1586–87, does not mention it.

‡ *braza* equals 1·7 m; *dedo* equals 1·8 cm.

§ 'Urrosas' (or 'urronas') is a puzzle. It is not Spanish, and is either a word from some Mexican language or a mistranscription.

The curious character, Thomas Gage, an English Dominican friar who turned Puritan preacher, wrote[18] as though it were still used during his sojourn in Mexico (1625–26), but a close examination of the passage shows it again to be plagiarized from Gómara, this time (with some modernization of spelling) from the English translation by Nicholas[19]. Humboldt[4], who missed nothing, has no word of it; but by his time (1803) the draining of the lake had gone so far that it occupied only a fraction of its area at the Conquest.

The key phrase among these quotations is that of Sahagún, who refers to the 'clear blue' colour of tecuitlatl. This identifies it almost certainly as a member of the Cyanophyta, or blue-green algae. These primitive plants owe their colour to the presence of phycocyanin, a blue tetrapyrrole-protein pigment, which is sometimes accompanied by the related reddish phycoerythrin. On some sheets of water in the United States and Canada they grow in abundance at some seasons, and are known as "water bloom". They thrive in both fresh and brackish water, and some species are able to make use of atmospheric nitrogen[20], though this may not have been necessary in Lake Tezcoco, which presumably received most of the sewage from the city. The chroniclers do not make it clear whether tecuitlatl grew on the fresh or salt-water portions of the lake; but the latter was by far the larger, and the accounts stress the salty taste and good keeping qualities of the product. Humboldt[21] gave a figure for the density of the water which corresponds to about 2·5–3·0 per cent of dissolved salts, which were mainly sodium chloride and carbonate; sulphate was absent.

No published work has been traced on the use of any species of Cyanophyta as food. Indeed, cases of cattle poisoning have been ascribed on good evidence to "water bloom", and toxic substances have been isolated from the genera *Microcystis* and *Anabaena*[22]. Tecuitlatl, however, seems to have been eaten without ill effect, and even enjoyed. There is probably now little hope of identifying the alga on the spot; the great drainage schemes of 1607–1789 and even more of 1885–1900, followed by huge urban expansion, have radically altered the terrain of the Valley of Mexico. Indeed, the disuse of tecuitlatl may have been the consequence of a slight change of environment, causing the replacement of a palatable dominant species by an unpalatable or even toxic one.

THE EXISTENCE OF THE CROSSROADS POLICEMAN

By JOHN SHOTTER
Department of Psychology, University of Nottingham

In the physical world, according to the Second Law of Thermodynamics, there is a general tendency towards a decrease of order. Maxwell once lamented the lack of demons. He said that the fight against increasing entropy could be won if there were demons who could sit by a door in the side of a vessel containing a gas at some temperature above absolute zero, and who would open the door and let through particles satisfying some definition of "fast". The same demons would otherwise do nothing. (This is a slight reformulation of the principle; a single attribute dimension of linear velocity has been used to name the particle, and a certain value on it, namely, "faster than n ft./sec", has been taken as the criterion for the decision of the demon. The demon has the relatively simple task* of recognizing these names.)

It would seem that in the biological world the equivalents of Maxwell demons exist as there is a possibility that there is increasing organization in the same sense as that which the Second Law of Thermodynamics infers. If we were able to construct a machine that would make use of the patterns of inputs and outputs from a process and extract them from the "rules of ordering" that the process exhibited in its performances, then it would be possible for the machine to construct in part of itself a sub-machine that would mimic, in every way known† to the machine, the process under observation[2].

This article briefly sketches the nature of a mechanical procedure whereby the presence of an elementary class* of Maxwell demons can be detected and machines constructed automatically to mimic their behaviour. No weighting or averaging processes are used as were applied, for example, by Selfridge[3]. The idea here is that if demons, in making decisions about events, make use only of distinctive features of events, then these must ultimately be accessible to an external observer. If a demon's decision rule is thought of as a relational structure embodying these distinctive features linked to each other by the appropriate ordering relation, then it is possible to discover the nature of this structure simply from the performance of the demon. This is done by noting that each individual ordering produced by the demon gives rise to a set of ordered distinctive features; every observation is used to reveal fragments of different possible relational structures. As the decision rule is determinate, it is found that, as experience accumulates, only one set of fragments when collected together produces a coherent structure. The process makes use of both a passive initial process, which is sensitive to and extracts the set of distinctive features (which may be thought of as something like Hubel and Wiesel[4] units) and the ordering relations between them, and then later an active process which makes use of this information to form the relational structure which represents the decision rule used by the demon; an analogy with present-day approaches to the central nervous system is intended. The procedure is more of the nature of a discovery process than a learning process for the reason that there is no component in the procedure equivalent to reinforcement. (Elsewhere, I have sketched out[5] the procedure more fully and have outlined a mechanical scheme that extracts a recursive rule system using only example productions of that system. Moreover, in a forthcoming paper, I shall extend the scheme so that a machine learns a systematic way of providing descriptions of objects sensed by it in its environment. The description provided comes from within a closed system of descriptions in the sense of that proposed by Grimsdale *et al.*[6].)

The nature of the problem and its solution can be stated in very simple terms, using an everyday example. A number of important assumptions will be involved; these will be indicated by $A1$, $A2$, $A3$. The problem is:

> P: "By observing only the patterns of time intervals between cars entering and leaving a crossroads, where the cars involved have distinctive features, can we decide whether or not the state of affairs is the same as if a policeman were at the crossroads directing the traffic in an orderly fashion ?"

To make the problem quite explicit, it must be considerably idealized. There are two main one-way roads. No left or right turns are allowed; neither are crashes, overtakings and spontaneous creations, and furthermore the crossing point must be clear of cars before observation is started (that is, the initial state of affairs is known). In other words, we assume ($A1$) that the specific ordering of the cars that prevailed when they were observed, on the two roads, just before they entered the cross-over point is preserved when they are observed leaving it. Only the pattern of inter-car time intervals is disturbed; this is because cars on the two roads will occasionally coincide and, because they can only cross one at a time, they must be ordered, and in the process one car will suffer a relative delay. The crucial assumption ($A2$) is: If the policeman imposes certain distinctions Dp on the cars so that he can direct them, then the number of these is finite and, moreover, the observers of the process must be able to make a finite number of distinctions Do which include at least Dp, that is, $Do \supseteq Dp$. The "shape" of the name by which these distinctions are known to both parties involved is not important so long as they are distinct for the parties concerned; arbitrary names can be assigned. The policeman may be following the rule (PR): "Whenever there is a coincidence of cars at the crossroads, always allow the make 'X' through before the make 'Y' and 'Y' before 'Z'. And when two cars of the same make coincide, allow that on road one ($r1$), the road on my right, through first. Otherwise, do nothing." The observers may, however, know the makes that the policeman calls "X", "Y" and "Z" by the names "A", "B" and "C", and the roads that he calls "$r1$" and "$r2$" they may call "$R1$" and "$R2$"; it does not matter. Clearly the policeman's rule must be comprehensive; if there are n makes of car (n finite), it must include an ordering of all the n makes; he must not be confronted with a make that he does not recognize. In our example we shall assume that there exist just four makes of cars in all the world, called by the observers (A, B, C, D).

* If the demon's task were to let through particles named with grammatical, but not necessarily sensible sentences, and not let through any named with non-grammatical sentences—for example, to let through a particle named "Colourless green ideas sleep furiously" and not to let through "Furiously sleep ideas green colourless"—then the automatic procedure discussed here would be inadequate. A more competent demon would be required; we must posit a range of classes of demons with varying competences. (The example given is derived from Chomsky[1], whose publication also provided most of the inspiration for the work reported here.)

† By "every way known" I mean that the mimic will exhibit behaviour which will correspond to a rule system (an input/output transformation matrix) derived from the experience that it has gained, so far, of the process controlled by the Maxwell demon; for every example of behaviour, exemplifying a particular rule, emitted by the process controlled by the Maxwell demon, the mimic will be able to provide an example illustrating the same rule. If the Maxwell demon has never had occasion to exemplify one of its rules, then clearly the mimic has been denied the appropriate information, but soon after receipt of such an example the mimic will be able to supply an example performance which will also exemplify that. This is an important point.

To show how the process observers could be mechanized the nature of their task must be shown quite clearly. The arrangement of process observation is shown in Fig. 1.

It will be seen that there are four clerks (iC_1, iC_2, oC_1, oC_2), who quite passively react to events on the television screens. They have each been provided with a coding sheet and a print-out clock. When a car passes, the clerks record both its time of passing and its make. A fragment from a typical record written by clerk iC_j, $j=1,2$, might be:

$$\ldots, ({}_0t_{10}, R_j, A), ({}_0t_{11}, R_j, B), ({}_0t_{12} R_j, D), ({}_0t_{13}, R_j, A), \ldots \quad (1)$$

where ${}_0t_{10}$ denotes the magnitude of the tenth time interval, the recording of which was occasioned by the passing of a car and it was a car of make "A". (The time at which the observation period was begun is arbitrary, but all the clocks were started at the same time and synchronized.) The clerk oC_j uses a similar recording procedure but slightly different marks, so that the fragment of his record that relates to the same cars (we know they are the same due to $A1$) will appear as:

$$\ldots, ({}_0t'_{10}, R_j, A), ({}_0t'_{11}, R_j, B), ({}_0t'_{12}, R_j, D), ({}_0t'_{13}, R_j, A), \ldots \quad (2)$$

I think it is clear from the duties of the clerks as stated that their task could be mechanized quite easily. The four makes of car could each carry a plate engraved with a two-place binary code, A-00, B-01, C-10, D-11, and photocells could then activate the print-out clock and assign one of the binary coded names. Thus records such as (1) and (2) could be produced mechanically.

At the end of the observation period, which is of an arbitrary length (but see †), the clerks bring their records to the co-ordinator (CO). He co-ordinates the two input records and the two output records by ordering the individual observations in order of time of observation. As the clock supplies a time assignment of finite length, if there have been any crossroad coincidences then the CO is bound to find cars within the input records with identical time assignments. (The problem is slightly glossed over here, but it is clearly possible to state the proper conditions for this specific problem.) A typical record that the CO forms, by amalgamating the records of iC_1 and iC_2, might be:

$$I/P: \; //({}_0t_1{}^{(1)}, R1, A), \left\{\begin{matrix}({}_0t_2{}^{(2)}, R1, A)\\ ({}_0t_1{}^{(2)}, R2, B)\end{matrix}\right\}, ({}_0t_3{}^{(3)}, R1, C), ({}_0t_2{}^{(4)}, R2, A), \left\{\begin{matrix}({}_0t_4{}^{(5)}, R1, B)\\ ({}_0t_3{}^{(5)}, R2, C)\end{matrix}\right\},$$
$$({}_0t_4{}^{(6)}, R2, C), \left\{\begin{matrix}({}_0t_5{}^{(7)}, R1, B)\\ ({}_0t_5{}^{(7)}, R2, A)\end{matrix}\right\}, \left\{\begin{matrix}({}_0t_6{}^{(8)}, R1, B)\\ ({}_0t_6{}^{(8)}, R2, C)\end{matrix}\right\}, ({}_0t_7{}^{(9)}, R2, C), \left\{\begin{matrix}({}_0t_7{}^{(10)}, R1, A)\\ ({}_0t_8{}^{(10)}, R2, A)\end{matrix}\right\} // \quad (3)$$

where "//" is a beginning and an end marker, and k in ${}_0t_k{}^{(j)}$ is the time ordering before the amalgamation of the records, while (j) is the time ordering after. The ordering depends only on a magnitude judgment and can easily be mechanized (it is one-dimensional). Clearly in the O/P record there will be no coincidences; those that appear in the I/P record will be ordered. The output record formed by the CO from the records of oC_1 and oC_2 which corresponds to the foregoing can now be presented:

$$O/P: \; \overset{1.}{//({}_0t_1{}'^{(1)}, R1, A)}, \overset{}{({}_0t_2{}'^{(2)}, R1, A)}, \overset{}{({}_0t_1{}'^{(3)}, R2, B)}, \overset{}{({}_0t_3{}'^{(4)}, R1, C)}, \overset{}{({}_0t_2{}'^{(5)}, R2, A)},$$
$$\overset{2.}{({}_0t_4{}'^{(6)}, R1, B)}, \overset{}{({}_0t_3{}'^{(7)}, R2, C)}, \overset{3.}{({}_0t_4{}'^{(8)}, R2, C)}, \overset{}{({}_0t_5{}'^{(9)}, R2, A)}, \overset{}{({}_0t_5{}'^{(10)}, R1, B)}, \quad (4)$$
$$\overset{4.}{({}_0t_6{}'^{(11)}, R1, B)}, \overset{}{({}_0t_6{}'^{(12)}, R2, C)}, \overset{5.}{({}_0t_7{}'^{(13)}, R2, C)}, \overset{}{({}_0t_7{}'^{(14)}, R1, A)}, \overset{}{({}_0t_8{}'^{(15)}, R2, A)}//$$

Given that the records as shown in (3) and (4) are marked as complete (the beginning and end are marked with "//"), can we now decide whether the ordering is systematic or not?

We shall now consider the coincidences marked "1" to "5" in (4). If there is any ordering, according to $A2$, it must arise from distinctive features. We can now consider a record reduced just to the relations:

$$//(R1/R2, A/B), (R1/R2, B/C), (R2/R1, A/B), (R1/R2, B/C), (R1/R2, A/A)// \quad (5)$$

where "/" means "precedes" and is transitive.

Bearing in mind $A2$ and introducing a further assumption ($A3$)—namely, that policemen are determinate beings, that is to say that once they have decided to follow a certain course of action they do not change, we can allow the CO to search for identical relations exhibited in (5). The CO does not have to take all the distinctions Do that he knows and form preliminary "hypotheses"; in the first term of expression (5) there are already two suggestions. The CO now takes these and systematically searches among the others (that is not difficult to arrange) for others identical to them. Only an "identical or different" judgment is involved here; the process of taking an item, comparing it with a set of other items and making such a judgment is an everyday task for a computer if the item can be represented in a binary code—here it can. Thus, this process can be mechanized. As a result of his search and comparison procedure, the CO finds that the only set of relations that does not (on the information available to him, see †) transgress $A3$ is:

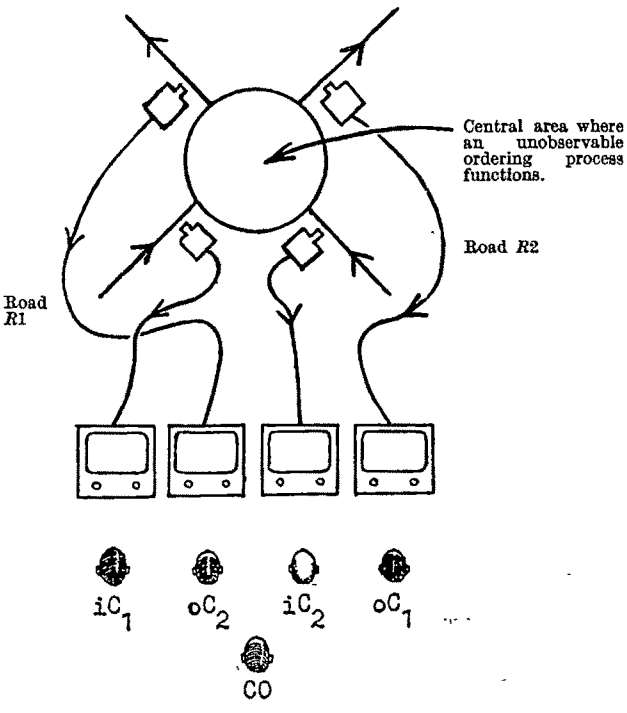

Fig. 1

$$//(A/B), (B/C), (A/B), (B/C), (A/A)// \quad (6)$$

These may be summarized by:

$$\begin{bmatrix} A/B/C \\ A/A \end{bmatrix} \quad (7)$$

In expression (6) the last term (A/A) suggests the possibility of a further distinction. If it were found that

associated with every relation, such as A/A, there was some other specific relation, for example (fragment):

$$\ldots (R1/R2,A/A), \ldots, (R1/R2,C/C), \ldots, (R1/R2,B/B), \ldots \quad (8)$$

then, with the information which we have so far (see †), we could summarize the policeman's hierarchical decision rule as:

$$\begin{bmatrix} A/B/C \\ R1/R2 \end{bmatrix} \quad (9)$$

This means that he is behaving as if he were following a rule like the PR one already mentioned. If the relations between the distinctions mentioned on the top line of (9), that is, "$A/B/C$", are insufficient to make a decision, then he ignores them and turns to the relation between the distinctions mentioned on the next line of (9), that is, $R1/R2$.

The sketch of the discovery procedure is now in essence complete. The CO as a result of his search among the two sets of relations used here, the $(R1,R2)$ set and the (A,B,C,D) set, may conclude that so far as it is known (see †) the (A,B,C) set is systematic and that the state of affairs at the crossroads is the same as if there were a policeman there directing the traffic according to the hierarchical decision rule (9). However, the way in which the CO and the clerks do this and the way in which it may be mechanized has been sketched and thus they may all be replaced by a general-purpose computer provided with photocell inputs and a suitable programme. In this way the computer is able to structure part of itself, by following the procedure already outlined, so that as a result of observing the pattern of inter-car time intervals at the inputs to the crossroads, it could activate something which would order the cars leaving the crossroads in an identical fashion to that which has just been demonstrated with a policeman. (There is an inherent and very important time lag.) Thus the computer has mimicked the behaviour of a living thing; actually the behaviour of the policeman with respect to the cars was so systematic that he could have been replaced by a machine in the first place, but that is a peculiarly human intuitive judgment and not one that a computer could make.

We must now briefly discuss what would happen if the policeman were not there. If, and only if, the pattern of relations (10) had been obtained:

$$//(R1/R2,A/B),(R2/R1,B/A),(R1/R2,B/C),(R1/R2,C/B)// \quad (10)$$

then no systematic set of relations can be found and we must assume that it is just as if a policeman were not there and that individual motorists were deciding for themselves using their own individual 'precedence criteria'.

We note in this example that the policeman did not ever encounter the make of car that the observers knew as "D"; thus although the policeman's rule system contained a rule appropriate to "D" and was, in the terms of the names assigned by the observers:

$$\begin{bmatrix} A/B/C/D \\ R1/R2 \end{bmatrix} \quad (11)$$

the observers have only sufficient information to construct (9). The discussion in relation to the specific problem is now complete.

I would now like to discuss the generality of the procedure and to state a problem. Perhaps it will be best to begin by discussing the nature of decision rules. $A2$ is equivalent to an assumption that if the policeman is using some distinction related to the cars, then it must be possible to code that distinction (in, say, binary code). If that is the case, then it is not too difficult to see how the procedure could be extended to cope with a finite number of attribute dimensions each containing a finite number of distinctions. What now happens if the policeman uses a table of random binary digits such that when there is a coincidence and his table shows an "0", he lets the car on his right go first, and when it shows "1" he lets the car on his left through? In this event, the CO decides that the state of affairs is the same as if there were no policeman there at all. If the policeman is consulting a table of numbers generated by a specific infinite non-recurring decimal, then the CO can only discover this by pursuing the specific hypothesis that this is so and cannot work in the manner described, that is, without a hypothesis. The assumptions $A1$ and $A3$ must now be discussed. Assumption $A3$ is essential in this sense; the procedure here takes time to extract the policeman's rule system, but would eventually achieve the characterization (11) of the policeman's system. The policeman might now reverse all his rules for a while and then change back to the system (11); in this event the procedure would extract:

$$|\underline{\rightarrow RS1 \rightarrow RS2}|$$

(where $RS1$ is $\begin{bmatrix} A/B/C/D \\ R1/R2 \end{bmatrix}$, $RS2$ is $\begin{bmatrix} D/C/B/A \\ R2/R1 \end{bmatrix}$, and "$\rightarrow$" means "... followed by ...")

so long as the rate of change of the rule systems by the policeman was sufficiently slow for the procedure to work, otherwise the CO would decide that the policeman was behaving in a random manner.

I would now like to state a problem—it is in two parts: "Can the individual decision rules of the policeman be extracted in the situation depicted in Fig. 2, under the following conditions: (i) when assumption $A1$ still holds? (ii) when the restriction on left or right turns is relaxed?

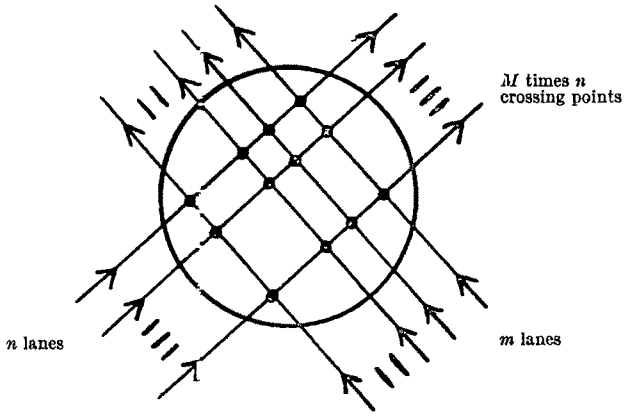

Fig. 2

A solution of this problem will have: (*a*) if (i) is solved, a relevance for automatic discovery procedures for phrase structure grammars; (*b*) if (ii) is solved, a relevance for transformational grammars. Only transformational grammars are adequate for natural language[1]. The possibility that the solution to (ii) will provide a specification for automatic machines capable of describing patterns will be considered elsewhere.

I thank Dr. Alan Gauld, who pointed out the similarity between the policeman problem and the Maxwell demon situation, and Dr. John Newson for a discussion which forced me to think even more about these problems.

BOOK REVIEWS

THE GEORGIAN PLANET

The Planet Uranus

A History of Observation, Theory and Discovery. By A. F. O'D. Alexander. Pp. 316. (London: Faber and Faber, 1965.) 70*s*.

URANUS, the "Georgian Planet" as William Herschel liked to call it after his discovery on March 13, 1781, is the third largest planet in the solar system, and with its five satellites, Uranus has provided amateur observers, astronomers and mathematicians with some fascinating problems over the past 180 years.

The planet is remote from the Earth, at twice the distance of Saturn. It is therefore too far away to excite the attention of even the most advanced planners of space travel. However, it is almost visible to the naked eye, and it can certainly be easily examined, when suitably placed in the sky, by anyone using binoculars and a small telescope. Dr. Alexander wrote an extremely well-documented account of the planet Saturn in 1962, and he has now followed this up by an equally scholarly book on Uranus. He has compiled from primary sources an encyclopaedic history, arranged chronologically, of the initial discovery, and subsequent observations up to 1963, of Uranus and its satellites. The wealth of detail provided and the historical references cannot be found elsewhere within one volume. There are quotations (translated), diagrams, data and photographs from many of the original sources and from reports of past astronomers, both American and European. Those who are interested in names will be delighted with the discussions on how the "Georgian" planet changed its name to Uranus and how the names chosen for the satellites have a relationship with Shakespeare. Those who like the thrill of detection can read how the satellites were lost and how in looking for them three others were found, and also how difficulties encountered in the calculation of the orbit of Uranus led to the mathematical discovery of the planet Neptune. For the spectroscopist and physicist, the spectral investigation will be of considerable interest, since they finally proved that, as was first recorded in *Nature* (134, 418; 1934), methane is a major constituent of the atmosphere of Uranus. It was on February 16, 1948, that the fifth satellite, Miranda, was photographed by P. P. Kuiper for the first time. The satellite is 123,000 km from Uranus and of about the seventeenth magnitude. It had not previously been observed visually. The exceptional thing about Uranus and its system is that Uranus rotates and its satellites revolve in the retrograde sense, when referred to the ecliptic. Dr. Alexander tells us that during 1966 the Sun passed through the plane of the satellite orbits during February, and the Earth in March with another passage to come in July.

The Planet Uranus is a standard work and reference source for use by both specialists and others. The masterly description, though fully detailed, is pleasant to read. It is almost too thrilling to leave before completion. Doubtless during the next decade there will be many new exciting discoveries to add, as astronomy (both from the Earth and from space) is now in a stage of rapid advance, and it is to be hoped that Dr. Alexander will not only continue his series of volumes on the planets, but will also follow up his present book with a sequel, including perhaps any radioastronomical observations of interest which have been omitted from *The Planet Uranus*.

S. WEINTROUB

GRAVITATIONAL COLLAPSE

Gravitation Theory and Gravitational Collapse

By B. Kent Harrison, Kip S. Thorne, Masami Wakano and John Archibald Wheeler. Pp. xvii+177. (Chicago and London: University of Chicago Press, 1965.) 6.50 dollars; 48*s*.

GRAVITATIONAL collapse occurs when a collection of matter is of such a size that the inward gravitational attraction is greater than the elastic forces generated by compression. It is obvious that collections of matter of about planetary mass are stable, but it was found by Landau in 1932 that when an amount of cold matter of a critical mass of the order of the mass of the Sun is assembled together the system becomes unstable. During the late 'thirties a beginning was made in studying such collapse, notably by Oppenheimer and Volkoff. Although such collapse could be studied in Newtonian gravitation it is evident that eventually the matter will reach such a state of compression that general relativity becomes essential. As a result of the theoretical analysis of this problem which has been pursued for the past few years, two questions present themselves urgently for consideration: (1) Does the theory introduce any restrictions which would prevent collapse from proceeding to completion? (2) When matter collapses can the baryons in it escape destruction?

Wheeler's opinion is that at least in the case of cold matter, for which he has carried out the analysis in detail, there is no escape from eventual collapse and no escape from the disappearance of baryons. By the same token there is no escape from the serious contradiction between general relativity and any quantum field theory which holds to the conservation of baryon number. In the present book the authors expound their theory starting from the basic principles. The starting point could be described by saying that a first-rate genius ignorant of general relativity would be able to read the book without trouble from the beginning. Lesser mortals may well find training in general relativity and quantum mechanics an advantage.

C. W. KILMISTER

GROUP THEORY IN CLASSICAL AND QUANTUM PHYSICS

Theory of Groups in Classical and Quantum Physics

By Théo Kahan, in collaboration with P. Cavaillès, T. D. Newton, G. Lochak, R. Gouarné, G. Rideau and R. Nataf. English translation edited by A. R. Edmonds. Vol. 1: Mathematical Structures and the Foundations of Quantum Theory. Translated by H. Ingram. Pp. xxiii+566. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 210*s*.

SINCE the beginning of the nineteenth century, the influence of the physical sciences on the development of mathematics has gradually diminished until, at the present time, the theoretical physicist depends to a large extent on the pure mathematician for the mathematical techniques that he may require in his attempts at creating order out of the data provided by the experimental physicist. Regrettably, many theoretical physicists still remain unacquainted with the methods of modern abstract mathematics even though they are well aware that without the pre-existence of abstract algebra and in

particular group theory, the remarkable recent developments in the study of the fundamental symmetries of elementary particles would have been seriously retarded.

The volume under review is the first of a treatise written by Théo Kahan and several eminent collaborators which is devoted mainly to the group structure. It was originally written in French and published in 1960 by Dunod, of Paris, under the title *Théorie des Groupes en Physique Classique et Quantique*. The translation into English by H. Ingram is good. The main objectives of the treatise are, first, to provide an account of axiomatized mathematics and the theory of abstract groups directed specifically towards the theoretical physicist, and secondly, to investigate with considerable thoroughness the different applications of group theory to the various branches of physics.

The book is divided into seven parts. The first of these is entitled "Theory of Groups and Axiomatized Mathematics for the Use of Physicists" and was written by P. Cavaillès and T. Kahan following the axiomatic method of the team of French mathematicians calling themselves Nicolas Bourbaki. The first part concludes with an appendix by G. Lochak on integration over the topological groups. The next part of the book is concerned with the "Inhomogeneous Lorentz Group" and was written by T. D. Newton. This is followed by a part on the "Theory of Abstract Groups", written by R. Gouarné. Inevitably, a certain degree of overlap with the contents of the first part of the book occurs here. Some repetition is, of course, quite helpful to the reader although it would have been advantageous if the authors had used the same notation. Parts IV and V, written by G. Rideau, deal with the "Theory of Representations" and the "Permutation Group", respectively. Then comes a part written by T. Kahan concerned with the "Theory of Groups and Axiomatics of Quantum Mechanics". It is quite short and develops the elements of quantum theory from five axioms, the Dirac approach being followed fairly closely and the connexion with group theory discussed. Lastly, there is a part on the "Group of Rotations", written by R. Nataf.

The general aim which motivated the preparation of this treatise is certainly a good one and, on the whole, the first volume has turned out very well, although it could have been written in a more unified manner by a single author. However, the translation of the first volume is very welcome particularly when taken together with the second volume, so far unpublished, which deals with the applications of group theory to the various branches of physics. B. L. MOISEIWITSCH

SURFACE IMPACT

Atomic and Ionic Impact Phenomena on Metal Surfaces

By Manfred Kaminsky. (Struktur und Eigenschaften der Materie, Band 25.) Pp. xii+402. (Berlin and New York: Springer-Verlag, 1965.) 58 D.M.

A MONOGRAPH on a large subject imposes rigid limits on an author. Dr. Kaminsky decided to restrict *Atomic and Ionic Impact Phenomena on Metal Surfaces* strictly to metal surfaces and even within this framework he had to be selective. He states plainly in the preface that his selection of topics reflects principally his own interests in the various activities in the field and is not intended to reflect their relative importance.

In five introductory chapters Dr. Kaminsky gives brief descriptions of the structure of metal surfaces, forces which can act on an atom or molecule impinging on the surface and the energetics of surface reactions. Each of these topics could easily become a subject of a separate monograph, and readers familiar with these fields will feel that perhaps less than justice has been done to their subjects. I was certainly disappointed to find no reference to the work of Farnsworth, Landner and Morrison and others on the atomic structures of metal surfaces, but this was compensated by very full treatment given to some of the other topics.

The chapter on sputtering by ion bombardment is long and detailed and much information and data are also to be found in the chapters dealing with accommodation coefficients, surface ionization, ion scattering, ion neutralization and the kinetic emission of electrons by bombardment with charged and uncharged particles. There are briefer chapters which deal with the elastic collisions, formation and emission of negative ions and the de-excitation of metastable atoms and ions on metal surfaces.

There is a considerable degree of uniformity in presentation throughout the book. Each chapter starts with a clear physical picture of the phenomenon which is to be discussed and this is followed by the theoretical treatment, experimental methods and results. Whenever possible experimental data published by a large number of workers are collected into tables most convenient for easy reference and comparison. Chapters are divided under numerous sub-headings which are very useful when the reader is hunting for a specific information or reference; in consequence, however, the list of contents is difficult to read and looks monotonous. Printing main chapter titles in heavier type would help to relieve the monotony and make it easier for the reader to find his bearings.

The rate of growth of surface science is considerable and appears to be increasing. There are new graduates entering the field and older research workers established in other fields of science are developing interest in surfaces. Dr. Kaminsky's book satisfies, therefore, a real need in providing a very readable account of an important topic. The book should be of value to senior students and research workers. There are more than 800 references to papers, books and review articles published before 1963, including many classics published at the beginning of this century or earlier. J. ADAM

INTERPRETING ORGANIC SPECTRA

Interpretation of Organic Spectra

Edited by D. W. Mathieson. Pp. ix+179. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965. Published in association with the Royal Institute of Chemistry.) 42*s*.

NUMEROUS text-books have been written on the interpretation of infra-red, nuclear magnetic resonance and mass spectra, in which group frequencies, chemical shifts and fragmentation patterns have been discussed and tabulated. With these to hand, the main hurdle to be faced by the novice spectroscopist is the interpretation of actual spectra.

In *Interpretation of Organic Spectra*, based on seminar sessions at one of the Summer Schools in Organic Chemistry held under the aegis of the Royal Institute of Chemistry, about ten spectra of each type are analysed in detail. For pedagogic reasons the amount of ancillary information regarding each sample is kept to a minimum, in order that both the strength and the limitations of each technique may be apparent. Additional infra-red and nuclear magnetic resonance spectra of unknown compounds are included as problems.

In each section the samples have been well chosen to show the capabilities of the particular technique, and the substances are obviously representative of those examined in a typical analytical laboratory. As such, a number of them contain impurities, which are usually indicated in the worked examples and may themselves provide useful experience. However, at least two of the unknown infra-red spectra include extraneous bands, which can only cause confusion. The novice is also liable to be confused by the three different formats used for the infra-

red spectra and by the absence of a τ scale from several of the nuclear magnetic resonance spectra which are nevertheless interpreted in terms of τ values.

The treatment of the three sections varies in the amount of background information given. The nuclear magnetic section, contributed by J. A. Elvidge, includes sufficient data on chemical shifts, spin-coupling constants, etc., for it to be used without reference to other works. In the interpretation it is assumed that the empirical formula of each sample is known, a circumstance not always achieved in actual practice. The infra-red section, by J. K. Brown, K. J. Morgan, C. J. Timmons and D. Whiffen, is based on assignments published in specialist works, such as that of Bellamy, and some such reference book is required for the interpretation of the unknown spectra. In the section on mass spectrometry, by A. Quayle and R. I. Reed, the examples are chosen to illustrate the fragmentation behaviour of most classes of compound, and appropriate literature references are given. Each spectrum is interpreted either on the basis of the "z-number" or of the relative abundance of the parent and $(P+1)^+$ ions. Complete identification is frequently only possible by reference to published spectra.

For anyone concerned with only one branch of spectroscopy the price may seem a little high, but the book has an added value in providing a unique comparison of the scope of these techniques and of the different approaches required for interpretation of the three types of spectra.

R. J. MESLEY

PRACTICAL INFRA-RED SPECTROSCOPY

Laboratory Methods in Infrared Spectroscopy

Edited by R. G. J. Miller. Pp. 164. (London: Heyden and Son, Ltd., 1965.) 45*s*.; 6.50 dollars.

ONLY a few years ago infra-red spectroscopy was the almost exclusive province of the specialists, who knew every optical and mechanical principle involved in the construction of their spectrometers and who by trial and error had developed effective means of extracting spectral information from even the most intractable samples. To-day, with the easy availability of relatively inexpensive spectrometers, it is inevitable that many of them are in the hands of operators with little spectroscopic experience. The aim of this book is to pass on to such people some of the accumulated "know-how" of the experienced spectroscopists and the specialists in particular fields.

There are chapters on the operation of a spectrometer, the recording of a spectrum and on infra-red optical materials, but the bulk of the book is concerned with sample preparation. In addition to a general chapter on the handling of solid, liquid and gaseous samples, there are sections on high- and low-temperature spectroscopy, chromatography as a means of sample preparation, and special types of sample such as aqueous solutions and dispersions, natural and synthetic fibres, and insoluble polymers and rubbers. A final chapter on the orientation of crystals differs from the remainder in introducing a number of theoretical calculations, but for the most part this is essentially a practical manual.

The contributors, who are too numerous to mention individually, are acknowledged experts in their respective fields, and between the covers of this slim volume may be found a wealth of practical suggestions and recommendations based on years of experience. The book is intended primarily for those with little spectroscopic experience, with the object of improving the quality of the spectra they produce, but there can be few spectroscopists who will not find in it some useful hints or stimulus for further work.

R. J. MESLEY

TISSUES AND ORGANS

Organogenesis

Edited by Robert L. DeHaan and Heinrich Ursprung. Pp. xi+804. (New York and London: Holt, Rinehart and Winston, 1965.) n.p.

FOR those who might expect *Organogenesis* to be a compilation of embryo morphology there are some surprises. We are introduced to work which should be better known and to younger and older workers whom we might not otherwise encounter. In the first section, Heinrich Ursprung reviews biochemical genetics, but does not mention the essential chemical contributions of Gobind Khorana. The author's principal purpose is to imply that specific non-histone molecules stimulate normal development by attachment to and detachment from particular loci, at the right times and within the right cells. This has not been shown. E. H. Mercer describes the histogenesis of the skin of the tadpole and J. P. Trinkaus discusses morphogenetic movements.

Bengt Kallen contends that early proliferations and migrations within the brain determine its morphogenesis. Ray Watterson discusses, principally, the migration of pre-mitotic and post-mitotic nuclei, to and from the ependyma. R. W. Sperry concludes that the growing tip of a neurone must possess a unique specificity which determines its growth, connexions and functions. This paper should be read by every young biologist. Rita Levi-Montalcini and Pietro Angeletti describe recent work with the nerve growth factor discovered in consequence of Elmer Bueker's discovery, in 1948, of the neurogenic effect of mouse sarcoma 180. Vincent Wigglesworth reminds us that arthropod nervous systems display differentiations as interesting as those of vertebrates. Alfred Coulombre assesses the development of the vertebrate eye with the aid of 274 references. This is a formidable conclusion to a sterling section.

Rudolpho Amprino reviews the dispute about the inductive role of the apical, ectodermal ridge of the chicken limb bud. The dispute is placed in context by J. Milaire, who discusses the genetics of abnormal limb development in mammals. Benjamin Moffett concludes that normal joints undergo morphogenetic change throughout the life of the individual. Elizabeth Hay confirms the occurrence of dedifferentiations following the amputation of the urodele limb. Hay argues that dedifferentiation strips muscle and cartilage cells of their differences and both kinds of dedifferentiated cells form cartilage and muscle during regeneration. Irwin Konigsberg describes the fusion of mononuclear cells to form skeletal muscle. There is a reference to the difficulty of preparing pure skeletal myosin from embryos, but it is not pointed out that myosin preparations from adults are variable and inhomogeneous also. (Kay, C. M., in *Muscle*, edit. by Paul, W. M., *et al.*, 109. Pergamon, 1965.)

Eugene Bell reports that feather follicles accumulate polysomes which do not begin to incorporate amino-acids into protein until late on the thirteenth day of incubation of the chicken egg. At this time the RNA strands of the polysomes become susceptible to degradation by exogenous ribonuclease and to unknown, endogenous agents. The endogenous degradation is slow. Bell does not report experiments which distinguish between low levels of endogenous ribonuclease and resistance to the endogenous ribonucleases which are ubiquitous in living tissues according to Wilfred Razzell.

The formation of the amniote heart is linked to the formation of the liver. Contact with presumptive heart mesoderm endues some of the endoderm with the capacity to form liver, and the presumptive heart cells then migrate caudad over the surface of the endoderm which, itself, shifts anteriad and mediad as both tissues swing into the midline during the formation of the foregut; the cardiac mesoderm in front, the hepatic endoderm behind, and

additional mesoderm between them. This additional mesoderm induces the hepatic endoderm to form the liver. The formation of the foregut is essential to the full fusion of the cardiac primordia (Szepsenwohl, J., *Arch. d'Anat. d'Hist. et d'Embryol.*, 17, 307; 1933). Excepting the omission of references to Szepsenwohl, to the apparent inability of the medial endoderm to facilitate fusion except by forming the foregut, and to C. Dareste who first produced double heart embryos and inferred that the heart arises from a pair of bilateral primordia, the readable review by Robert Dehaan of cardiac morphogenesis is comprehensive. Y. Croisille and N. M. LeDouarin discuss the morphogenetic and biochemical differentiations of the liver. The discussion of lactate dehydrogenase might have made fuller use of the quantitative data of Joel Solomon. On p. 450, the authors strip the subject of growth regulation of its semantic gloss and reveal its chemical inadequacies.

Sergei Sorokin, Thomas Shepard and Robert Auerbach discuss the lung, the thyroid, and the thymus, respectively. Sorokin's paper is a model of authoritative elegance and Shepard's is a clear exposition. The functions of the thymus have been elucidated because of Auerbach's restatement of the origin of the thymus. There must be very few instances of embryological work which prompted new insight into adult physiology.

Adesanya Grillo and Theodore Torrey discuss the pancreas and the kidney, respectively. Grillo's discussion includes the effects of insulin on the embryo. Torrey argues for the concept of a 'holonephros' for which some of the evidence has been provided by the electron microscopy of T. S. Leeson.

The final section is devoted to the reproductive system. L. G. Gallien reviews the genetic control of sex differentiation. On p. 595, in referring to fertile ovaries of *XO* mice, the wording should read "an insufficient quantity of masculinizing genes". Alfred Jost suggests that the mammalian testis secretes an inhibitor of the ovary and the Müllerian duct which is not identical with the steroid androgens. Dorothy Price and Evelina Ortiz suggest that the inhibitor is a steroid androgen. Giovanni Chieffi places this difference of opinion in perspective by comparing mammals with other vertebrates. He infers that the gonads secrete sex-determining substances which are not identical with the classical oestrogens and androgens. Lemen Wells briefly reports some of the evidence for endocrine function in the foetus. Terrell Hamilton and Ching-sung Teng report increased ribonuclease and decreased RNA in regressing Müllerian ducts. Helene Charniaux-Cotton summarizes the hormonal control of sex among the invertebrates.

The text is unusually free of bromides: "it is tempting to" (conclude or postulate) occurs twice. The authors and editors deserve congratulations for a coherent, sometimes eloquent, summation and projection of animal development. Their task took effort and co-operation which show. We find here a re-assertion of the importance of tissue structure in determining development and a recurrent implication that the essential mechanisms are located in the periphery of each cell. The assertion and the implication are timely reminders that metazoan cells depend on each other and their environment in ways that microbes do not know. R. F. RUTH

INVESTIGATING ACCIDENTS

Accident Research

Methods and Approaches. By William Haddon, jun., Edward A. Suchman and David Klein. Pp. xvi+752. (New York and London: Harper and Row, Publishers, 1964.) 15 dollars.

THERE is evidence in this book of the extent to which accidents cut across established medical disciplines and how many approaches are required before a composite picture begins to emerge. There is clear evidence of the difficulty of interpreting retrospective investigations where the level of reliability of the information on which these are based is variable; also of planning realistic prospective studies. This leads to "the use of generalizations based upon data known by informed research workers to be faulty". Such generalizations are then contradicted, leading to confusion and lack of confidence in the result of such enquiries. Many examples of conclusions based on inadequate information and issued with official authority are cited, particularly in relation to road traffic accidents. It is argued that "in many situations it is not practicable to conduct research that is completely adequate in every respect; but some would hold that so long as the research is done honestly and with complete awareness of the deficiencies of both material and methods employed such efforts may produce worth while contributions". This is a considerable pitfall in accident research. For example, because investigators are convinced that one or two factors play an important part in accidents of all or any kind, they investigate only these factors and even ignore the need for controls. An example given here is the statement that 20 per cent of those involved in accidents exceeded the speed limit, therefore 80 per cent of those involved were not exceeding the speed limit, therefore if 50 per cent of drivers exceed the speed limit they are safer than the ones who do not! The same kind of argument can be applied to accidents in the home, in industry, age groups, etc. As already mentioned, this is pointed out in the book, but should perhaps appear a bit more often and in bolder type.

The risk taken in crossing a road is reported from "studies representing highly original experimental work on the kind of decisions that are made by individuals in everyday life". The authors afterwards became aware that similar work had already been done and reported that the agreed conclusion was that "pedestrians are concerned with a time gap and not a distance gap in the traffic".

The risk of driving under the influence of drink, or drugs, is another case in which confusion has been produced by conflicting statistics, and support can be found in this volume for almost any point of view. Figures bearing on the influence of this factor in accidents vary from 0·5 to 50 per cent. However it is investigated, there is no doubt that an increasing quantity of alcohol influences first judgment then performance, and the two together in direct proportion to the quantity.

There is no doubt that some people are "accident-prone", and investigations are reported into various aspects of this problem. It is not surprising in view of factors already mentioned that no very firm conclusions are reached in, for example, an investigation "designed to test the hypotheses that accident prone children have greater aggressive drive as a result of nurturance frustration in an authoritarian home environment and greater aggression anxiety as a result of punishment for expression of aggression when compared with accident free children".

There is much valuable information painstakingly collected and appraised, making a start at trying to apply scientific parameters to preventive medicine in the accident field. There are many difficulties and pitfalls, but the effort and the volume are very worth while. J. C. SCOTT

MYXOMATOSIS

Myxomatosis

By Frank Fenner and F. N. Ratcliffe. Pp. xiv+379+15 plates. (London: Cambridge University Press, 1965.) 100*s*. net; 19.50 dollars.

IN 1859 a Thomas Austin imported twenty-four rabbits into Victoria, Australia. Rabbits had previously been imported into the country from the time of the first

settlement, but they had been mainly domestic. The 1859 consignment included some wild rabbits, and on liberation they multiplied rapidly. By 1886 the rabbits had reached all States in Australia and were proving a pest, mainly by competitive grazing on pastures with sheep and damage to young shoots and trees. This rate of spread was, however, paralleled and surpassed by that of the myxomatosis virus introduced in 1951. Originating in South America, where it was first noted as a disease affecting European rabbits kept in the laboratory, myxomatosis was the main cause of the reduction of the Australian rabbit population in certain areas to 20 per cent of the original numbers by 1955 and made it possible to control the menace. Similar introductions of the disease into France, England and Chile also caused a reduction in rabbit numbers. The choice of the correct strain, whether of rabbits or virus, led to successful spread of the virus, and it is appropriate that two scientists from Australia, where the rabbit problem was urgent and important and its investigation and control given scientific and financial support, should collect published and unpublished results and produce an authoritative work on myxomatosis.

Myxomatosis, which is caused by the myxoma virus, is characterized in the European rabbit, *Oryctolagus cuniculus*, by the mucinous tumours it produces on the skin of infective animals, leading eventually to death. In the American rabbit, *Sylvilagus brasiliensis*, the virus has formed a symbiotic relationship with its host, in which it only causes tumours at the sites of infection. In the book Prof. Fenner and Mr. Ratcliffe cover all aspects of the interaction of virus with the hosts it may affect. The chapters on the behaviour and ecology of rabbits contain many new findings based mainly on investigations carried out on animals kept in enclosures and show that the European rabbit is essentially gregarious with a striving for each individual to be part of a social group. Possibly because the main emphasis was on applied investigations, little has been reported on the fundamental aspects of myxovirus, despite the attractive dust cover, but the behaviour of the virus in tissue culture, its pathogenesis in animal hosts and the development of immunity are extensively covered. Studies in the laboratory and in the field on the transmission of myxovirus show the importance of winged insects, especially mosquitoes, and much basic information is given on the mechanical spread of virus from infected rabbit skin tumours to clean rabbits by way of the mouth-parts of the insect.

Of special interest are the investigations of the virulence of the virus after the initial outbreaks. The virus virulence was reduced from 99 per cent for laboratory rabbits to about 90 per cent. At the same time, there is evidence of genetic resistance developing in European rabbits.

The final chapters deal with the history and evolution of myxomatosis in North and South America, Australia and Europe. It is regrettable that in South America the relationship between myxoma virus and its natural host, *S. brasiliensis*, has not been extensively studied, despite the pioneer work of the late Dr. H. Aragão in Brazil, since it is possible that eventually a similar symbiotic relationship may exist in Europe and Australia between genetically resistant European rabbits and an attenuated myxoma virus. The spread of the virus in Australia and in France was equally rapid due to transmission by mosquitoes. In England it was slower, since transmission was by the rabbit flea. In California, where a different strain of virus is found, European rabbits have been equally at risk. In the Argentine an interesting epidemiological position exists, with European rabbits affected with myxomatosis in the south and American rabbits affected in the north.

The book throughout is interesting and pleasant to read, and contains many informative figures, tables, photographs and maps. Besides providing much information to workers in many disciplines on epidemiological methods and the hazards of biological control, it also emphasizes how much both of fundamental and applied importance can be discovered as a result of concentration on a practical problem.

R. F. SELLERS

WAYS OF WATERFOWL

Handbook of Waterfowl Behaviour

By Paul A. Johnsgard. Pp. xiv + 378 + 20 plates. (London: Constable and Co., Ltd., 1966.) 75*s*.

THE coming of the theory of evolution by natural selection resulted sooner or later in a rebirth, or at least a reorientation, of almost every branch of biology. But although Darwin himself wrote a pioneer book on behaviour, namely, *The Expression of the Emotions in Man and Animals*, the evolutionary way of looking at animal behaviour was slow to develop. Although Darwin's book had a great effect, it was a delayed effect—and it was not, in fact, until the coming of the modern ethologists that the species-characteristic fixed-action patterns of animals began to be sufficiently well described to use as taxonomic characters. This development represented a new tool that could be used to develop the comparative study of behavioural characters so as to throw new light on the evolution and relationships of species and also of higher categories. Among the pioneers in this field perhaps as many as four-fifths chose to work with birds. This was understandable. The Aves are characterized by the possession of highly elaborate stereotyped species-specific display activities ideal for comparative investigation. Among the groups most intensively studied were the *Anatidae*, the ducks, geese and swans, and the names of Heinroth and Lorenz will always be associated with the ethology of this group. Lorenz, in his classic comparative study of the movements of *Anatidae* (1941), was perhaps the first to show the great promise of this method. But no one man can get far with the inventory, the itemization, of the behaviour patterns found in a big group such as this without having access to a very extensive collection of material maintained under the best possible conditions. Even Lorenz in 1941, great wildfowl fancier though he is, lacked the facilities to carry the investigation beyond a certain point. Modern students of wildfowl behaviour have a unique advantage over all their predecessors. Mr. Peter Scott, by establishing the Wildfowl Trust at Slimbridge in Gloucestershire, and endowing it with the finest collection of waterfowl in the world, has provided research facilities which are unsurpassed. Many ethologists have worked at Slimbridge, but none has done more thorough and intensive work there than Mr. Paul A. Johnsgard of the University of Nebraska. This book gives the conclusions resulting from many years of investigation both at Slimbridge and in the field in many parts of the world. It is a fine piece of work containing detailed descriptions and more than a hundred pages of illustration. It will be indispensable to students of ethology, especially those concerned with bird behaviour.

W. H. THORPE

High Speed Pulse Technology

By Frank B. A. Früngel. Vol. 1: Capacitor Discharges—Magnetohydrodynamics; X-rays—Ultrasonics. Pp. xiii + 620. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 192*s*.

High Speed Pulse Technology is a translation, brought up to date, of the second edition of Dr. Frank Früngel's book in German. The translation is the work of three of his German collaborators; and though the English often falls short of the standards of Fowler, it is adequate.

Capacitor discharges have an enormously wide field of application in physics and in technology. They can be used first of all to produce very high-voltage pulses, as in the Marx generator, and shaped discharges of all sorts, from purposes ranging from the operation of magnetrons and klystrons to electric fishing. They can be also used for producing megamp current pulses for the operation of theta-pinch devices and the like. The energy can be converted into light-flashes for spectroscopy and for high-speed photography or into X-ray flashes for high-speed radiography. It can be converted into heat as in spot welding or into strong magnetic fields, which can find such varied applications as plasma generation, magneto-optical shuttering, and even metal forming by intense electrodynamic forces. In many of these applications the maximum of power is reached in a few nanoseconds and the current rise can be of the order of 10^{11} amp/sec. The sudden discharge of energy in gases and in liquids produces shock waves which can be used in echo-sounding and even for the explosive shaping of metals.

All these applications are thoroughly covered in the 600 pages of the book. Any physicist or engineer who is interested in impulsive processes in which the energy is stored capacitatively in the first place can find full descriptions of the state of the art in any of the branches, amply illustrated, and with a complete list of references. It is a standard work of reference which will be a valuable time and labour saver for anybody working in these fields.

D. GABOR

The Riemann Hypothesis and Hilbert's Tenth Problem

By S. Chowla. (Mathematics and Its Applications, Vol. 4.) Pp. xv+119. (London and Glasgow : Blackie and Son, Ltd., 1965.) 40*s*.

PROF. CHOWLA discusses a number of more or less related matters in number theory linked with various forms of the Riemann hypothesis or with Hilbert's problem of discovering a finite algorithm for determining all integer solutions of the equation $f(x, y) = 0$, where f is a polynomial with integer coefficients. The book treats character sums, Gaussian sums, the law of quadratic reciprocity, Burgess's estimate of the least quadratic non-residue of a prime, the results of Jacobsthal, Eisenstein *et al.*, on the expression of a prime as the sum of two squares, the Mordell–Weil work on the generation of rational points on a cubic, and a discussion of various diophantine equations. There is also a useful list of conjectures and unsolved problems.

The book thus contains a variety of interesting and important material, some of very recent date, and it is unfortunate that the author appears to have put it together in some haste and has not exercised any considerable gifts of exposition. Certain easy matters are expounded rather fully while difficult steps are often left to the skill of the reader. Since the material is on the whole by no means simple, the claim that "not much knowledge of mathematics" is assumed seems to me to be without substantial foundation. In addition, the proof reading is quite exceptionally defective: wrong or inconsistent symbols and fount are frequent, while punctuation is erratic and full stops almost (but not quite) always omitted in arguments conducted in mathematical notation. A sample check showed no page to be free of several such defects, though I had some consolation from the sentence with three full stops and an exclamation mark in the middle, and from the attribution of Hilbert's problem to the International Congress of 1800. The style varies greatly, sometimes flowery and sometimes in the form of headline notes. There is a good deal of unintentional repetition and a couple of pages are, for no very clear reason, left in their original French.

All this is a pity, for the book contains substantial and rewarding work which may well repay a reader of patience, perspicacity and fortitude.

S. R. TIMS

MEETINGS

ATHEROSCLEROSIS

ATHENS—1966

AN international symposium on "Recent Advances in Atherosclerosis Research" was held in Athens during May 30–June 2, under the presidency of Prof. B. Malamos, with Dr. A. N. Howard as general secretary. The main purpose of the symposium was to encourage multi-disciplinary discussion of epidemiology, lipid metabolism and thrombosis in relation to arterial degenerations.

C. Aravanis (Athens) reported his group's epidemiological investigations in Crete and Corfu, where ischaemic heart disease is responsible for only 1–5 per cent of the death-rate. He found a low incidence of hypertension and obesity among these islanders; their serum cholesterol is low by European and American standards, while they tend to eat little animal fat and be engaged in much hard physical work. J. Stamler (Chicago) re-emphasized the role of hypercholesterolaemia, hypertension and cigarette smoking in the aetiology of atherosclerosis. However, J. J. Groen (Jerusalem) pointed out that hypertension and cerebrovascular disease are just as common among Jewish immigrants from Afro-Asian countries as they are in those from Europe and the United States, yet only the latter group is peculiarly prone to coronary heart disease. Thus, hypertension clearly plays a significant contributory part in atherogenesis, but some other factor appears to be the major determinant of the disease. Most speakers tacitly, or more vocally, implied that this other aetiological factor is the effect of the diet on the serum lipids. H. C. McGill (New Orleans) summarized his geographical investigations and showed that atherosclerosis is more severe in Negroes domiciled in a North American community than in those living in less affluent countries. These collective findings —as well as the relationship between obesity and serum lipid levels (B. Rifkind, Glasgow)—suggest that the prevalence of hyperlipaemia and obesity in Western societies is the most important hurdle to be overcome in the effective prophylaxis of atherosclerosis. However, although epidemiological studies often prompt ideas for further investigation, they seldom themselves provide that degree of proof which can be used as a sheet-anchor in scientific argument.

The atherogenic effect of saturated dietary lipids was emphasized by D. Kritchevsky (Philadelphia), who showed that triglycerides containing palmitic and myristic acids cause more atheroma in the cholesterol-fed rabbit than does "polyunsaturated" corn-oil. R. Paoletti (Milan) mentioned that polyunsaturated fatty acids act as precursors for prostaglandins. These latter substances inhibit catecholamine-induced lipolysis in adipose tissue and thus reduce the serum lipid level. The theme of polyunsaturated fatty acids was pursued by L. W. Kinsell and his colleagues from Oakland, California; they showed that dietary trilinolein increases human biliary excretion of cholesterol and bile acids. T. Miettinen (Helsinki) confirmed previous conclusions that excess dietary cholesterol suppresses sterol synthesis in the rat liver but, like many other investigators, he obtained inconclusive results about the occurrence of such "feed-back" control in man.

E. H. Ahrens (New York) made the important point that cholesterol is chemically degraded in the human intestine; this process could well help to protect man against the effects of excess dietary cholesterol. S. Gerö (Budapest) tentatively suggested that cholesterol absorp-

tion may be influenced by gastro-intestinal secretion of mucopolysaccharides; he reported that the amount of gastric mucin is inversely proportional to the cholesterol level of the blood. Clearly, degradation and absorption of sterol in the human intestine are worth-while problems for more detailed investigation.

The lipoprotein vehicles for plasma lipid transport were discussed by many speakers. D. S. Frederickson (Bethesda) outlined techniques for isolating lipoproteins by electrophoresis or ultracentrifugation, and considered the diagnostic value and limitations of these methods in disease states. A. Scanu and his colleagues from Chicago described the molecular structure of the apolipoprotein moiety of these vehicles; lipids play no part in maintaining the secondary structure of the protein, but they do link the protein sub-units together. Thus, it can be inferred that peroxidation or other chemical changes in the lipid moiety would so alter the dispersion forces within the macromolecule that the lipoprotein would become physically unstable. Such instability of β-lipoprotein could directly result in lipid deposition within the arterial wall, as was first postulated by I. H. Page in 1954. Results presented by K. W. Walton (Birmingham) indicate that the metabolic turnover of low-density lipoprotein in the plasma may also be an important factor in atherogenesis. Because the metabolic turnover of low-density lipoprotein is twice as fast in premenopausal women as in men, it is possible that relative metabolic inertia is responsible for the accumulation of such lipoprotein in the male's plasma.

The interesting curiosity of "autoimmune hyperlipaemia" was reported by J. L. Beaumont (Paris); circulating anti-β-lipoprotein antibody was identified in two patients who clinically presented with severe atherosclerosis and excessively high serum cholesterol and triglyceride levels.

The entry of lipid into the arterial wall was discussed by S. Christensen (Aarhus, Denmark); he measured the transfer rates of radioactive cholesterol, phospholipid and protein across the intimal surface of the cockerel's aorta. The entry rates of phospholipid and protein into the aortic wall were closely correlated with each other in both normal and hyperlipaemic birds. This biochemical evidence suggests that lipid enters the arterial wall in lipoprotein form. Using fluoroscein- or ferritin-labelled specific antibodies, M. D. Haust (Ontario) and K. W. Walton (Birmingham) confirmed microscopically that low-density lipoprotein, albumin and fibrin are present in human atherosclerotic lesions. Haust noted—as had B. Watts and R. W. Wissler—that lipoprotein is more abundant in early than in old sclerotic plaques. She considered that such protein partly enters the arterial wall by "insudation"; this process is essentially the same as Virchow's "plasma imbibition" and Lendrum's "plasmatic vasculosis". G. H. Rothblat, D. Kritchevsky *et al.* (Philadelphia) presented evidence that the uptake of cholesterol by the cell is a non-enzymatic physical process; they hinted that it may depend on the binding of cholesterol by phospholipid in the cell wall.

Lipid metabolism in the arterial wall is clearly an important element of atherosclerosis; it could play an important part in either initiating or resolving the lesion. D. E. Bowyer, A. N. Howard and their colleagues at Cambridge reported that normal rat, rabbit and baboon arteries synthesize triglycerides and phospholipids—but not cholesterol esters—from carbon-14-labelled fatty acids. Likewise, H. B. Lofland (Winston-Salem, North Carolina) showed that normal arteries from the 'White Carneau' pigeon synthesize triglycerides and phospholipids, but atherosclerotic arteries from these birds divert lipid synthesis towards cholesterol esters. Because recent studies show that polyunsaturated cholesterol esters are rapidly mobilized from tissues and promote less tissue reaction than free cholesterol, Lofland's demonstration of cholesterol esterification in atherosclerotic arteries delineates a possibly important defence mechanism of the diseased tissue against cholesterol deposition.

J. Patelski (Poznan, Poland)—in co-operation with the Cambridge group—characterized phospholipase *A*, lipase and cholesterol esterase in animal arteries; the first two enzymatic activities are increased in rats fed an atherogenic diet, but cholesterol ester hydrolysis is suppressed by this dietary regime. In double-labelling experiments on human and canine arteries, Y. and O. Stein (Jerusalem) demonstrated that these tissues synthesize lecithin by acylation of lysolecithin. However, J. D. Billimoria (London) reported that the isolated rat aorta incorporates considerably more phosphorus-32 into cephalin phospholipids than it does into either lecithin or sphingomyelin. Following Zilversmit's pioneer investigations, it is now widely accepted that the arterial wall synthesizes phospholipid. However, previous biochemical and histochemical analyses have shown that sphingomyelin and, to a lesser extent, lecithin are the characteristic phospholipids of normal and atherosclerotic arteries. The importance of Billimoria's finding is that phospholipids which are synthesized most rapidly (that is, cephalins) may have an even faster metabolic turnover, so that they do not accumulate in the arterial wall.

The metabolic implications of ischaemia of the ageing arterial wall were discussed by several speakers. Histochemical and cytochemical studies, reported by C. W. M. Adams (London), showed that oxidative and esterolytic activities decline in the middle of the muscular coat of the ageing human aorta. This effect was attributed to ischaemia of the medial muscle-fibres at the watershed between the blood-supply from the adventitial vasa vasorum and outward diffusion from the lumen. Lipase activity declines throughout the whole thickness of the vessel, while lactic dehydrogenase activity increases in the ischaemic mid-zone. T. Zemplényi (Prague) attributed the increased activity of the latter enzyme to its anaerobic "*M*" isoenzyme. Zemplényi also described decreased activity of Krebs cycle enzymes in the ageing abdominal aorta in man and in various animals; he attributed this metabolic impairment to age-dependent changes in the aortic smooth-muscle fibres. A. Lazzarini Robertson (Cleveland, Ohio) postulated that the tunica intima also suffers from incipient hypoxia. From tissue-culture studies of human "intimacytes" he found that lipid deposition in these cells increases their oxygen requirements and thus initiates a vicious circle of hypoxia. These various observations indicate that the local catabolism and outward transport of lipids are impaired by ischaemia of the ageing artery.

Discussion of the pathology of atherosclerosis was mainly centred on the disease in primates. T. Clarkson (Winston-Salem, North Carolina), A. N. Howard (Cambridge) and R. W. Wissler (Chicago) described the atherosclerotic process in squirrel monkeys, spider monkeys, baboons and rhesus monkeys; the main emphasis of these reports was on the similarity of atherosclerosis in man to that in other primates.

G. A. Gresham (Cambridge) stressed the genetic factors that operate in atherosclerosis. For example, the 'White Carneau' breed of pigeon develops severe spontaneous atherosclerosis (Clarkson and Lofland), while mice with genetic diabetes mellitus suffer from generalized lipid deposition (A. E. Renold, Geneva).

In the pharmacological field, R. G. Gould (Palo Alto, California) described the hypotriglyceridaemic effect of *p*-chlorophenoxyisobutyrate ('Atromid *S*'); he tentatively suggested that inhibition of hepatic cholesterol synthesis may depress lipoprotein secretion and, as a result of this, the plasma-triglyceride level falls. J. M. Thorp and M. F. Oliver (Macclesfield and Edinburgh) considered that 'Atromid *S*' reduces the binding of thyroxine by plasma albumin, so that the hormone accumulates in the liver and acts locally against lipid synthesis. In this connexion, R. Pick (Chicago) reported

that hypothyroidism reduces the protective effect of oestrogens on the coronary arteries of cholesterol-fed chicks.

The final session of the symposium was concerned with the mechanism of thrombosis. Ultrastructural features of platelet aggregation were clearly illustrated by J. E. French (Oxford). G. V. R. Born (London) expressed the view that adenosine diphosphate (ADP) released from the vessel-wall may initiate platelet aggregation; a chain-reaction is set up by the production of ADP from the adenosinetriphosphate within such aggregated platelets. Born reported that adenosine and its 2-chloro derivative are strong *in vitro* inhibitors of ADP-induced platelet aggregation. Moreover, these inhibitors suppress thrombogenesis in the experimental animal. Both Born and J. F. Mustard (Toronto) mentioned the possible thrombogenic effect of collagen exposure in the injured vessel. In this connexion, P. Constantinides (Vancouver) presented histological evidence that fissures in atherosclerotic plaques frequently underlie arterial thrombi.

Mustard considered that the platelet aggregates formed during the initial stage of thrombosis are later stabilized by the deposition of fibrin fibrils. C. Hawkey (London) produced experimental evidence to support this concept; she showed that experimental thrombi progressively disintegrate if the plasma fibrinolysin system is activated with streptokinase. This observation indicates that fibrin "cements" the platelet aggregates in the thrombus and explains the efficacy of anticoagulant therapy in some forms of human thrombosis. C. W. M. ADAMS

MUSEUMS ASSOCIATION 1966

THE seventy-second annual conference of the Museums Association was held in Sheffield during July 4–9 under the presidency of Sir Frank Francis, director of the British Museum, London. In his presidential address, Sir Frank deplored the distinction now being made between "living" and "dead" art, and said it was ludicrous that while the Government White Paper recognized that museums might play the part of local art centres, they were not included in the grant proposals. He emphasized the value of the relatively recently formed Area Museum Councils and made a plea for scholarly research by museum staffs. Museums throughout Britain were becoming more and more attractive to the communities they served and were endeavouring to kill the traditional image that they had unfortunately acquired.

The relationship of the national and provincial museums formed the general theme of the conference, and this was discussed in the fields of archaeology, art and natural history. Speakers included Mr. R. L. S. Bruce-Mitford (British Museum), Dr. G. B. Corbet (British Museum (Natural History)) and Mr. M. Levey (National Gallery) for the national institutions, and Mr. D. T.-D. Clarke (Colchester and Essex Museum), Mr. I. M. Evans (Leicester Museum and Art Gallery) and Mr. H. Scrutton (Walker Art Gallery, Liverpool) for the provincial institutions. At many times during the papers and in subsequent discussions the present friendly co-operation between national and provincial staffs was emphasized, but it was strongly felt that this help should be co-ordinated. The exchange of staffs was advocated, though it was emphasized that this would entail standardizing the status and salaries of national and provincial personnel. It was also considered that the problem varied in the different disciplines dealt with by museums and art galleries and was a simpler matter in archaeology and natural history than in art. In the former subjects the acquisition and display of local and regional objects were desirable in all but the larger institutions, but in art the solution of the problem was more complicated.

The concentration of natural history and geological type specimens in national institutions was considered to be a matter for further discussion, for although the larger provincial museums could deal with various groups in an adequate manner it was certainly not desirable for the smaller institutions to hold type material.

At the annual general meeting, Mr. G. L. Conran, director of the City Art Galleries, Manchester, was elected president for 1967. The next conference will be held in Glasgow during June 26–30, 1967. F. S. WALLIS

OBITUARIES

Prof. K. J. Franklin

PROF. K. J. FRANKLIN, emeritus professor of physiology in the University of London, died on May 8 at the age of 68. "K. J.", as he was known to a wide circle of friends and colleagues, held the chair of physiology at St. Bartholomew's Hospital Medical College from 1947 until 1958. He came from Oxford with a reputation as an authority on the renal circulation and with a wide background of circulatory physiology.

Franklin was born in London in November 1897. He was educated at the Bluecoat School, and in 1915 won a scholarship in classics to Hertford College, Oxford. Instead of going to Oxford, however, he joined the Royal Artillery and served with a field battery in France until the Armistice. He went up to Oxford in 1919, and decided to study medicine rather than classics. He went to St. Bartholomew's Hospital as a clinical student in 1922, qualified in 1924 and returned to Oxford as a fellow of Oriel College. From 1924 until 1938 he was demonstrator of pharmacology at Oxford and combined that duty with that of tutor in physiology and librarian at Oriel College. When the Nuffield Institute for Medical Research was established in 1935, Franklin became assistant director and continued in this post until he was appointed professor of physiology at Bart's in 1947.

His ability to do several tasks at once had been proved at an early age when he had combined clinical studies with the post of part-time demonstrator in physiology under Prof. (now Sir Charles) Lovatt Evans at Bart's and, in his final year, that of part-time lecturer in physiology at Brasenose College, Oxford. As a good classical scholar, Franklin turned to a study of medical history. He also combined the techniques of cinematography and radiography in a study of the renal circulation. Between 1947 and 1958, Franklin was occupied with his work on the renal circulation, his classical interests in making new translations of some of the works of William Harvey, and in supervising the construction of the new buildings which house the Departments of Physiology and Pharmacology. He was elected a Fellow of the Royal Society in 1955.

His last series of experiments was aimed at determining whether the phenomenon of cortical necrosis of the kidney, which is a serious complication in concealed accidental haemorrhage, could be explained on the basis of a utero-renal reflex. Ill-health unfortunately forced him to retire before any firm conclusions could be drawn.

Those of us who worked with him will always remember him as a tall and impressive figure with a shy manner and very softly spoken. Further acquaintance soon revealed that he had a fine sense of humour and a most kindly personality.

Prof. Franklin is survived by his wife and one daughter.

F. J. AUMONIER

GALACTIC COSMIC-RAY SOURCE AND LOSS PROBLEM

By PAUL BAKER, JUN.*, PROF. R. L. CHASSON and V. J. KISSELBACH

University of Denver, Denver, Colorado

SUBSTANTIAL direct evidence of a sidereal anisotropy is indicated for the charged galactic cosmic radiation:

$$(> 20\,\frac{gV}{c}\ \text{primary rigidity})$$

The results have been obtained with a technique of celestial scanning, using a battery of paired narrow-angle muon telescopes, two of which are vertical, and the others with axes tilted at about 38° with respect to zenith and in the north, south, east and west geographic planes. (The technique is referred to as "crossed-telescopes".) The apparatus is located in Denver at 1,600 m altitude and with a Quenby-Wenk threshold of about $3\frac{gV}{c}$. Details of the instrumentation have been given elsewhere[1], and in this article we shall discuss the first year of data obtained with the S and E pairs of tilted telescopes. These results are additionally interesting as they are directly concerned with the recently-concluded observational programme of the International Years of the Quiet Sun and, furthermore, afford some verification of basic assumptions underlying certain techniques of the new cosmic-ray astronomy. (More detailed remarks regarding these direct scanning techniques can be found in a recent review by Reber[2].)

The telescopes operate in directional pairs, and the total counting rate from each direction is about $4{\cdot}5 \times 10^4$ per hour. The directional response is such that the telescope opening angle at half-maximum of intensity is about 17° (about 1 h in right ascension). The integrated counts from each directional channel are recorded every solar minute, and the results are eventually computed in 6-min sidereal time intervals by a cumulative time-shifting formula. The sidereal 6-min intervals lag the solar intervals by about 1 sec in solar time; thus in 15 days our time conversion is in error only by about 1 min, and we process data each 15 days as a unit.

The findings to be discussed here are derived from data taken from two isolated periods of time: (1) 60 days bracketing the summer solstice of 1965; and (2) 84 days bracketing the winter solstice of 1965. The two solstice periods were considered and intervening data ignored in order to avoid spurious interference-type variations having basic solar periodicity that may be introduced into the sidereal scaling as a result of the unique one-day difference between the sidereal and the solar year[3]. Final reduction of observations consisted of summing the 6-min data into half-hour spans, computing south-minus-east half-hourly differences, and then superposing the results to give half-hourly means of sidereal diurnal variation. The taking of such differences accomplishes two important purposes: (*a*) we eliminate the major portion of the complex of meteorological corrections ordinarily required to reduce muon intensity to a standard basis as the telescopes view through essentially the same air mass; and (*b*) the telescope tracking in right ascension (east leading south) gives a check on variations observed.

The latter point is brought out more clearly in Fig. 1, which is a plot of the asymptotic directions of arrival[4] for primary particles giving rise to muons detectable by the tilted telescopes. Since the cut-off at Denver is about $3\frac{gV}{c}$, we estimate the lower limit of primary rigidity to be $20\frac{gV}{c}$ for production of a muon just capable of reaching our apparatus. The $P^{-2.5}$ differential rigidity spectrum for such charged primaries yields the value of $60\frac{gV}{c}$ for the mean primary rigidity to be considered in our observations, corresponding to a range typical of galactic cosmic rays. It should be noted from Fig. 1 that the east telescope leads the south by about 3 h in right ascension, with south sensing almost exclusively along the celestial equator and east sensing to a celestial latitude of 25° north and almost entirely in its meridian plane.

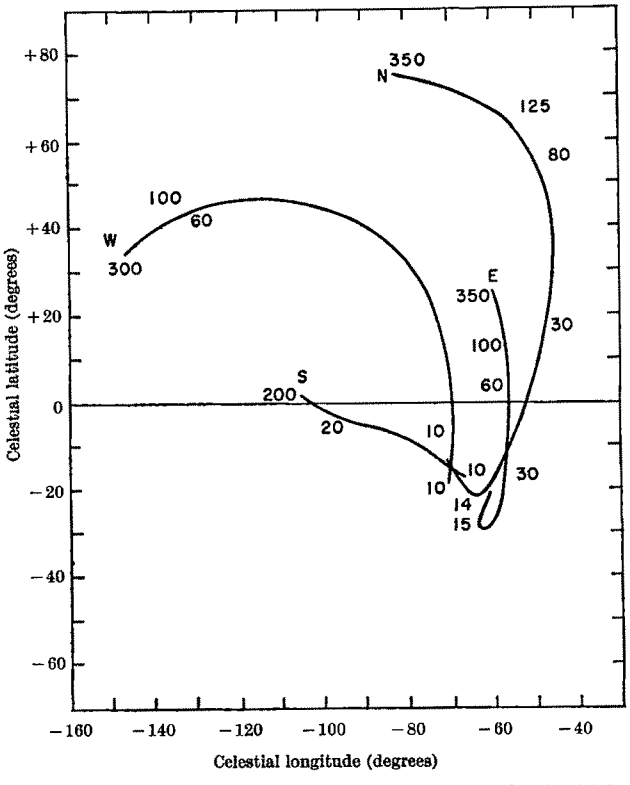

Fig. 1. Asymptotic directions of approach of primaries (ref. 4) for tilted telescopes. Numbers on curves indicate magnetic rigidities in $\frac{gV}{c}$

One then examines the sidereal south-minus-east results for characteristic oscillatory signatures in the trend of daily variation; since east leads south, the signature will first tend to be negative and then reverse to positive if the scanning pair encounters a region of excess intensity,

* On a research appointment from the U.S. Air Force Academy.

where the zero baseline is that of the daily average difference. Conversely, the sign performance will be positive to negative if a region of reduced intensity is encountered.

Fig. 2 contains the results of the two isolated solstice periods and, finally, their superposition, giving a sidereal diurnal plot where solar effects are largely cancelled due to the 180° phase shift within sidereal time. Error bars are based on the standard error of the total counting statistics going into the differences (about 3×10^6 total counts per 30 min for the accumulated 144 days). Solar-time plots (not shown) for the equivalent period, taking south and east telescopes independently, gave typical strong maxima at about 1500 h local solar time with an amplitude of about 0·5 per cent. This solar diurnal variation is consistent with the results of many other investigators[5]; its directional and time dependence is also of considerable interest, and will be discussed in future publications.

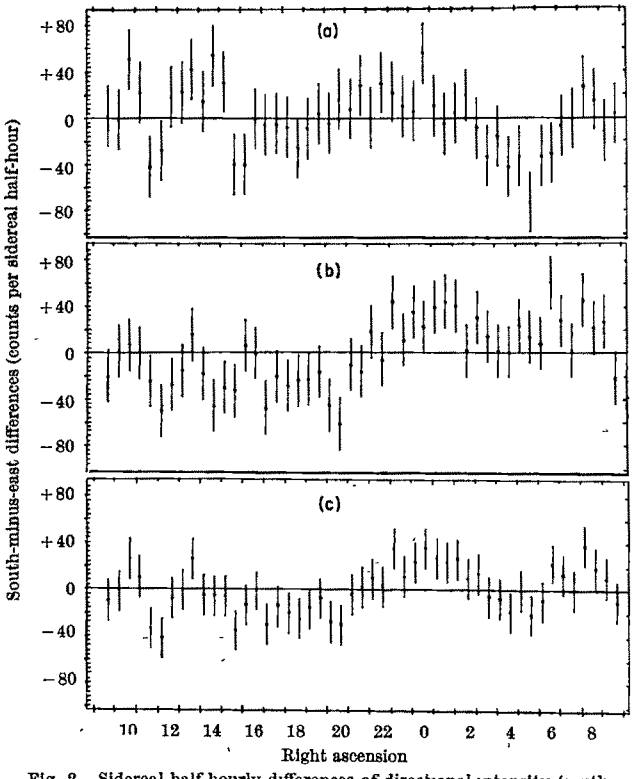

Fig 2. Sidereal half-hourly differences of directional intensity (south-minus-east) averaged over: (*a*) 60 days bracketing summer solstice 1965 (May 18–July 20); (*b*) 84 days bracketing winter solstice 1965 (November 20–February 23); (*c*) combination of above results. (Referred to zero counts per half-hour average difference)

The sidereal anisotropy indicated in Fig. 2*c* is of the order of 0·06 per cent, quite in agreement with the magnitudes found previously[5] using techniques of harmonic analysis. Without attempting to invoke specific causes for each detail of this curve, we wish to direct attention to the striking peak at about 0 h right ascension (R.A.), apparently corresponding to a diminution of intensity as it is followed so well by a related dip in the signature starting at 3 h. Because the south telescope lies in the local meridian plane, its axial orientation is regarded as the fiducial one in reckoning the direction in space for assignment of R.A. of structure found in the results; thus we assign the location of this feature to lie between 3 and 5 h R.A. There is also an apparent non-random sequence of points indicating a lowering of the galactic intensity centred at 11 h, and a similar, but less strong, indication at 9 h R.A. We did not observe anisotropy at all approaching the magnitude reported by Standil and Bukata[6].

A runs analysis of the values shown in Fig. 2*c* yielded eight runs (consecutive oscillations of sign about the mean south-minus-east difference). Now, to force a conclusion that our sign change sequence is random (a 48-point sample) one should expect between fourteen and twenty-eight such runs to exceed the 5 per cent confidence limits. Our markedly low number of runs leads us to say, then, that the 144-day sample departs very significantly from randomness and, further, to assert that the fluctuating sequences are possibly related to some astrophysical processes or galactic structure features. The apparent minima at 4, 9 and 11 h are associated with viewing directions roughly perpendicular to the winter plane of our galaxy. The long, consistent sequence of points between 13 h and 20 h is considered to be "standard background" and spans the summer plane of the Milky Way. Argument that the feature between 13 h and 20 h is not a source irregularity is as follows: the south–east difference is roughly constant; thus either the eastern intensity keeps increasing linearly as the south follows it by 3 h, causing a constant south–east difference, or south and east are looking at equal intensity values for the whole period. We assume the latter, as it is very difficult to believe the existence of such a vast and constantly increasing intensity structure, even though it does span the summer plane of the galaxy, and, finally, a similar feature does not appear in the traversal of the winter plane.

The following mechanisms may be responsible for a decreased intensity from a localized direction: (1) a large expanding cosmic ray trap operating in a neighbouring part of the galaxy, which could have some extremely interesting time-dependent properties; or (2) extensive magnetic modulating mechanisms. (The known fields in the near spiral arm at about 6 h R.A. and in the Crab Nebula at 5·5 h are noted.) Or we can consider the possibility of (3) reduced density of cosmic-ray sources in certain directions as compared with the general background, or (4) excessive absorption along the paths from certain source directions. (In the last-mentioned case, unreasonably high interstellar densities might be required if nominal trajectories, say $\lesssim$ 1,000 parsec, were assumed for the primary particles the progeny of which are detected by our instruments.)

Further calculations are planned involving the recent equinoctial period and similar selected data to be collected by the continuing operation of the telescopes. Other directional differences will also be taken to isolate strips of the celestial sphere with limited extent in declination, as provided by the dissimilar asymptotic cones viewed by the various telescopes. We will then continue our mapping as we look, for example, at the latitude of Cygnus and Cassiopeia and also hope to be able to delineate the position of the Crab Nebula if it is a source of anisotropy within our range of rigidities.

This work was supported by the National Science Foundation. We thank the staffs of the computing centres of the University of Denver and the U.S. Air Force Academy for their help, Prof. H. Bondi and Dr. A. G. Wilson for useful discussions, and Prof. K. G. McCracken for making the asymptotic direction computer programme available. We also thank Prof. Mario Iona for his advice.

ROTATION OF NEUTRON STARS

By SACHIKO TSURUTA
Smithsonian Astrophysical Observatory, Cambridge, Massachusetts
AND
A. G. W. CAMERON
Institute for Space Studies, Goddard Space Flight Center, National Aeronautics and Space Administration, New York, and Belfer Graduate School of Science, Yeshiva University, New York

THIS discussion is prompted by some calculations of Zee and Wheeler concerning energy loss by gravitational radiation from the quadrupole oscillations of a neutron star. Zee and Wheeler[1] estimate a half-life for radiation of the quadrupole vibrational energy of the order of seconds. Meltzer and Thorne[1] have further suggested that if the neutron star is rotating, the rotational flattening will provide a coupling between the purely radial oscillations of the star and the quadrupole oscillations, in which the radial vibrational energy will be drained away through the quadrupole mode with a half-life of about a day even with very moderate rotational flattening. As energy storage in radial vibrations has been suggested as a reservoir giving rise to X-rays from the circumstellar regions of neutron stars by synchrotron and bremsstrahlung mechanisms[2], it is of interest to examine the degree to which rotational flattening may be expected to persist after formation of a neutron star in a supernova implosion.

Recent hydrodynamical calculations on the supernova collapse problem by W. D. Arnett (ref. 3 and personal communication) show that the collapse of a star of several solar masses will leave a remnant in the range 0·5–2 solar masses, the uncertainty partially representing differences in starting conditions and partially representing the approximations which have so far been made in handling the equation of state during the collapse. We have recently shown that the maximum stable mass of a neutron star probably lies in the range 1–2 solar masses[4,5]. It may readily be shown that if a star $\sim$ 10 solar masses is rotating on the verge of rotational instability at the equator while on the main sequence (as is usually observed to be the case), and if it continues to rotate rigidly (owing to magnetic and turbulent viscosity) after evolving to the red giant phase, then the central one solar mass will rotate at much less than the verge of rotational instability after being suddenly compressed to neutron star dimensions with local conservation of angular momentum. This consideration is strengthened if one includes the effects of angular momentum loss accompanying mass loss in the red giant phase, but it is weakened to the extent that turbulence and magnetic fields may not be able to maintain rigid rotation of the core with the envelope in the red giant phase. For complete generality we discuss the case of a fast-rotating neutron star remnant.

Hoyle, Narlikar and Wheeler[6] have suggested that the remnant of a supernova explosion will be a rapidly-rotating flattened disk. If the disk is very thin, the implication is that the hydrodynamic time scale of the collapse will be lengthened and the gravitational potential energy release will be less localized. For this reason energy transfer by neutrino diffusion will be very inefficient and Arnett's calculations would then suggest that a strong shock wave is not formed to eject the outer envelope. Thus the disk will be very massive, and if there is outward transport of angular momentum and inward transport of mass as a result of turbulence, the central part of the disk is likely to collapse through its Schwarzschild radius, thus precluding the possibility of long-term storage of energy.

It must also be enquired whether a very flat disk may not be unstable to deformation into a Jacobi ellipsoid with three unequal axes, thus forming a mass quadrupole. A related question has been investigated by Roberts[7], who found that a rapidly spinning polytrope will deform into a Jacobi ellipsoid if the polytropic index is less than about unity. We have assigned rough effective polytropic indices to our models of neutron stars[5] by comparing the ratio of central to mean densities for our models with those for polytropes. The results are shown in Fig. 1.

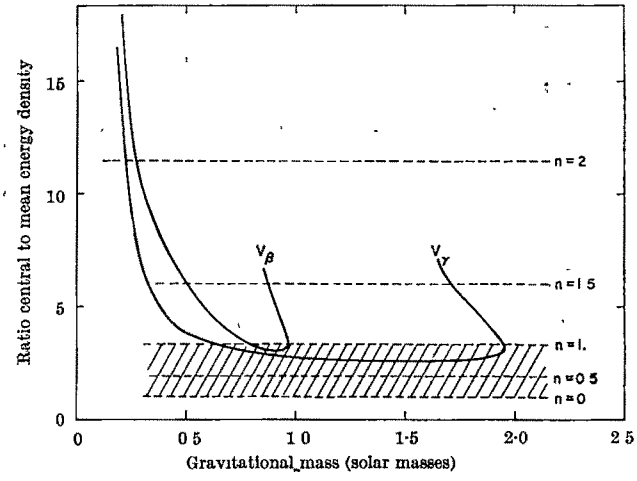

Fig 1. Plot of the ratio of the central to the mean proper energy density for the Tsuruta–Cameron neutron star model sequences characterized by the Levinger–Simmons potentials V_β and V_γ. Also given are the ratios of central to mean densities for various polytropic indices n. The shaded region below $n = 1$ will be unstable to deformation into Jacobi ellipsoids

The two model sequences shown in Fig. 1 represent two different expressions for the nuclear interaction potential which enters the equation of state used in the construction of the models. The correct model sequence may well lie between these two. It may be seen that the effective polytropic index of the models in the vicinity of one solar mass is indeed near or below unity. Thus there is a good chance that neutron stars can deform into Jacobi ellipsoids if they are spinning rapidly enough. The resulting mass quadrupole can emit gravitational radiation, and this will slow the spin rate until the ellipsoid relaxes to a spheroid. Chin has shown that the characteristic time for this is of the order of a second[8].

We now consider the slowing of the spin of a neutron star due to loss of angular momentum when an external magnetic field exerts a torque on mass which is flowing away in the form of a stellar wind. The stellar wind is likely to arise from the heating of a corona around the neutron star by shock waves and hydrodynamic waves generated by the radial vibrations[2,9]; its expansion will be

assisted by radiation pressure owing to the high surface temperature at the photosphere. The outflowing plasma will tend to pull the magnetic field radially away from the star, and the rotation will tend to wrap the field lines into a spiral. The following calculation of angular momentum loss is similar in principle to one previously carried out by Schatzman[10] in connexion with the Sun.

We may expect that close to the neutron star the magnetic field causes the corona to co-rotate with the star, but at large distances the corona rotates slower and the field is wrapped into a tight spiral. The condition of co-rotation may be expected to break down at roughly that distance r such that the radius of curvature of the field lines is also r. The Coriolis pressure gradient[7] on the gas $2\rho v\omega$ will be approximately equal to the magnetic tension:

$$2\rho v\omega = B^2/4\pi r \qquad (1)$$

where ρ is the gas density, v is the expansion velocity, ω is the angular velocity of the neutron star and B is the magnetic field. We take the mass flow f through any spherical surface concentric with the star to be constant:

$$f = 4\pi\rho r^2 v = \text{constant}$$

If we designate physical quantities at the neutron star surface by subscripts zero, then:

$$\frac{\rho v}{\rho_0 v_0} = \left(\frac{r_0}{r}\right)^2$$

For the radial magnetic field:

$$\frac{B}{B_0} = \left(\frac{r_0}{r}\right)^2$$

Thus from equation (1) we obtain:

$$r^3 = \frac{B_0^2}{8\pi}\,\frac{r_0^2}{\rho_0 v_0 \omega}$$

Let the angular momentum of the neutron star be:

$$L = KMr_0^2\omega$$

where M is the stellar mass.

The rate of loss of angular momentum is:

$$\frac{dL}{dt} = -fr^2\omega = KMr_0^2\,\frac{d\omega}{dt}$$

The solution to this equation is:

$$\omega_i^{2/3} - \omega^{2/3} = bt$$

where t is the time required for the angular velocity to be reduced from an initial value ω_i to a smaller value ω, and

$$b = \frac{2}{3}\,\frac{f^{1/3}}{KM}\left[\frac{B_0^2 r_0}{2}\right]^{2/3}$$

Thus the time required to remove the initial angular momentum is:

$$t = \frac{3KM\omega_i^{2/3}}{2^{1/3}f^{1/3}B_0^{4/3}r_0^{2/3}} \qquad (2)$$

Let us estimate some reasonable values of the quantities in connexion with equation (2). We take as rough values for a neutron star $M = 2 \times 10^{33}$ g, $r_0 = 10^6$ cm, and $K = 0{\cdot}2$. The Kepler orbital velocity at the surface is $(GM/r_0^3)^{1/2} = 1.15 \times 10^4$, so we take $\omega_i = 10^4$ radians/sec. The initial rotational energy is:

$$\tfrac{1}{2}KMr_0^2\omega^2 = 2 \times 10^{52} \text{ ergs}$$

This must be dissipated during the slowing of the spin; let us suppose this energy goes into mass loss in order to get a crude estimate of f. The resulting mass ejection is roughly $Kr_0^3\omega^2/2G \approx 10^{32}$ grams. Thus $f \approx 10^{32}/t$, and equation (2) becomes:

$$t \approx 3 \times 10^{31}/B_0^2 \qquad (3)$$

Now Woltjer[11] has estimated that a neutron star is likely to be formed with a magnetic field B_0 of the order of 10^{14}–10^{16} gauss. If this is correct, then from equation (3) we find that the spin of a neutron star is likely to be eliminated on a time scale of seconds.

Thus we conclude that there is no assurance that rotational flattening of a neutron star will be responsible for eliminating radial vibrational energy by providing a coupling to the quadrupole oscillation mode. Furthermore, it appears that rotational energy storage in a neutron star is most unlikely to provide a reservoir which can lead to energetic radiation processes for very long after the star is formed. More careful detailed considerations of all these processes are needed.

INTERCONTINENTAL CONODONT CORRELATION OF THE PALAEOZOIC SEDIMENTS OF THE BONAPARTE GULF BASIN, NORTH-WESTERN AUSTRALIA

By P. J. JONES and E. C. DRUCE

Bureau of Mineral Resources, Geology and Geophysics, Canberra

A PRELIMINARY investigation of the geology of the Bonaparte Gulf Basin was published by the Australian Bureau of Mineral Resources in 1955 (ref. 1). In 1963, the Bureau began a detailed study of the geology of the basin; the initial observations were recorded by Veevers *et al.*[2] (see Fig. 1 for the localities mentioned herein). Previous published accounts of the geology include McWhae *et al.*[3] and Thomas[4], who summarized the knowledge of Carboniferous stratigraphy up to 1958. Geological investigations before 1952 have been concisely reviewed by Noakes *et al.*[5].

Conodonts were first discovered in the Bonaparte Gulf Basin by Öpik[1,6], who recorded the presence of a Lower Ordovician (Tremadocian) fauna in a glauconitic sandstone which he named the Pander Greensand. A preliminary investigation of our material supports Öpik's conclusion. Glenister[7] noted the occurrence of Carboniferous conodonts in the upper parts of both the Burt Range Limestone (herein referred to as the Burt Range Formation) and the Septimus Limestone. The conodont locality (*c*) of Glenister (ref. 7, p. 214), which he tentatively referred to the Spirit Hill Limestone, is on brachiopod evidence[4,8] the same age as the Septimus Limestone.

Conodont zonations of European and North American Devonian and Carboniferous standard sections have been

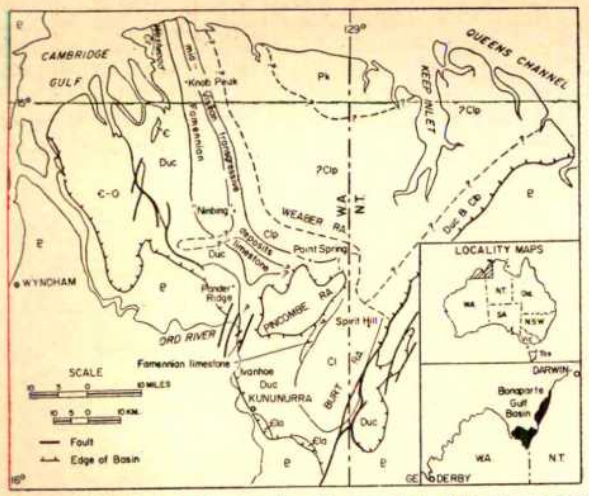

Fig. 1. Geological sketch-map of southern portion of Bonaparte Gulf Basin. e, Proterozoic; Cla, Lower Cambrian Volcanics; C, Cambrian; C-O, Cambrian and Ordovician undifferentiated; Duc, Cockatoo Sandstone; Cl, Lower Carboniferous undifferentiated—includes Burt Range Formation, Enga Sandstone and Septimus Limestone; Clb, Burt Range Formation; Clp, Point Spring Sandstone; PK, Lower Permian Keep Inlet Beds

published by Bischoff[9], Bischoff and Ziegler[10], Collinson, Scott and Rexroad[11], and Ziegler[12]. British Carboniferous conodont faunas have been studied by Austin, Druce and Rhodes[13]. Information contained in these works has enabled us to correlate the Upper Palaeozoic succession of the Bonaparte Gulf Basin with the classical sections of the northern hemisphere (Fig. 2). Such information will provide a stratigraphical framework for the detailed investigations being conducted by the Bureau.

Detailed palaeontological investigations of samples collected by a survey party led by J. J. Veevers in 1963 have disclosed abundant conodont faunas in limestone formations previously known to contain conodonts. In addition, conodonts were discovered in the unnamed Viséan calcarenite of Veevers *et al.*[2], in intercalated calcareous beds at the base of the Enga Sandstone and in a belt of limestone in the Ninbing region which Traves[1] referred to the Burt Range Limestone (Fig. 3).

Conodonts have only been recovered from the calcareous middle part of the Cockatoo Sandstone in the north-west part of the basin, at Westwood Creek. This fauna contains the species *Ancyrognathus* sp., *Polygnathus* cf. *brevilamina* Branson and Mehl[14], and *Polygnathus normalis* Miller and Youngquist[15], which indicate a Frasnian (toI) age. However, the upper boundary of the Cockatoo Sandstone may possibly be as young as the toII stage of the Famennian, because about 2,000 ft. of sandstone, which has so far yielded no conodonts, overlies the fossiliferous limestones, and is in turn succeeded by the limestones of the Knob Peak area, of upper toIIβ–lower toIIIα age (see following, and Fig. 1). Furthermore, the possibility that the non-fossiliferous basal beds may be of uppermost Middle Devonian age cannot be excluded.

Upper Devonian conodonts have also been discovered in limestones[16] exposed as a long narrow belt from Knob Peak southwards through Ninbing, to the east band of the Ord River at Buttons Crossing (5·5 miles north of Ivanhoe Homestead). The presence of the conodont species *Palmatolepis glabra elongata* Holmes[17] and *P. glabra pectinata* Ziegler[18] indicates that these beds belong to the upper toIIβ–lower toIIIα ammonoid zones of the German standard section. Traves[1] and Veevers *et al.*[2] have referred these limestones to the Burt Range Formation.

The conodont faunas of the Burt Range Formation, however, include the species *Polygnathus inornata* E. R. Branson[19], *Pseudopolygnathus* sp. of the *prima* group and *Siphonodella cooperi* Hass[20], which are comparable with those from the CuI–CuIIα ammonoid zones of the German standard section, and the Hannibal–Chouteau interval of the Upper Mississippi Valley. The presence of *Siphonodella duplicata* (Branson and Mehl)[21] within the basal strata clearly shows that the Burt Range Formation is restricted to the Lower Carboniferous.

Therefore, our evidence shows that the limestones at Ninbing are older than the Burt Range Formation, and are separated from it by a considerable hiatus. These limestones constitute a hitherto unnamed formation, which will be described and named in a forthcoming publication of the Bureau.

The conodont faunas discovered in the basal beds of the Enga Sandstone include species found in the upper part of the Burt Range Formation, such as *Polygnathus inornata* E. R. Branson[19], and species of the genus *Spathognathodus*. These indicate a CuIIα age for the basal portion of the Enga Sandstone, which confirms the

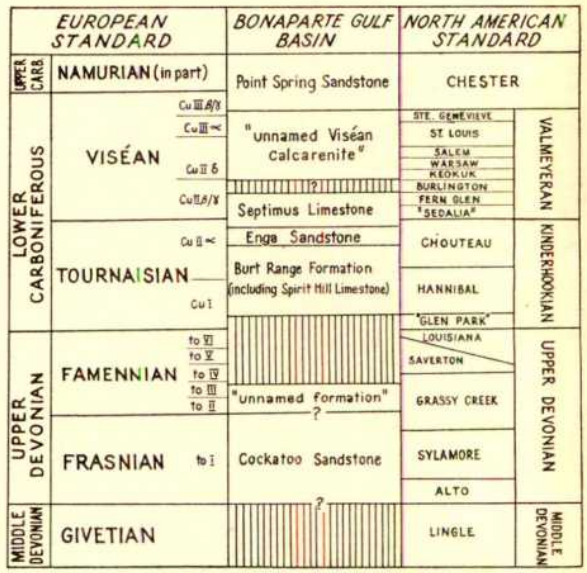

Fig. 2. Intercontinental correlation of the formations of the Bonaparte Gulf Basin. Vertical hatching denotes apparent absence of time-rock units; thicknesses of formations are not to scale

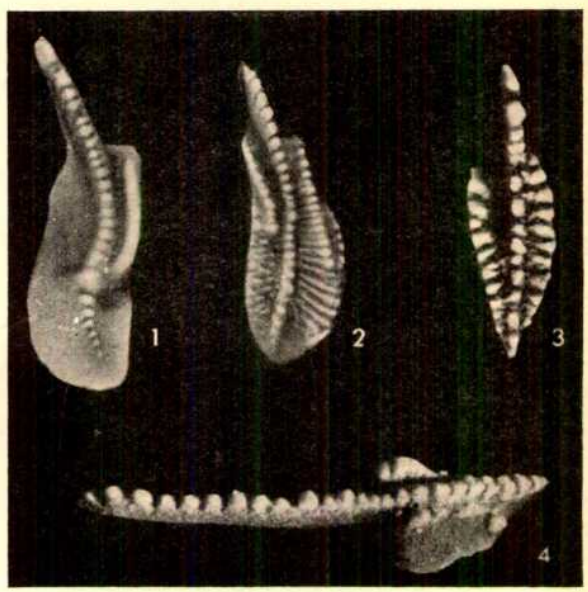

Fig. 3. Conodonts from the Bonaparte Gulf Basin. Oral views × *c.* 35. (1) *Palmatolepis glabra pectinata* Ziegler, 1960, from unnamed Famennian limestone. (2) *Siphonodella cooperi* Hass, 1959, from Burt Range Formation. (3) *Polygnathus nodomarginata* Branson, 1934, from Septimus Limestone. (4) *Gnathodus texanus* Roundy, 1926, from unnamed Viséan calcarenite

Tournaisian age previously assigned by Thomas[4], and the Kinderhookian age suggested by Öpik[1].

The late Tournaisian to early Viséan age of the Septimus Limestone, based on the brachiopod studies of Thomas[4,8] and Roberts (personal communication), is supported by our investigation of the conodonts. The fauna includes the species *Polygnathus nodomarginata* E. R. Branson[19] and new and re-described species from the *Z* coral–brachiopod zone of the type Avonian at Bristol[13].

The unnamed Viséan calcarenite of Veevers *et al.*[2] has yielded an abundant conodont fauna, including the species *Geniculatus claviger* Hass[22], *Gnathodus girtyi* Hass[22], *G. texanus* Roundy[23], *Mestognathus beckmanni* Bischoff[9], *M. bipluti* Higgins[24], and *Spathognathodus scitulus* (Hinde)[25]. This fauna indicates a CuIII age, although the presence of *Gnathodus* cf. *G. cuneiformis* Mehl and Thomas[26] in the basal portion suggests that the formation may be as old as the CuIIδ zone. The apparent absence of species characteristic of the CuIIIγ zone suggests that it is doubtful whether the top of the formation is any younger than the early part of the CuIII zone. In terms of the Upper Mississippi Valley standard succession[11], the formation can be correlated with part of the Valmeyeran stage; it is no older than the lower portion of the Burlington Formation, and no younger than the Ste. Genevieve Formation. Thus, the conodont evidence suggests a slightly younger age than the early Viséan age assigned to it by Thomas[27].

No conodonts have yet been found in calcareous samples of the Point Spring Sandstone; Thomas[8,27] and Roberts indicate, on brachiopod evidence, a late Viséan to early Namurian age for this formation.

The systematics and biostratigraphy of the conodont faunas from the Upper Palaeozoic sequence of the Bonaparte Gulf Basin are being investigated by one of us (E. C. D.) and similar studies on the Lower Palaeozoic succession are in progress (P. J. J.).

We thank Drs. J. J. Veevers and J. Roberts for valuable discussions in the field on the stratigraphy and structure of the basin, and for systematically collecting conodont samples in measured sections. We also thank Dr. Günther Bischoff, of Gewerkshaft Elwerath Erdölwerke, Hannover, West Germany, for examining and discussing these faunas, and Mr. A. T. Wilson, who prepared and picked the residues.

TRANSPORT PROCESSES AND THERMODYNAMIC EQUILIBRIUM

By PROF. A. G. McLELLAN
Department of Physics, University of Canterbury, Christchurch, New Zealand

IN a recent series of articles[1–3], Prof. Melehy has presented a thermodynamic theory applicable to transport phenomena for liquids, gases and electrons in matter. Important quantities in his theory are the particle diffusion force and the corresponding diffusion potential. In cases where the system of particles is subject to long-range forces such as gravitational or electrostatic, he contends that the conventional condition of equilibrium expressed as:

$$f_e + f_d = 0 \qquad (1)$$

leads logically to results which contradict experimental observations like the Peltier effect. In (1) f_e is the force on the particle as a result of long-range forces, f_d is the particle diffusion force. Since (1) expresses that the net force on the particle is zero, it is argued[2] that the net work in transferring the particle between two points, whatever the gravitational or electrostatic potential difference may be, is zero, that is, the transfer would be at constant energy. It is further argued that direct consequences would be: (*a*) a denial of the existence of such effects as the Peltier effect; (*b*) the necessity in thermal equilibrium for the conduction bands to line up throughout a crystal containing a non-degenerate *p–n* junction.

The theory is used to prove[2] that the Fermi level of the crystal in case (*b*) cannot have the same value throughout the crystal.

In the most recent paper[3] a treatment generalizing this theory on a thermodynamic basis is given; here it is claimed that the usual proof of the constancy of the chemical potential throughout a system in thermodynamic equilibrium is invalid.

In the present article, it is shown that these results of Melehy's theory are themselves invalid. It will be convenient to consider first his criticism of the conventional treatment of the chemical potential, then to consider the properties of the particle diffusion force and to show that the work done in transferring a particle from point *A* to point *B* in a system is not solely due to that done against the forces f_e and f_d and hence zero. It will be shown that the contribution to the work done in changing the volume occupied by the particle from that at *A* to that at *B* must also be taken into account. This contribution is not necessarily zero, and taking it into account, for instance, leads to the result for a perfect gas that the work done in transferring a particle from *A* to *B* is equal to the potential energy difference per particle between *A* and *B*. Thus Melehy's argument that (1) cannot be true, since it denies the existence of well-known experimental results, breaks down. Equation (1) must be true since it is an expression of the constancy of the chemical potential throughout the system, and the empirical assumption made by Melehy that the left-hand side of (1) is not itself zero but has a zero vector curl is

wrong. In any case, the extra work term, introduced as here, makes it not only wrong but unnecessary to depart from the usual treatment of equilibrium.

Chemical Potential and Thermodynamic Equilibrium

Ref. 3 considers the increment dF of the Helmholtz free energy:

$$dF = -SdT - PdV + \sum_k \mu_k dN_k \qquad (2)$$

The argument goes on as follows: "The last term in (2) is a summation of more than one product, since it is needed here supposedly to test whether or not the particles would have the same chemical potential at different points.

"The conventional argument supposedly proving that for electrons in solids $d\mu = 0$ in thermal equilibrium proceeds as follows. First it is assumed that dF is zero. This particular assumption will be shown in the next section to be unjustifiable. For the time being, however, let us accept the conventional assumption that $dF = 0$ in thermal equilibrium. It is then reasoned conventionally that if dN particles were transferred from point A to point B at constant volume, then:

$$dF = (\mu_a - \mu_b)dN = 0 \qquad (3)$$

[(2) and (3) are equations (24) and (25) respectively of ref. 3]. From equation (25) [(3) here] it would follow that $\mu_a = \mu_b$.

"The weakness in the preceding argument is that if dN particles were transferred from point A of high particle concentration n_a to point B of low particle concentration n_b, this could not possibly be done at constant volume. To explain this point let us calculate specifically the volumes occupied by dN particles at point A and at point B. At the former point, the volume $dV_a = (dN)/n_a$, and at point B, the volume $dV_b = (dN)/n_b$. Thus $dV_b = (n_a/n_b)dV_a$.

"If points A and B are on either side of, for example, an interface between a metal and a p-type semi-conductor, respectively, the ratio of (n_a/n_b) could be 10^{16} or higher. Thus the assumption that dN particles could be transported at constant volume in any system is obviously invalid."

In fact, the conventional argument as outlined is not rigorous—it implies that dV is the change in the volume occupied by the dN particles. Further, equation (2) as quoted applies to a macroscopic system of volume V and entropy S, and should be used only when it has been proved that the μ_k are constant throughout the system. It is, in fact, possible to transport in the system dN particles from A to B without altering the volume of the system. The conventional treatment takes account of the work required to change the volume of the region outside the neighbourhoods of the points A and B, so that the total volume remains constant. Since the foregoing account of the conventional theory is not clearly rigorous, it would appear desirable to give a rigorous account which does not beg the question of the constancy of μ throughout the system. The proof to be given is in the spirit of that of Gibbs[4] but is not identical with it. It has the advantage of not assuming the presence of the last term in:

$$dU = TdS - PdV + \mu dN \qquad (4)$$

an assumption which is not obvious, for example, in the case of systems under non-hydrostatic stresses, where the work done in injecting dN particles into the system is not obviously independent of where the injection is carried out. For simplicity, a system of one chemical component is considered—the generalization to a multi-component system is obvious. Following Gibbs[5], the conditions of equilibrium of a system may be obtained on the supposition that the system is enclosed in a perfectly rigid and perfectly non-conducting impermeable envelope. Under these conditions the equilibrium condition is taken to be that $\delta U = 0$, for a virtual reversible infinitesimal displacement in which $\delta S = \delta V = 0$.

Let the system be imagined to be divided into many fixed small regions $i = 1,2, \ldots$. For example, two of these regions could be infinitesimal regions containing the points A and B of the argument quoted here. Let t_i, p_i, V_i, U_i, S_i, v_i, u_i, s_i and φ_i be respectively the temperature, pressure, volume, energy, entropy, molar volume, molar energy, molar entropy, and the molar potential energy of the material in region i. The regions are assumed sufficiently small so that the foregoing quantities may be taken to be uniform through each region. Consider a virtual reversible displacement of the whole system, involving an injection of δM_i moles of material into region i. Then:

$$\delta U = \Sigma[\delta U_i + u_i \delta M_i + \varphi_i \delta M_i] = 0 \qquad (5)$$

where:

$$\delta U_i = t_i \delta S_i - p_i \delta V_i \qquad (6)$$

we have the restrictions:

$$\delta V = \sum_i (\delta V_i + v_i \delta M_i) = 0 \qquad (7)$$

$$\delta S = \sum_i (\delta S_i + s_i \delta M_i) = 0 \qquad (8)$$

$$\delta M = \sum_i \delta M_i = 0 \qquad (9)$$

It should be noted that u_i is the molar energy at region i, that is, it is an intrinsic quantity independent of φ_i. On substituting (6) into (5), and introducing undetermined multipliers P, T, μ for (7), (8), (9) respectively, one obtains the set of three equations:

$$\begin{aligned} t_i &= T \\ p_i &= P \\ \mu &= u_i - Ts_i + Pv_i + \varphi_i \end{aligned} \qquad (10)$$

Thus it is seen how the chemical potential μ may be introduced as a constant throughout the system, which may have several phases. The validity of this proof cannot be in doubt, as it is based on a most general condition of thermodynamic equilibrium. Recently[6], I have generalized this treatment to a multi-phase system in chemical equilibrium under non-hydrostatic stresses, for which the expression for the work in (6) is, of course, different.

Equation (10) thus shows that the intrinsic potential $u - Ts + Pv$ plus the molar potential energy φ is a constant throughout the system. Thus if an increment dN of material is added to the system at any region i, (10) yields:

$$dU_a = TdS_a - PdV_a + \mu dN \qquad (11)$$

where $dU_a = (u_i + \varphi_i)dN$, $dS_a = s_i dN$, $dV_a = v_i dN$ are the increments to U, S and V, for the whole system, arising from the injection of mass dN. If, further, a deformation of the whole system occurs, with no change of total mass, the changes in U, S and V are given by:

$$dU_b = TdS_b - PdV_b \qquad (12)$$

Combining (11) and (12) one obtains for a general virtual displacement of the whole system:

$$dU = TdS - PdV + \mu dN \qquad (13)$$

where (13) has been shown to be independent of where in the system dN has been injected. The method of this proof shows that Melehy's objection is not valid and that the correct treatment takes into account the deformation of the surrounding medium, necessary for the total volume to remain constant under the transfer of dN particles from one point to another in the system.

Particle Diffusion Force and Potential

It is true that from the condition:

$$\mu^i + \varphi = \mu = \text{constant} \quad (14)$$

where μ^i is the intrinsic potential (see ref. 4, p. 146, for the introduction of this term), and φ the molar potential energy, one may obtain a force equation by differentiating, thus:

$$\nabla\mu^i + \nabla\varphi = 0 \quad (15)$$

and if one defines, after Melehy[3]:

$f_d = -\nabla\mu^i$, the diffusion force, and $f_e = -\nabla\varphi$, the long-range force (15) can be written:

$$f_e + f_d = 0 \quad (16)$$

Since f_e represents the long-range forces, f_d must be the force per mole exerted on a particle by the surrounding medium. It should be mentioned that the term "particle" as used by Melehy can be interpreted as a small part of the thermodynamic system constant in mass, for example, one electron. That is, the volume occupied by the particle may vary and would be mv where m is the mass in moles of the particle and v is the molar volume in the region occupied by the particle.

It is claimed[2] that it is a consequence of (16) that a transfer of a particle from point A to point B in the system would be at constant energy. The fallacy of this assertion lies simply in the fact that in the transfer the volume occupied by the particle changes and work is required to deform the surroundings of the particle sufficiently to accommodate it.

Consider a particle of small mass m (in moles) which occupies a volume mv at point A, v being the molar volume at that point. In a small displacement $\delta\mathbf{r}$ of the particle, the work which must be done on it is easily seen to consist of three terms, first, that required to translate the particle against the pressure forces of its surroundings $(\delta\mathbf{r}.\nabla P)mv$; secondly, the work against these forces required to change the volume of the particle $(\delta\mathbf{r}.\nabla v)mP$; thirdly, the work to be done against the long-range forces $(\delta\mathbf{r}.\nabla\varphi)m$. That is, the total work:

$$\delta W = \delta\mathbf{r}.(v\nabla P + P\nabla v + \nabla\varphi)m \quad (17)$$

$$= \delta\mathbf{r}.[\nabla(Pv) + \nabla\varphi]m \quad (18)$$

Thus for a perfect gas with a uniform temperature:

$$\delta W = (\delta\mathbf{r}.\nabla\varphi)m \quad (19)$$

Equation (19) is in agreement with the classical explanation of the Peltier effect, and may, in fact, be used to relate the electrostatic potential difference to the energy which must be provided for the transport of electrons in metals.

For a system with a uniform temperature (for example, see ref. 3):

$$\nabla\mu^i = v\nabla P \quad (20)$$

and it is thus seen that (17) contains not only the work required against f_e and f_d, but the additional third term involving the change of volume occupied by the particle. (18) shows that the work to be done in a displacement of a "constant mass particle" involves the gradient of Pv and not of μ^i.

(15) becomes:

$$-\nabla\varphi = v\nabla P \quad (21)$$

and expresses the fact that for thermodynamic equilibrium the net force on the particle must be zero, whereas in a virtual displacement the work done does not solely arise from these two forces.

This argument shows that the work done against the surroundings of the particle, in transferring it from one point to another in the medium, cannot be described as a diffusion potential the gradient of which yields the particle diffusion force, f_d of refs. 1 and 2, which is equal and opposite to the long-range force f_e in equilibrium. Also, since it has been shown here that the chemical potential is a constant of the whole system, the basis of Melehy's theory is invalid, and consequently, for example, the application to the discussion of the properties of a p–n junction.

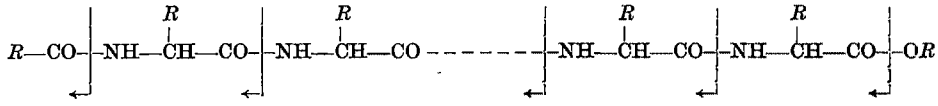
MASS SPECTROMETRIC DETERMINATION OF THE AMINO-ACID SEQUENCE OF PEPTIDES*

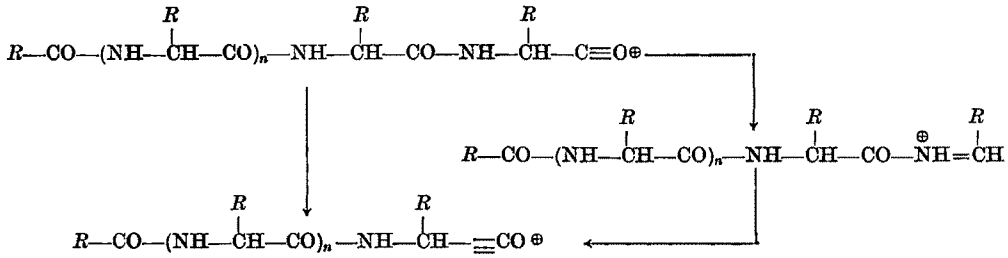
By Prof M. M. SHEMYAKIN, YU. A. OVCHINNIKOV, A. A. KIRYUSHKIN, E. I. VINOGRADOVA, A. I. MIROSHNIKOV, YU. B. ALAKHOV, V. M. LIPKIN, YU. B. SHVETSOV, N. S. WULFSON, B. V. ROSINOV, V. N. BOCHKAREV and V. M. BURIKOV

Institute for Chemistry of Natural Products, U.S.S.R. Academy of Sciences, Moscow



One of the most difficult and cumbersome tasks in the elucidation of the primary structure of proteins is the determination of the amino-acid sequence of peptides —a veritable barrier to the rapid solution of many chemical and biochemical problems. The use of mass spectrometry for this purpose with its great saving in time and in the requirement of material used (micro-amounts) could greatly facilitate this task.

* For preliminary communications, see refs 1–3.



Because of their low volatility and tendency to undergo irregular fragmentation, the free peptides are not very suitable for direct mass spectrometric analysis[4]. More convenient are the methyl (*tert*-butyl) esters of the acyl-peptides which can readily be prepared from the peptides by a method described in one of our preliminary communications[2] (see also refs. 5–8).

The unit sequence in the peptides follows quite readily from an analysis of the amino-acid type of fragmentation[1],

which involves rupture of the amide bonds of the acyl-peptide ester, beginning with the C-terminus:

Although fragmentation of the peptide chain may start at any of the various amide bonds, this does not distort the over-all picture of the spectrum. The stepwise elimination of the amino-acid residues in the resulting fragments may proceed in one or in two stages, according to the following scheme:

Frequently such transformations can be confirmed by the corresponding metastable ions.

The data presented in Table 1 clearly illustrate the universality of the amino-acid type of fragmentation—peptides with the most varied amino-acid residues tending to undergo this kind of fragmentation. Mass spectrometry can therefore be considered as a novel technique for the determination of amino-acid sequences—a technique based on fundamentally different principles from those previously used. It should be added that each amino-acid makes its own contribution to the mass spectrum, which usually facilitates an analysis of the latter. Furthermore, the fragmentation picture is influenced by the position and chemical environment of the amino-acid in the peptide chain.

Specific types of fragmentation, dependent on the nature of the amino-acids, will be illustrated below for a number of examples.

Table 1*

Amino-acid	Peptides containing the amino-acid in the previous column	Sequence of elimination of amino-acid residues (*m/e* of the fragments)
Gly	Dec-Gly-Leu-Val-OMe (1)	M^+(455)→OMe(424)→Val(325)→Leu(212)→Gly(155)

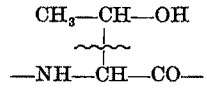
* The mass spectra were taken on commercial *MX*-1303 and *RMU*-6*D* (Hitachi) instruments at 150°–350° C with the sample introduced directly into the ion source.



Aliphatic monoamino monocarboxylic acids (glycine, alanine, valine, leucine, isoleucine and proline) essentially do not complicate the general picture of the spectrum. It is true, however, that branched chain amino-acids may sometimes partly lose their chain; especially is that so in the case of leucine and isoleucine (see, for example, Fig. 1). The elimination may involve part of the chain (for example, methyl in valine or isoleucine) or the chain as a whole, depending on the neighbouring amino-acids. This usually gives low-peak intensities as compared with the peaks of the amino-acid type of fragmentation. The mass spectra of peptides containing proline residues often exhibit quite strong peaks, due to the ions resulting from elimination of the carbonyl groups and ring contraction:

As might be expected, the fragmentation of peptides containing amino-acid residues with functional substituents in the β-position is accompanied by elimination (usually only partly) of the function from the molecular ion or the resultant fragments:

Examples of such peptides are those containing serine, threonine and/or cysteine residues (see, for example, Fig. 2 and compare with ref. 5). A further type of side-chain elimination is also possible for threonine derivatives (compare ref. 6):

Elimination of the β-substituent is always observed in the fragmentation of peptides containing the residues of asparagine or the β-ester of aspartic acid. This process is characterized by its stepwise developments—first the elements of ammonia/alcohol and then CO are eliminated. Such mechanisms are often supported by the presence of the corresponding metastable ions.

The same two-stage elimination picture is shown by the γ-esters of glutamic acid and by glutamine (see, for example, Fig. 3), although here the relative intensity of the corresponding peaks is somewhat lower than for the aspartic acid derivatives. For the γ-substituted amino-acids (derivatives of glutamic acid and methionine), elimination of the entire side-chain also partially occurs, as can be seen in the example of the peptide (30) (Fig. 4).

Peptides containing citrulline may suffer loss of the $CONH_2$ group from the δ-substituent; weaker peaks can also be seen in the spectrum, and these are due to the ions resulting from the elimination of the 'fractions' of NH_3 or $NHCONH_2$.

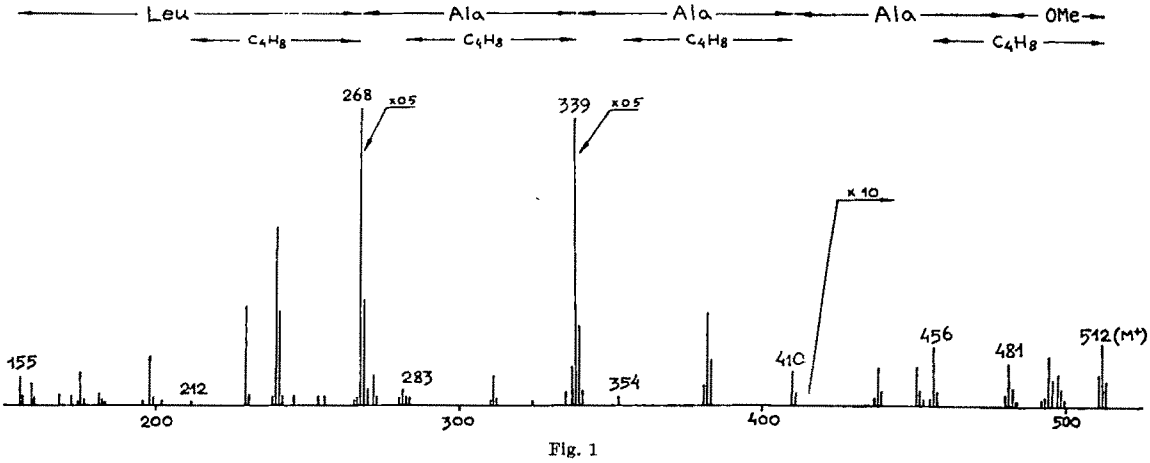


Fig. 1

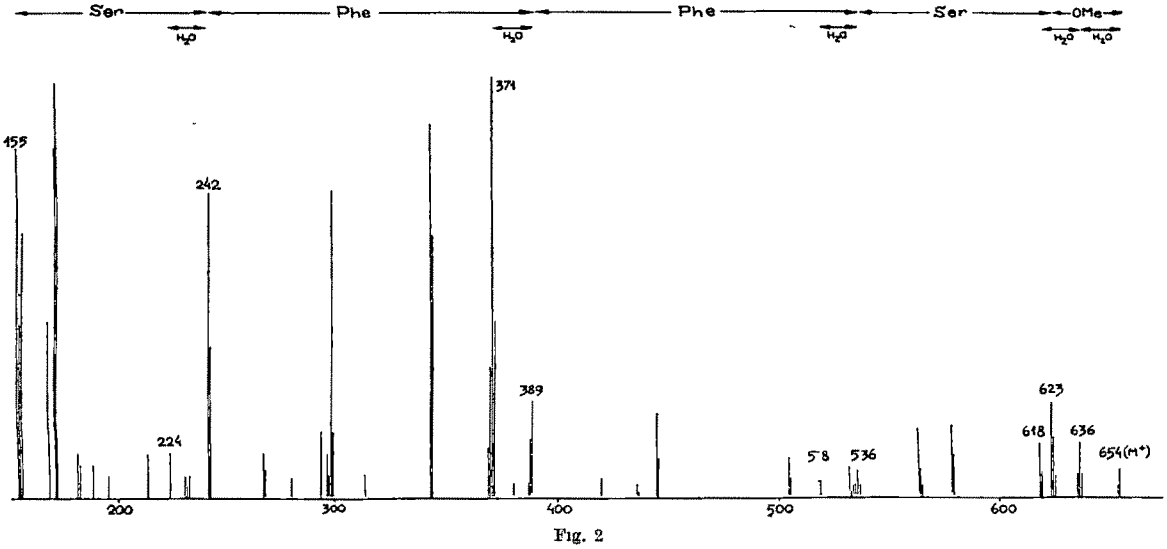

Fig. 2

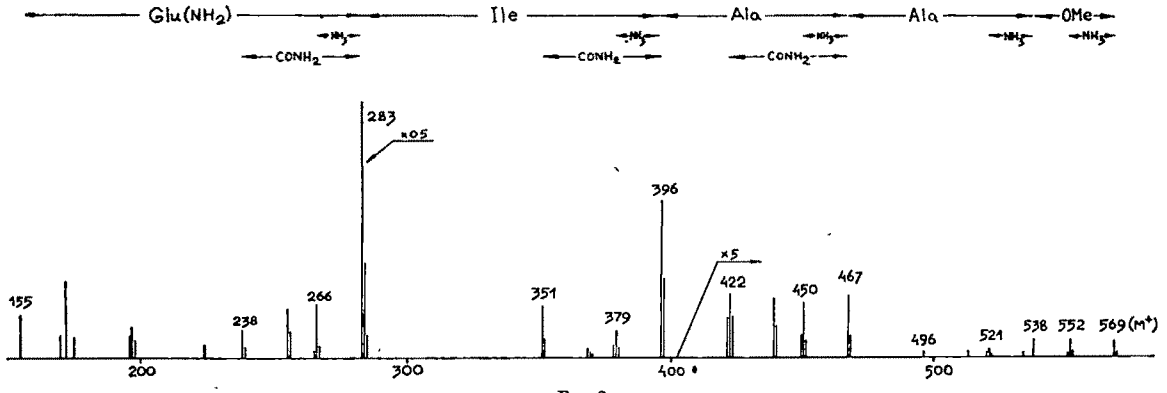

Fig 3

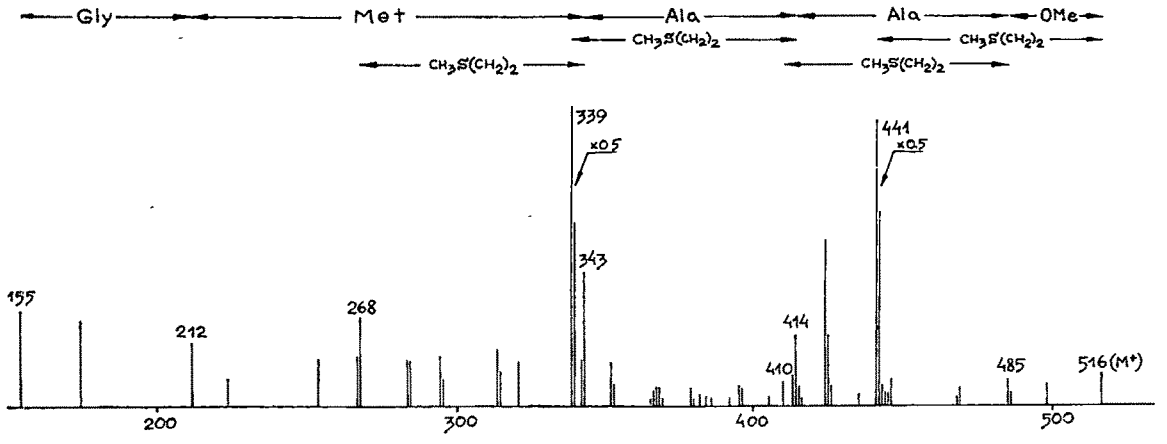

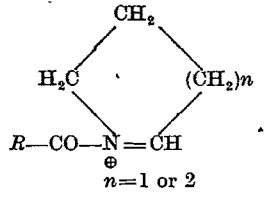

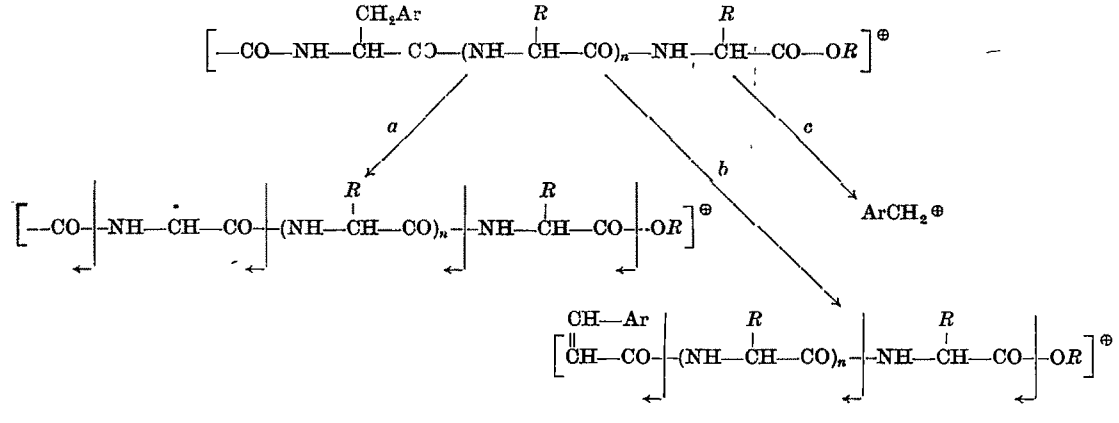

Fig. 4

Before mass spectrometry is carried out of peptides containing diamino monocarboxylic acids (lysine and ornithine), the ω-amino group must be protected by acylation simultaneously with the α-amino group of the N-terminal amino-acid. For peptides with N-terminal lysine and ornithine, one of the strongest peaks is due to ions of the type (see, for example, the *m/e* 238 peak in Fig. 5 and the *m/e* 224 peak in Fig. 6):

It would seem feasible that arginine residues in peptides containing this amino-acid are converted into citrulline or ornithine residues, after which such peptides readily undergo the amino-acid type of fragmentation (as already outlined).

Peptides containing aromatic and heterocyclic amino-acids (phenylalanine, tyrosine, tryptophan, histidine) are characterized by: (*a*) partial elimination of the side-chain as $ArCH_2^{\cdot}$ during the amino-acid type of fragmentation; (*b*) initial rupture of the N—C_α bond of the aromatic/heterocyclic amino-acid residue followed by the amino-acid type of fragmentation; (*c*) elimination of the side-chain in the form of $ArCH_2^{\oplus}$ (for example, tropylium in the case of phenylalanine) (see Fig. 7). All three processes are most clearly manifested in tryptophan-containing peptides:

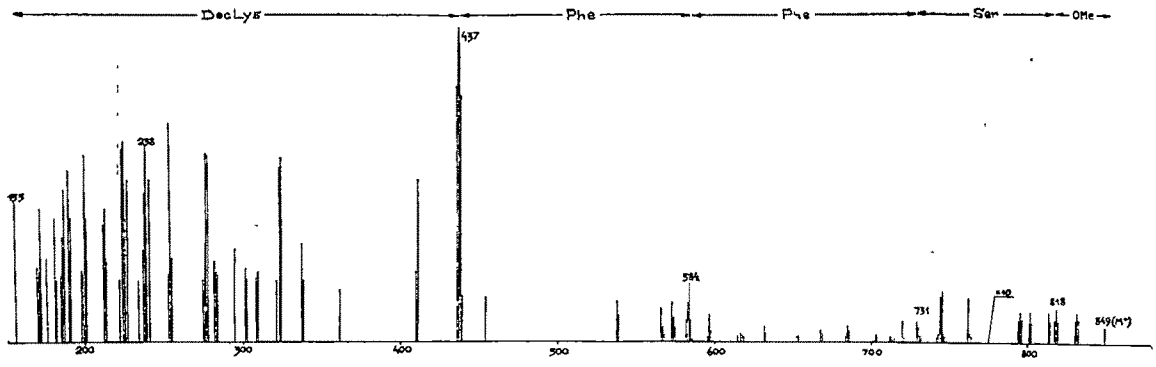

Fig 5

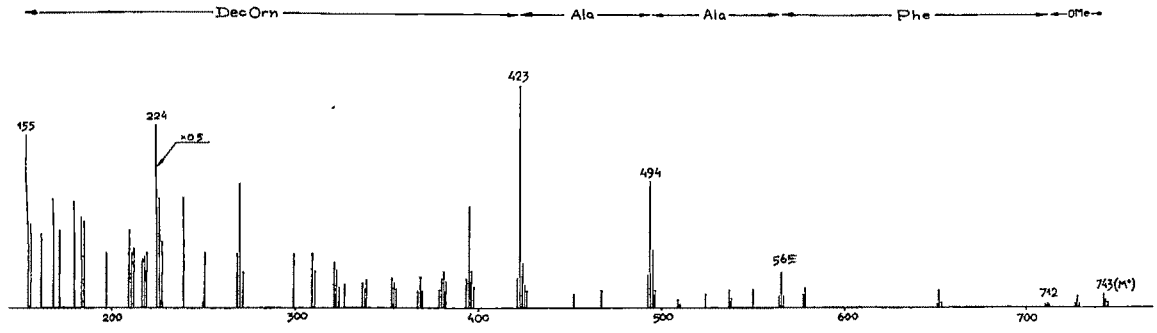

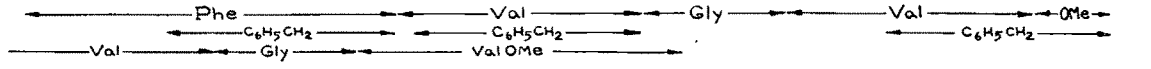

Fig. 6

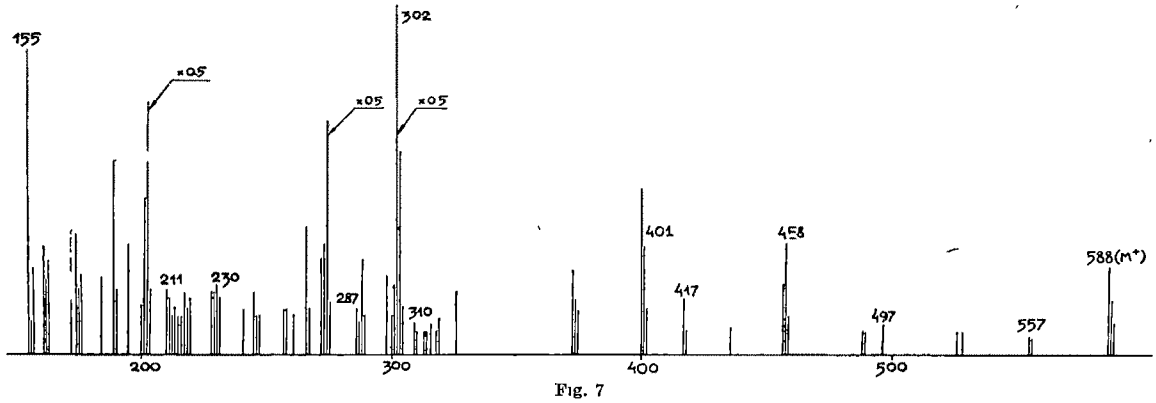

Fig. 7

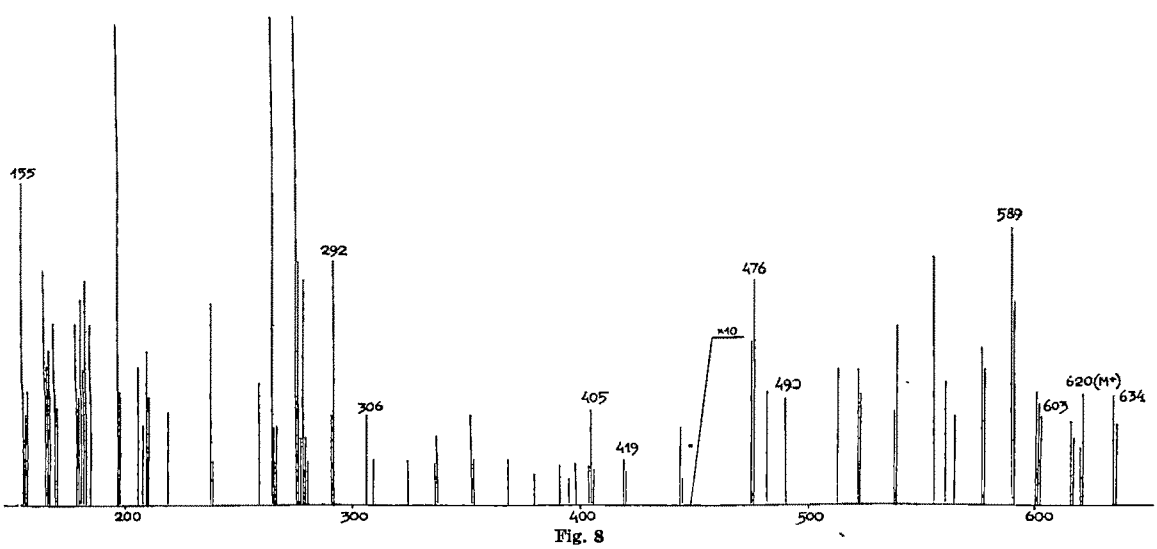

Fig. 8

Because of its strong basicity, the imidazole imino group suffers intermolecular methylation. Thus in peptides containing one histidine residue the peaks corresponding to the amino-acid type of fragmentation are accompanied by peaks shifted by 14 m.u. (see Fig. 8). Correspondingly, the mass spectra of peptides containing two histidine residues (for example, compound 37) exhibit two types of satellite peaks with 14 and 28 excess m.u.

The data presented here show that mass spectrometry can be used to determine the amino-acid sequence in peptides containing all the usual amino-acids. Analysis of the spectra is greatly facilitated if the amino-acid composition of the peptide is known beforehand. The method is limited only by the volatility of the acylpeptide ester, which depends on both the nature of the amino-acids and protective groupings. In the present work a very wide range of peptides, up to a nonapeptide (9), was investigated, but the latter is not the limiting case. The acylpeptide ester can be made more volatile by changing the protecting groups and thus broadening the possibilities of the method. Work is being carried out at present to determine the limits of the method, but even now the mass spectrometric analysis of peptides should make it possible to accelerate sharply and to simplify determinations of the primary structure of proteins.

ESTABLISHMENT OF A LINE OF MOSQUITO (*Aedes aegypti* L.) CELLS GROWN *IN VITRO*

By T. D. C. GRACE

C.S.I.R.O. Division of Entomology, Canberra

THE causal agents of many diseases, both viral and non-viral, that affect man and animals are transmitted by mosquitoes. Some of these agents, after ingestion, multiply in the tissues of the mosquito. Examples of these are western equine encephalomyelitis, yellow fever, and malaria. An interesting feature of the viruses in this group is that they do not appear to cause a disease in the tissues of the mosquito vector. The successful culture of mosquito cells *in vitro* would permit more intensive investigations of these viruses than could be achieved by using infectivity assays or techniques on whole insects.

In vitro culture of mosquito cells has been attempted many times[1–6]. In the majority of experiments no growth has been obtained although the tissues have survived for many weeks as evidenced by muscular contractions. However, Kitamura[7] has recently obtained growth and survival of cells from ovarian tissues of *Culex pipiens molestus* Forsk. for up to 4 weeks. This article reports the establishment, *in vitro*, of a line of cells from *Aedes aegypti* L. larval tissues.

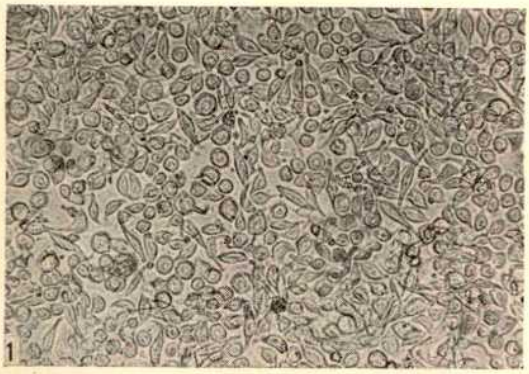
The mosquito tissues used in the experiments reported here were obtained from axenically grown larvae about to pupate[8]. The larvae were placed in insect culture medium[9] and the heads, tails and alimentary canals were removed. After discarding the peritrophic membranes, the alimentary canals and bodies were washed twice in fresh medium. The tissues were torn apart before cultivation.

Each culture consisted of the bodies and alimentary canals from three larvae in 1·0 ml. of medium in a $3 \times \frac{1}{4}$-in. round-bottomed tube slanted about 20° from the horizontal. The medium was the same as is used for the growth of the cell lines of *Antheraea eucalypti* Scott. established by Grace[9]. The cultures were incubated at 30° C.

In June 1963, four cultures were set up. Although the alimentary canals contracted vigorously when dissected the contractions stopped when they were first placed in the culture fluid, but resumed after about 15 h.

Two days after the cultures were made, cells had migrated from several masses of tissue. The number of cells continued to increase over the next 14 days and mitotic divisions were numerous. Most of the cells floated in the medium, but many remained in clumps attached to the surface of the culture tube.

Four weeks after the cultures were set up, the first subculture was made. Free-floating cells were transferred to a Porter flask containing 0·5 ml. of the medium in which the cells had been growing and 0·5 ml. of fresh medium. Since this time subcultures have been made at intervals of about 7 days. In the early subcultures, 3×10^5 cells in 3·0 ml. of medium were placed in 2-oz. half-flat medicine bottles. The later subcultures have consisted of 2×10^5 cells/ml. in 4-oz. and 8-oz. bottles (Fig. 1).



The cells have also been grown in suspension. Inocula for these cultures consisted of $2–4 \times 10^5$ cells/ml. of medium. In suspension the cells have a generation time of about 51 h at 30° C.

The cells have been deep-frozen at −80° C in medium containing 10 per cent glycerol and have been successfully regenerated after 8 months.

Initially there were a number of morphologically distinct types of cells in the cultures. However, after the cultures had been growing for about 3 months, many of the types had disappeared. At the present time the most common type is spindle-shaped, 40–50μ long and 8–10μ wide. These cells grow in clumps and usually remain attached to the culture vessel (Fig. 2). The second, slightly less common type of cell is round in outline, about 20μ in diameter and has a granular cytoplasm (Fig. 3). Some of these cells grow in clumps loosely attached to the surface of the culture vessel, but the majority float in the medium. Two other types of cells are present, but in very small numbers. One type consists of very large round cells, 55–60μ in diameter. The other type characteristically puts out long extensions which are very firmly attached to the glass.

It is not possible to determine from which tissues these cells have grown. In last-stage larvae about to pupate the imaginal disks that will develop into the adult gut, wings, gonads and other appendages have started to

grow and it is possible that the cells could have come from some of these tissues. From 1953 until the cultures just described were set up in June 1963, many cultures of mosquito tissues had been set up. In none of these did growth take place except to a limited extent in two cultures initiated in October 1962. In these cultures a few cells migrated from the tissues 7 months after they were set up. Over the next 4 weeks the number of migrating cells increased and several cells in each culture were seen to divide. Ten months after setting up the cultures there were still a few healthy cells but no mitotic divisions were seen and the cultures were discarded about 3 months later.

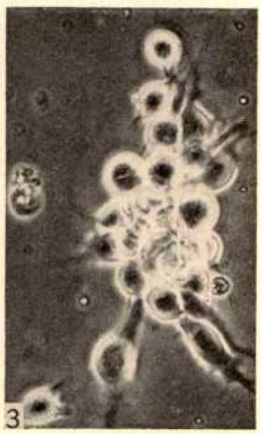


Fig. 1. Cells from the mosquito *Aedes aegypti*. From a culture 23 months old. (×*c*. 45)

Fig. 2. Spindle-shaped cells of the mosquito *Aedes aegypti* growing *in vitro*. Phase contrast. (×*c*. 90)

Fig. 3. Round cells of the mosquito *Aedes aegypti* growing *in vitro*. Phase contrast. (×*c*. 140)

In the past 18 months more than a hundred cultures of mosquito tissues have been made and in only two of these has growth comparable to that described for the cell line occurred. However, the growth continued for only 2·5 and 4 months respectively and then the cultures died. In these cultures the *A. eucalypti* haemolymph was replaced by 3 per cent *Antheraea pernyi* Guer. haemolymph.

Six months after the line had been established an investigation of the chromosome complement of the cells was made. In *Aedes aegypti* the diploid number of chromosomes is six, but many cells in the larvae are polyploid. Cells from the cultured line were stained and mounted as squash preparations in lactic-orcein[10]. The results were surprising in that no cells having the diploid number of chromosomes were observed. Most of the cells had chromosome complements of 96 (32*n*), while the next most frequent number was 48 (16*n*). A few cells contained many more than 96 chromosomes.

Originally the medium in which the cells were grown contained 5 per cent heat-treated haemolymph from *A. eucalypti*. As a constant and large supply of this haemolymph could not be assured, attempts were made to adapt the cells to grow in media containing either bovine plasma albumin (BPA), calf serum or the haemolymph from a related species of Saturniid, *Antheraea pernyi*, which can be obtained in large numbers. Media containing various concentrations of these supplements were tested; the most suitable were those containing either 3 per cent *A. pernyi* haemolymph or 1 per cent BPA or 1 per cent calf serum.

By December 1964, about 13 months after the adaptation experiments were begun, the growth of the cells in 3 per cent *A. pernyi* haemolymph and those in 1 per cent BPA were more satisfactory than the growth in medium containing 1 per cent calf serum. In none of the media, however, have the cells grown so well as those grown in media containing 5 per cent *A. eucalypti* haemolymph.

As the cells in the mosquito cultures are morphologically not unlike the cells from the ovarian cultures of *A. eucalypti* growing *in vitro*, it was necessary to confirm that the cells were of mosquito origin. To determine this, a serological method using the gel diffusion precipitation method (Ouchterlony technique) was used. Antiserum to the *A. eucalypti* cells was used. The antigens consisted of sonicated suspensions of (1) cells from the mosquito cultures, (2) mosquito larvae, (3) cells from the *A. eucalypti* cell lines and (4) ovarian tissues from *A. eucalypti* diapausing pupae.

The only precipitin lines which formed were between the *A. eucalypti* antiserum and the suspensions from the *A. eucalypti* cell lines and ovarian tissue.

Further evidence to support the view that the cells are of mosquito origin is furnished by the chromosome complements of the cells. In the line of cells described in this article the great majority of cells contained either 96 or 48 chromosomes and only a few contained more than 96 chromosomes. In the *A. eucalypti* cell lines the most frequent chromosome numbers were 100, 200 and 400, while cells of higher ploidy, although less numerous, were frequently seen[11]. The second piece of supporting evidence is that a virus, causing a cytoplasmic polyhedrosis in the *A. eucalypti* cell lines, would not grow in the cells described in this paper.

It is most unlikely that a group of cells from the *A. eucalypti* lines would change their serological characteristics, their chromosome number and their ability to maintain virus growth when other cells from the lines have retained these properties.

Cultures of the mosquito line have been sent to Dr. Earl C. Suitor at the United States Naval Medical Research Unit at Taipai in Taiwan. Suitor has successfully maintained the line and has adapted them to grow in medium containing 2 per cent and 0·5 per cent cynthia (*Samia walkeri* Dru.) haemolymph together with foetal bovine serum or bovine plasma albumin. Samples of these cells have been sent to me by Dr. Suitor and are being maintained in this laboratory.

I thank Mrs. N. Blunden for help in caring for and maintaining the cultures. This work was supported in part by a research grant from the U.S. Public Health Service.

INDUCED MUTATION AFFECTING THE CONTROL OF MEIOTIC CHROMOSOME PAIRING IN *Triticum aestivum*

By DR. RALPH RILEY, VICTOR CHAPMAN and ANGELA M. BELFIELD
Plant Breeding Institute, Cambridge

HOMOEOLOGOUS chromosomes of wheat (*Triticum aestivum* $2n = 6x = 42$), which are genetically corresponding members of the three different genomes of which the chromosome complement is composed, are prevented from pairing at meiosis by a genetic activity of chromosome 5*B* (ref. 1). Although pairing is normally confined to fully homologous partners, homoeologues will pair in the absence of chromosome 5*B*. This effect is produced by the deficiency of no other member of the complement.

Chromosome 5*B* is heterobrachial and the activity by which homoeologous pairing is prevented is confined to the long arm, which is about three times the length of the short[2]. It seems reasonable to suppose that the effect derives from the activity of a single locus, but this cannot be proved as allelic variation is unknown.

An investigation (of which the experiment described in this article forms part) was initiated with the aim of inducing such allelic variation by mutation. The availability of mutants would both allow the completion of the analysis of the formal genetics of the system and more readily permit the study of its functional basis. In addition, the use of genetically induced homoeologous recombination in wheat improvement would be greatly eased by the availability of allelic variation in the 5*B* system.

The most difficult problem posed by any attempt to induce mutations of genes affecting meiotic characters is that of recognition. This is especially true of work with the 5*B* system of *T. aestivum* as the occurrence of multivalents, resulting from the synapsis of homoeologous as well as homologous chromosomes, could easily be overlooked because they could well be relatively infrequent. Consequently, in the present work potential mutants were scored at meiosis in hybrids between *T. aestivum* and rye (*Secale cereale* $2n = 14$).

This method was used because of the ready distinction between the meiotic behaviour of *T. aestivum* × *S. cereale* hybrids with and without chromosome 5*B*. When chromosome 5*B* is present in such hybrids there is very little chromosome pairing at meiosis, whereas in its absence bivalents and trivalents are frequent. This was initially shown by Riley, Chapman and Kimber[3], and was again demonstrated in some of the products of the present work (Tables 1 and 2). The experiment was thus designed to enable the recognition of mutants that changed the normal expression of meiotic pairing towards that occurring in the absence of chromosome 5*B*.

Ethyl methanesulphonate (EMS), which has been shown to be efficiently mutagenic in *T. aestivum*[4], was used to treat seeds of plants of *T. aestivum* variety 'Chinese Spring', in which chromosome 5*B* was represented by a pair of telocentrics for the long arm, the short arm being entirely deficient. Chromosome 5*B* was thus marked by structural condition that enabled its presence to be established from preparations showing either meiotic or mitotic divisions. Seeds of this genotype were soaked in 0·5 or 1·0 per cent aqueous solutions of EMS for either 16 or 24 h. However, because differences in EMS concentration or in the time of exposure resulted in no detectable modification in effect, variations in treatment can be ignored.

Immediately after treatment with EMS the seeds were thoroughly washed with water and then germinated. When the resulting plants came into ear, one spike of each plant was bagged to ensure self-pollination and other spikes were emasculated and pollinated with *S. cereale*.

Table 1. CHROMOSOME PAIRING AT FIRST METAPHASE OF MEIOSIS IN A SAMPLE OF 28-CHROMOSOME HYBRIDS FROM THE CROSS OF EMS-TREATED *T. aestivum*, DITELOCENTRIC 5*B*, BY *S. cereale*

72/17	19·30	2·50	0·90	—	4·60
83/11	17·30	3·85	0·60	0·05	5·60

A total of 206 hybrid plants were grown from seeds resulting from crosses between the treated plants of *T. aestivum* ditelocentric 5*B* and *S. cereale*. All these hybrids were scored at first metaphase of meiosis in order to determine the pattern of chromosome pairing. In 199 plants the majority of chromosomes were unpaired, although occasionally there was one bivalent and more rarely two (Fig. 1*a*). The mean pairing of a typical sample of five such plants is shown in Table 1. Infrequent pairing like this is characteristic of *T. aestivum* × *S. cereale* hybrids and no modification of the normal genetic regulation of meiosis was displayed in these plants.

In seven other hybrids bivalents were frequent, ranging from one to eight per cell. There were also trivalents,

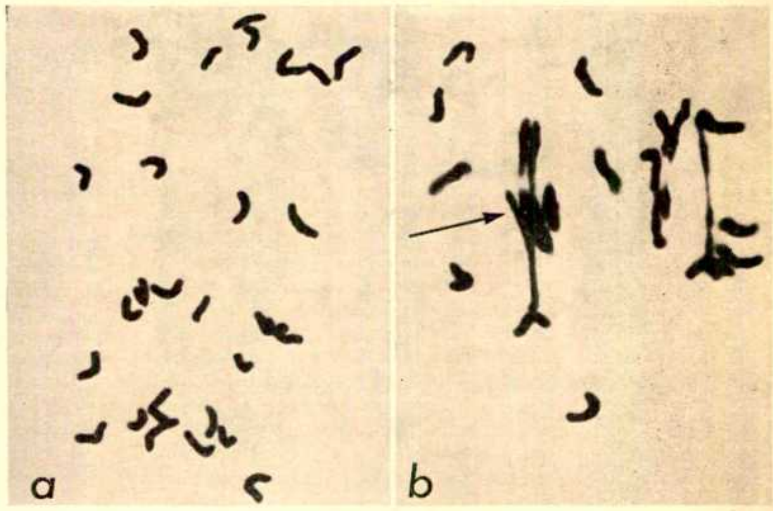

Fig. 1. Photomicrographs of first metaphase of meiosis in 28-chromosome hybrids from crosses between EMS-treated plants of *T. aestivum*, ditelocentric for chromosome 5*B*, and *S. cereale*. (*a*) Hybrid 5/10 with little chromosome pairing and therefore non-mutant, 28 univalents; (*b*) hybrid 81/15 with considerable chromosome pairing and therefore mutant, two trivalents, five bivalents and twelve univalents, the telocentric chromosome 5*B* is in a bivalent (arrowed)

Table 3. CHROMOSOME PAIRING AT FIRST METAPHASE OF MEIOSIS IN 28-CHROMOSOME HYBRIDS WITH HIGH PAIRING FROM THE CROSS OF EMS-TREATED *T. aestivum*, DITELOCENTRIC 5*B*, BY *S. cereale*

ranging from zero to six per cell, and occasionally a quadrivalent was present. The mean pairing in these hybrids is shown in Tables 2 and 3. The pattern of pairing was characteristic of that in *T. aestivum* × *S. cereale* hybrids deficient for chromosome 5*B* and it can be concluded that a change had occurred in the *T. aestivum* component of the genotype by which homoeologous pairing is normally prevented.

Of the seven plants with abnormally high pairing, three (9/1, 72/17 and 83/11) had only twenty-seven chromosomes, and were deficient for the telocentric by which the presence of chromosome 5*B* was normally marked. These plants were therefore totally deficient for chromosome 5*B* and displayed the meiotic behaviour characteristic of hybrids of this genotype (Table 2).

One other plant (9/2) had twenty-eight chromosomes, twenty-seven of which were apparently normal while one was a small centric fragment which was possibly an isochromosome. This fragment had apparently been formed by the deletion of a large terminal segment from the long arm of chromosome 5*B* because the telocentric for 5*B* was absent. Because the meiotic behaviour of this hybrid was very similar to that of those deficient for the entire chromosome, the region concerned with the prevention of homoeologous pairing must have been lost (Table 3). Consequently, this region is not immediately adjacent to the centromere.

Finally, three hybrids with high pairing at meiosis (5/12, 8/12 and 81/15) had normal chromosome complements, with twenty-eight chromosomes one of which was the 5*B* telocentric, apparently unchanged in structure. The meiotic behaviour of these plants was similar to that of those entirely deficient for chromosome 5*B* (Table 3) (Fig. 1*b*). The breakdown of the normally restricted pairing in these plants must be ascribed to gene mutation in the 5*B* system. This is not to imply that mutation had necessarily occurred at a locus on chromosome 5*B*, as the mutational origin of a suppressor of 5*B* activity elsewhere in the genotype could have given the same result.

All three hybrids displaying mutant phenotypes were derived from different EMS-treated parental plants of *T. aestivum*, so that all the mutants were of independent origin. In order to attempt to recover the mutants, seeds derived from self-pollination of the three parental plants of *T. aestivum* were grown. Eight plants, all of which had regular bivalent formation at meiosis, in the progeny of each parent were pollinated with *S. cereale*. In the resulting twenty-four families of *T. aestivum* × *S. cereale* hybrids, there were usually more than five plants and all these were checked at meiosis. A total of 159 hybrids were examined, but all had low levels of pairing comparable with that to be expected in normal *T. aestivum* × *S. cereale* hybrids. From this it was concluded that the mutants that had originated sectorially in the EMS-treated *T. aestivum* parents had not been transmitted to the progenies obtained by self-pollination. Because the *T. aestivum* × *S. cereale* hybrids with mutant phenotypes were sterile, the mutants responsible were therefore lost.

Nevertheless, important principles are displayed by this attempt to produce allelic variation in the 5*B* system. First, the origin by mutation of changes in the genetic control of chromosome behaviour is shown to be feasible. Secondly, by the use of EMS mutation can be induced with high frequency in the 5*B* system of *T. aestivum*. About 1·5 per cent of the gametes of the treated generation were mutant in the present work. In the absence of evidence as to whether the mutations had occurred on chromosome 5*B* or at suppressor loci elsewhere, nothing can be inferred about the nature of the regulation normally exercised by this chromosome. However, it is apparent that with appropriate modification of the experimental approach, further attempts to isolate and maintain mutants, giving homoeologous pairing in *T. aestivum*, are justified.

BIOSYNTHESIS OF IMMUNOGLOBULINS. FREE LIGHT CHAIN AS AN INTERMEDIATE IN THE ASSEMBLY OF γG-MOLECULES

By DR. BRIGITTE A. ASKONAS and DR. ALAN R. WILLIAMSON
National Institute for Medical Research, London, N.W.7

THE diversity and specificity of antibody molecules make their formation a unique problem in macromolecular biosynthesis. Apart from the immunological aspects of the problem, immunoglobulins are a fascinating model for the study of the synthesis and assembly of a multichain protein with interchain disulphide bonds. (For a review of the structure see Cohen and Porter, ref. 1.)

Our present investigations, at a sub-cellular level, on the synthesis of immunoglobulins, utilize as a model system a murine plasma cell tumour (5563)[2] which produces and secretes substantial quantities of 7*S* γG-myeloma protein[3]. We have examined, in sucrose density gradients, the polyribosomes obtained from tumour cells pulse labelled with tritiated leucine, and by the use of specific antisera against parts of the γG-myeloma protein have demonstrated that different classes of polyribosomes are involved in the synthesis of light and heavy chains[4]. Synthesis of each type of chain occurs on polyribosomes of sufficient size to accommodate *m*RNA molecules coding for complete individual light or heavy chains[4].

The chains are therefore synthesized separately and then have to be assembled to form the complete molecule. This article deals with the initial steps in assembly. The results of our investigations show that completed light chains are released from ribosomes autonomously and that there is a pool of free light chains which we propose controls the release of heavy chains, and thus the balanced formation of multi-chain 7*S* γ-globulin.

Preparation and use of specific antisera. Three antisera, obtained from rabbits hyperimmunized by several courses of injections, were used in this study. (1) Anti-Fc-fragment: Rabbits were immunized with papain fragment Fc prepared after treatment of 5563 myeloma protein with papain[5]. The antiserum was absorbed with papain fragment Fab and so rendered specific for the heavy chain. After absorption the antiserum reacted with Fc-fragment and also with freshly prepared heavy chain and whole myeloma protein. It contained 3·5 mg antibody/ml. serum. (2) Anti-Fab-fragment: Rabbits were immunized with papain fragment Fab, the antiserum was absorbed with

Fc fragments and three successive times with small amounts of light chain of the myeloma protein. The light chain was prepared according to the method of Fleischman, Pain and Porter[6]. The antiserum did not bind iodine-131 labelled light chain, but still precipitated Fab-fragment and myeloma protein and contained 1·5 mg of antibody/ml. (3) Anti-light chains: Light chains were used for hyperimmunizing rabbits, and the resulting antiserum was absorbed with Fc-fragment; it still reacted with the whole myeloma protein and contained 2 mg/ml. of antibody to light chain.

For analysis of labelled proteins with these antisera, antigen/antibody equivalence points were established for each antiserum. Carrier light chain, papain fragments Fab or Fc were added to appropriate tubes and afterwards a slight excess of the selected antiserum (50–100 μl.) was also added. The mixture was incubated for 30 min at 37° C, stored overnight at +4° C. Type III pneumococcal polysaccharide antibody/antigen precipitate was then added as carrier and the precipitates were washed twice with cold saline and then with trichloroacetic acid (TCA) before counting on Oxoid membranes. Control aliquots of the samples were mixed with purified rabbit γ-globulin followed by goat anti-rabbit γ-globulin serum and then treated in the same way. The amount of radioactivity in this control precipitate was usually less than twice the background in the scintillation counter and was subtracted from radioactivity found in the specific precipitates formed by the antisera against myeloma protein or its fragments.

Pulse-labelling of proteins formed by plasma cell tumour 5563. Ascitic tumour cells (5563) were incubated *in vitro* with ^{3}H-leucine for short time intervals and then disrupted by treatment with deoxycholate. The soluble proteins were separated from the particulate cell components by layering the mixture on to a density gradient made up of 8 ml. of 30 per cent, 1 ml. of 10 per cent and 1 ml. of 4 per cent (w/v) sucrose, and centrifuging at 104,000*g* for 60 min. The top layer (2–3 ml.) was removed and, after brief dialysis in the cold against 0·14 M sodium chloride buffered with phosphate to *p*H 7·4 and then against dry 'Sephadex *G*-100' to concentrate the sample, the soluble proteins were analysed on 5–20 per cent sucrose gradients (Fig. 1*A*). Conditions were chosen which separated the myeloma protein ($S_{20}=6·6$) and the smaller molecular weight light chains ($S_{20}=2·0$). There was a clean separation of iodine-131 labelled myeloma protein and iodine-131 labelled alkylated light chain when the mixture was centrifuged overnight at 35,000 r.p.m. in a Spinco '*SW* 39' rotor (Fig. 1*B*).

Immunological identification of labelled proteins. The proteins labelled after a 5-min exposure to ^{3}H-leucine comprise a wide range of sizes (Fig. 1*A*). In order to detect labelling of myeloma protein and its precursors, equal portions of each gradient fraction were coprecipitated with rabbit antisera specific for various parts of the globulin molecule as already described. Two peaks of radioactivity specifically precipitable with antiserum were found (Fig. 1*A*); one was precipitated only by anti-light chain sera and had a sedimentation similar to free light chains; the other was precipitated by both antibody to light chain and to Fc-fragment. It corresponded in sedimentation rate to whole myeloma protein. Thus, after a 5-min pulse of ^{3}H-leucine, not only was radioactivity incorporated into whole myeloma protein, as might be expected, but also a substantial proportion of the radioactivity was in slower sedimenting material containing light chain but not the Fc portion of the myeloma protein. This material could be either free light chain or Fab-fragment. The antiserum to light chain has a low antibody/antigen ratio with myeloma protein. Since we add carrier light chain to each fraction and only a slight excess of antiserum, not all the myeloma protein is precipitated by the anti-light chain serum (Fig. 1*A*). The anti-Fc-fragment has a high antibody/antigen ratio with myeloma protein and there was sufficient antibody to bind all the myeloma protein present in the fraction.

Further characterization of both peaks of radioactivity was effected by means of an antiserum prepared against papain fragment Fab, extensively absorbed with light chains. This serum, which does not react with iodine-131 labelled light chain but still precipitates Fab fragment, precipitated exclusively the radioactivity in a single peak coinciding with the myeloma protein peak (Fig. 2). We failed to find any radioactivity which could be precipitated in the 3·5 *S* region of the gradient; under these conditions of ultracentrifugation, 3·5 *S* material would be clearly separated from 6·6 *S*; the arrow on Fig. 1*B* shows the position of iodine-131 labelled Fab-fragments on the gradient. The slower sedimenting peak of radioactivity, which could be precipitated with antibody to light chain, was precipitated neither by anti-Fc serum nor by anti-Fab serum absorbed with light chains, and for this reason the material in it clearly has the properties of labelled-free light chains.

Time dependence of labelling pattern. It was of interest next to study the soluble proteins from cells labelled for various periods of time. The labelled proteins from cells exposed to ^{3}H-leucine for 2, 5 and 10 min were analysed

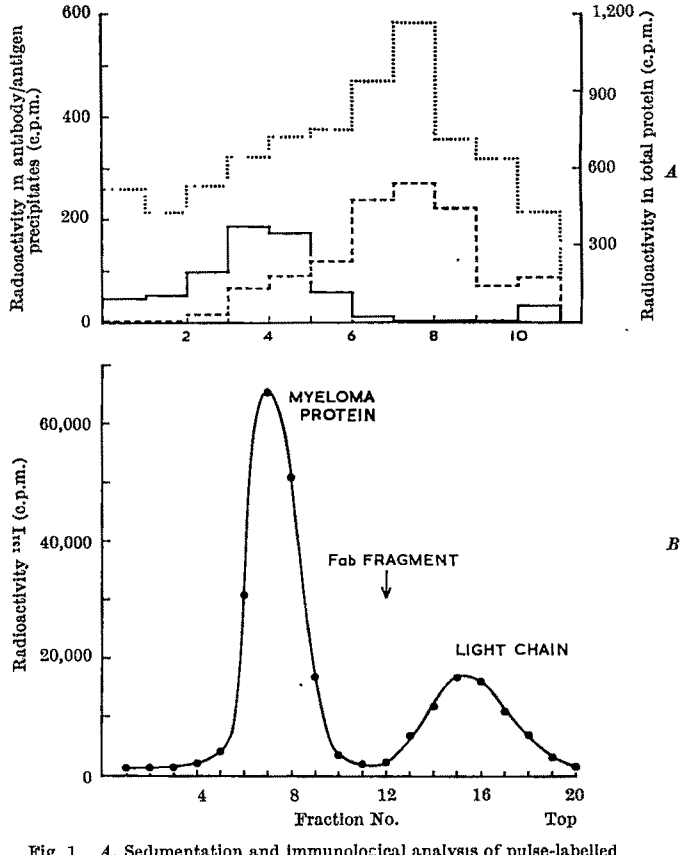

Fig. 1. *A*, Sedimentation and immunological analysis of pulse-labelled soluble proteins from 5563 ascitic tumour cells. Total radioactivity in protein, . . ; radioactivity in antibody/antigen complex precipitated with anti-Fc-fragment, ——; radioactivity in antibody/antigen complex precipitated with anti-light chain, - - - . Washed cells ($3·4\times10^8$) were incubated for 5 min at 37° C in Hanks's medium, containing 10 mg/ml bovine serum albumin, with 30 μc ^{3}H-leucine (specific activity 1·0 c/mmole) in a final volume of 4·6 ml. Cells were disrupted with deoxycholate (0·5 per cent), the soluble protein fraction isolated, and aliquots (0·5 ml.) applied to 4·8 ml. linear gradients 5–20 per cent sucrose w/v in phosphate buffer saline. After centrifugation at 35,000 r.p.m. for 16 h in Spinco '*SW* 39' rotor, fractions (thirty drops) were collected; equivalent fractions were pooled from two gradients. Equal portions of each fraction were precipitated with 5 per cent TCA and filtered on Oxoid membranes for counting in a Packard 'Tri-Carb' scintillation counter. Other portions were treated in the presence of carrier antigen with antisera specific for light chains or Fc papain fragment or, as control, with goat anti-rabbit γ-globulin serum. *B*, Sedimentation pattern of iodine-131-myeloma protein and iodine-131-light chains in a sucrose gradient. Centrifugation conditions were as already described. Fractions half the size of the fractions in Fig. 1*A* were counted for iodine-131 radioactivity directly in an Echo scintillation counter

Table 1

	Radioactivity of specific antibody/antigen precipitates (c.p.m.)	
Time of labelling:	4·5 min	10 min
Myeloma proteins*	1,307	3,305
Light chain†	953	1,360

* Myeloma protein precipitated with anti-Fc serum until no further counts are precipitated.
† Precipitation with anti-light chain following the treatment with antibody to anti-Fc-fragment which had precipitated the myeloma protein.

on sucrose gradients as already described. In each case only two peaks of specifically precipitable radioactivity were found, corresponding to myeloma protein and light chains (Fig. 3). The soluble proteins examined for each time point are derived from separate experiments and the absolute radioactivity of the peaks is not comparable from one experiment to the next. However, between 2 min and 10 min the extent of labelling of myeloma protein has been found to increase linearly (Table 1) and consequently the amount of radioactivity in the light chains compared with that in myeloma protein at each time point can be given an approximate quantitative interpretation. After exposure to ^{3}H-leucine for 2 min a considerable proportion of the radioactivity of the soluble protein fraction which can specifically be precipitated consists of free light chains, although radioactivity is already found in the whole myeloma protein peak (Fig. 3*A*). It must be emphasized that at this time most of the incorporated radioactivity is in the nascent peptide chains bound to ribosomes[4], which have already reached almost maximum specific activity. After exposure to labelled amino-acid for 5 min, radioactivity in free light chains is still of the same order as that found in myeloma protein, which implies that between 2 min and 5 min incorporation into both light chains and myeloma protein is proceeding at comparable rates. However, after 10 min exposure most of the radioactivity which can specifically be precipitated is found in 7*S* myeloma protein while only a small proportion is found in free light chains (Fig. 3*C*). We interpret this as meaning that the total radioactivity in free light chains tends towards a constant value, while incorporation into myeloma protein is still increasing linearly. This is clearly shown (Table 1) by measuring the total radioactivity of myeloma protein antibody/antigen precipitates, which increased greatly between 4·5 min and 10 min, whereas the radioactivity of the light chain showed a much smaller increase.

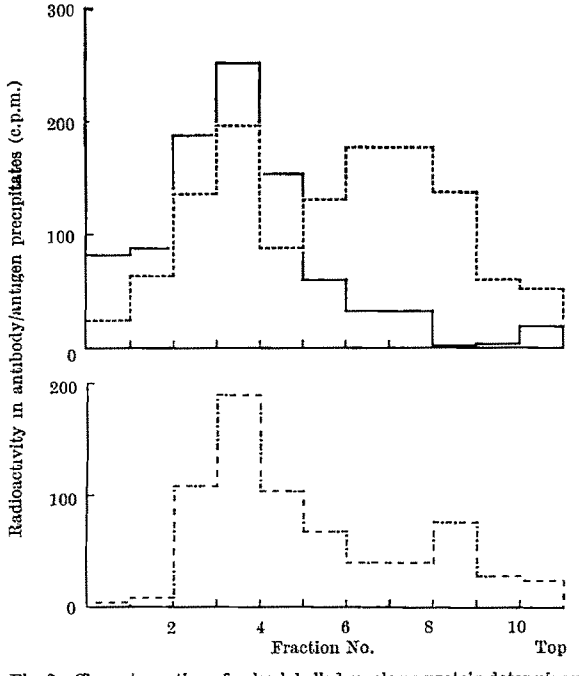

Fig. 2 Characterization of pulse-labelled myeloma protein determinants by sedimentation and immunological properties. Procedures were as described under Fig. 1, except that 3·3 × 10^6 cells were incubated with 20 μc. ^{3}H-leucine in a final volume of 2·6 ml.

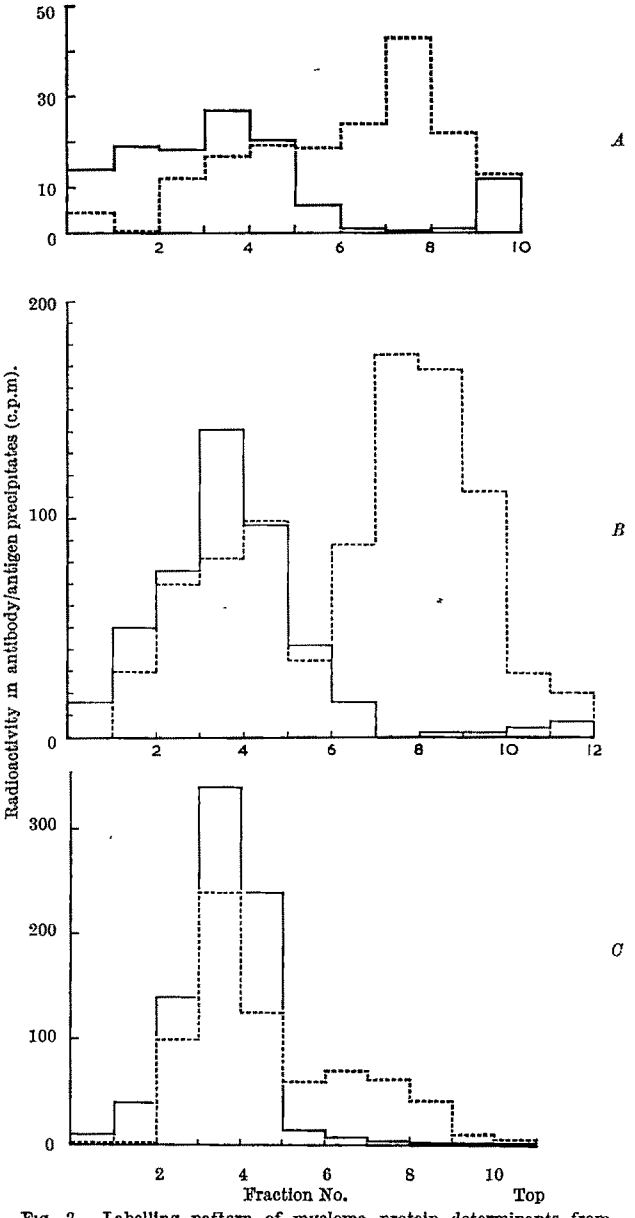

Fig. 3. Labelling pattern of myeloma protein determinants from ascitic cells incubated with ^{3}H-leucine at 37° for *A*, 2 min; *B*, 5 min, *C*, 10 min. Radioactivity antibody/antigen precipitated on reaction with antiserum to papain fragment Fc, ——; radioactivity in anti-light chain antibody/antigen precipitate, - - - - . Each time point represents a separate experiment, using incubation mixtures similar to those described in Fig 2. The volumes loaded on to the sucrose gradients were equal but represented varying proportions of the total soluble protein

It is apparent that the cell contains a small pool of free light chains in addition to completed myeloma protein. However, we would emphasize that 5563-tumour cells have been found to secrete only 7*S* myeloma protein[2] and do not produce an excess of light chains. Secretion of light chains in the serum or urine of mice bearing this tumour has not been detected. From the extent of labelling of the light-chain pool relative to that of myeloma protein at various times it would seem that free light chains are transient intermediates in the assembly of 7*S* γ-globulin. The data presented here do not permit an accurate measurement of the size of the pool of light chains, but it is small compared with the total content of intracellular

γ-globulin, which corresponds very approximately to 30 min production[7–9].

The failure to detect free heavy chains by the methods employed here does not rule out their presence, in small amounts, as heavy chains tend to aggregate and sediment in a similar position to 7*S* myeloma protein. However, the fact that antisera against both papain fragments Fab and Fc precipitated radioactivity only in the region of the myeloma protein in an identical manner, and failure to detect smaller molecular weight Fab and Fc fragments on the sucrose gradient, are highly indicative of the absence of naturally occurring Fc and Fab fragments. This suggests that these fragments are not intermediates in the biosynthesis of γ-globulin, but that the molecule is assembled directly from light and heavy chains. Light chains seem to be released autonomously from their site of synthesis and to exist for a short time as free chains before being incorporated into γ-globulin. Heavy chains, on the other hand, are either not capable of autonomous release or else are released much less efficiently than light chains, and we propose that heavy chain release is normally effected by association with light chains. On this hypothesis the pool of free light chains would control the rate of release and thus the rate of synthesis of heavy chains. Such a model provides for the balanced production of light and heavy chains under normal conditions. Moreover, the secretion of light chains (Bence Jones proteins), which occurs in some plasmacytomata, could be readily explained either by a defect in heavy chain synthesis or by an increased rate of light chain synthesis.

Our proposal of an initial assembly step, in which light chains release heavy chains, has a parallel in the mechanism of haemoglobin assembly, in which it has been postulated that free β-chains release completed α-chains from ribosomes[10]. While such an assembly mechanism for haemoglobin is supported by good evidence[10,11], no pool of labelled β-chains was found[10]. Although the model would predict the existence of a pool of free β chains, they would be in equilibrium with haemoglobin thus: $\alpha_2\beta_2 \rightleftarrows 2\alpha\beta \rightleftarrows 2\alpha + 2\beta$, as shown by Guidotti *et al.*[12]. The pool would therefore not be detected by pulse-labelling.

We thank Mr. Brian Wright and Mrs. Joyce Henderson for their excellent assistance and Dr. M. Potter, National Institutes of Health, for originally supplying the 5563 plasma cell tumour line.

INCREASE IN PLASMA GROWTH HORMONE LEVEL IN THE MONKEY FOLLOWING THE ADMINISTRATION OF SHEEP HYPOTHALAMIC EXTRACTS

By DR. JOSEPH F. GARCIA and PROF. IRVING I. GESCHWIND

Donner Laboratory, Lawrence Radiation Laboratory, University of California, Berkeley, California, and Department of Animal Husbandry, University of California, Davis, California

THE control of anterior pituitary secretion is now generally accepted as being mediated by hypothalamic neurohumoral factors which are secreted into the primary plexus of the portal circulation to the anterior pituitary and which, on arrival at the anterior pituitary, promote the release of most anterior pituitary hormones. Although much work has been done on the hypothalamic releasing factors for most of the anterior pituitary hormones, it has been only very recently that such investigations have been directed to the search for a growth hormone (GH) releasing factor. Both *in vitro* and *in vivo* studies have been carried out. In the *in vitro* investigations the release of GH into a medium in which pituitary fragments are incubated and to which hypothalamic extracts have been added has been quantitated[1]. The *in vivo* studies have been carried out by assaying for residual GH in the pituitaries of animals injected with hypothalamic extracts[2]. In both cases, the GH has been assayed by the tibia test[3]. With the availability of sensitive radioimmunoassay techniques for GH (refs. 4 and 5), it seemed worth while to explore the possibility of demonstrating the release of GH into the circulation after the administration of hypothalamic extracts.

The radioimmunoassay for human growth hormone has been shown to be useful in the measurement of the plasma concentration of other primate growth hormones[5]. The method used in the present experiments for the radioimmunoassay of GH has been modified from that of Hunter and Greenwood[6]. Human growth hormone (HGH) (kindly supplied by Prof. C. H. Li, University of California, Berkeley) was used to immunize rabbits, and also labelled with iodine-125 using the chloramine-*T* method of Hunter and Greenwood[6]. The antibody-bound HGH–iodine-125 was precipitated using a goat anti-rabbit gamma globulin serum (obtained from Antibodies, Inc., Davis, California). The percentage of the labelled HGH which was bound to antibody was plotted against the logarithms of the concentrations of standard HGH (a gift from Prof. A. E. Wilhelmi, Emory University, Atlanta, Georgia. Lot No. HS503A had a specific activity of 1·7 I.U./mg, standardized in terms of the bovine GH international standard). The concentrations of monkey plasma GH were read directly off such a curve and are therefore expressed in terms of the standard HGH preparation used.

The plasma GH level has been shown to respond to many factors; insulin-induced hypoglycaemia, prolonged fasting, muscular exercise and the administration of certain amino-acids will all result in high plasma GH levels[7–9]. On the other hand, administration of glucose will depress the elevated plasma GH level of the hypoglycaemic or fasting individual[7]. In the normal human the response to insulin hypoglycaemia is quite consistent.

Male rhesus monkeys (*Macaca mulatta*) weighing between 10 and 20 lb. were used throughout the course of this work. The animals were anaesthetized with 'Nembutal' and a polyethylene cannula was placed in a branch of the saphenous vein in the lower leg. At approximately 1 h after the administration of the anaesthetic, the collection of heparinized blood samples was begun and was continued over a period of approximately 6 h. Additional 'Nembutal' was administered as needed to maintain the anaesthetic state. After a 1–2-h period, during which control blood samples were taken, the test material was injected intravenously using the cephalic vein in the forearm.

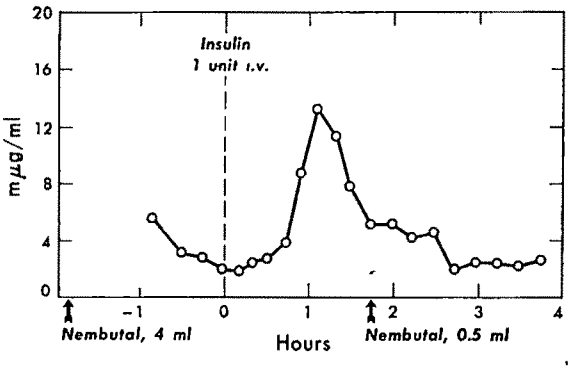

Fig. 1. Plasma growth hormone concentration in rhesus monkey after insulin hypoglycaemia

Initially, the investigations were carried out using insulin hypoglycaemia as the stimulus for GH release. Fig. 1 shows the results of one such study in which one unit of glucagon-free insulin (Lilly) was injected. The plasma GH level begins to rise at approximately 40 min, reaching a high level by 1 h. This response is not essentially different from that seen in the unanaesthetized normal human. The importance of this response, however, is that it shows that the mechanisms responsible for the reflex release of GH are intact in the nembutalized monkey and that such a preparation can be used to study the release of GH. Many of the monkeys show a high GH level at the beginning of such a study. This is perhaps due to stress or to muscular exercise expended by the monkey attempting to evade capture and restraint before the injection of the 'Nembutal'.

Extracts of sheep hypothalami were prepared by extracting acetone powder representing 200 gland (stalk-median eminence plus adjacent areas) equivalents of sheep hypothalami by homogenization with 10 ml. of 0·1 N hydrochloric acid. The homogenate was then diluted with an additional 40 ml. of acid and stirred for 30 min. The material was centrifuged for 40 min at 8,000*g*, and the residue was re-extracted with 30 ml. of 0·1 N hydrochloric acid for 30 min and then centrifuged as before. Up to this point all operations were carried out at 4° C. The supernatants were combined, heated to 90° C in a boiling water bath (approximately 5 min), chilled to 15° C, neutralized to *p*H 6·4 with 1 N sodium hydroxide and centrifuged for 20 min at 35,000*g* at 4° C. The supernatant was diluted to 100 ml. with distilled water, distributed into ten vials and frozen. The final concentration was two gland equivalents per ml. Extracts of sheep cerebral tissue were also prepared in the same manner and were diluted to a final concentration representing a weight of tissue equivalent to that of the hypothalamic extract.

The response to the intravenous injection of sheep hypothalamic extracts was investigated in eight experiments. In seven of the eight experiments a release of GH was observed following the injection. Four such studies, in which 4·5–5·0 ml. (nine or ten sheep hypothalami) of the extract was administered, are presented in Fig. 2. There was a great variation in the magnitude of the response. The reasons for this great variation are not entirely clear and at this point one can only speculate on their possible causes. It would seem possible that the state of the anterior pituitary before the administration of the extract may be a factor. The recent release of a large quantity of GH may make impossible a further large release in response to the administration of these extracts. Other factors influencing this variation may be related to possible variations in the anterior pituitary portal blood flow or to the depth of the anaesthetic state. Investigations directed to minimizing the variations in the magnitude of these responses will be necessary before the monkey can be used as an assay animal for determining GH releasing factor levels.

The responses of the plasma GH level to the injection of hypothalamic extracts are all similar, however, in their time relationships. The GH level begins to rise between 20 and 30 min and reaches peak values between 45 and 60 min after the injection. At this time GH secretion may stop rather abruptly, for the GH levels decrease thereafter at a rate consistent with the half-life found in man for HGH (ref. 10). These temporal relationships are consistent with the type of response seen following the injection of insulin.

Since hypoglycaemia appears to be a potent releaser of GH, plasma glucose determinations were made in most of these investigations. In no case was a fall in plasma glucose observed; in fact, usually a slight rise in plasma glucose was observed following the injection of the hypothalamic extract. However, in order to rule out positively the possibility of a GH release mediated by changes in plasma glucose level, in two of the hypothalamic extract studies the animals were infused, as well, with glucose. Glucose infusion, at a rate of 75 mg/min, was started 1 h before the injection and continued for 3 h. This brought the plasma glucose level to approximately 300 mg/100 ml. at the time of the injection of the hypothalamic extract, and it remained between this value and 340 mg/100 ml. throughout the remaining glucose infusion period. In both the glucose infusion experiments the hypothalamic extract caused a release of GH similar to those depicted in Fig. 2 (peak values of 12 and 36 mμg per ml.).

As a control to the investigations using hypothalamic extracts, extracts of cerebral tissue were injected. The results of four such experiments are shown in Fig. 3. In two of the experiments there was no change in the plasma GH level after the administration of the extracts. In the other two investigations there was a release of GH after the injection. This release, however, occurred much later than that following the injection of hypothalamic extracts, for a period of approximately 2 h elapsed before rises in plasma GH levels were observed.

Although these late responses are disturbing, it must be emphasized that in all four of the cerebral extract experiments no rise in plasma GH occurred during the period of time in which responses to hypothalamic extract or to insulin hypoglycaemia are evident. It is felt that these responses, although real, are not specific to a releasing factor but are reflex responses to other stimuli. In this regard, it is perhaps worth while to mention that an increase in plasma GH levels has been observed following the injection of certain amino-acids[9]. The depth of the anaesthetic state and stress must also be considered as possible contributing factors in these late GH responses.

Although several recent investigations in rats have failed to implicate vasopressin as a mediator of GH

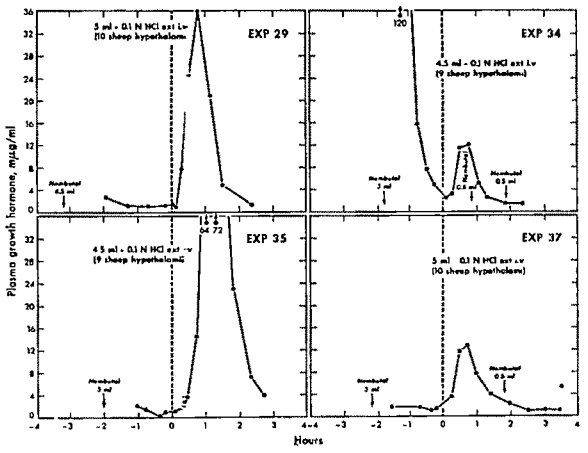

Fig 2. Plasma growth hormone concentration after administration of hypothalamic tissue extract

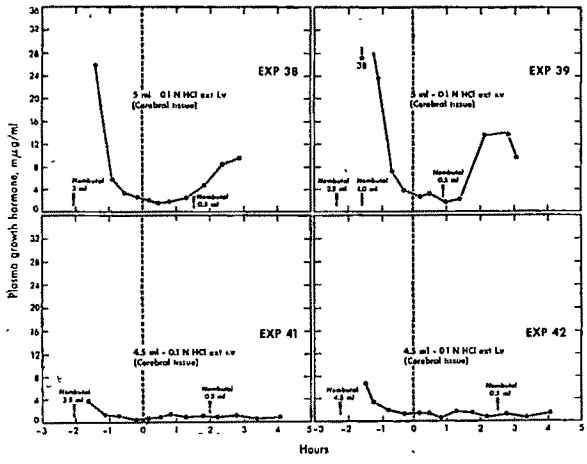

Fig. 3. Plasma growth hormone concentration after administration of cerebral tissue extract

secretion[11,12], the effect of vasopressin injection was studied in the present experiments. In our hypothalamic extract the concentration of vasopressin was 0·506 U./ml. (We thank Prof. R. Guillemin, Baylor University, Houston, Texas, for this assay.) Therefore, in the volume of hypothalamic extract injected, 2·28 or 2·53 U. of vasopressin were present. Two animals were therefore each injected with 5 U. of 'Pitressin', which resulted in a small, immediate increase in the plasma GH level. The first samples, taken about 15 min after the injection, were twice the basal level, and from this maximum the levels then decreased exponentially. Since the response to an amount of vasopressin twice that present in the hypothalamic extract was so minimal, the responses observed with the hypothalamic extract could not be due solely to its vasopressin content. The GH response to vasopressin injection is perhaps a non-specific response resulting from the well-known vasomotor effects of this hormone. In still another study the injection of 5 U. of 'Pitocin' did not result in a release of GH.

In conclusion, we feel that this preliminary work supports the concept that the secretion of anterior pituitary GH is mediated by a hypothalamic neurohumoral factor.

We thank Mrs. Patricia Smith and Mr. Robert Dewey for expert technical assistance, and Dr. J. A. Linfoot for his advice.

This work was supported in part by the U.S. Atomic Energy Commission, in part by Cancer Research Funds of the University of California, and in part by a grant from the U.S. Public Health Service.

Since the article was prepared for publication, a report on similar experiments by E. Knobil has appeared[13]. This investigator has found responses to the administration of porcine hypothalamic extract similar to those reported here. The results differ, however, in that the responses to the extract were more rapid than those we have observed, and the responses to the injection of vasopressin were more marked than ours, the greatest responses in any of the experiments having been obtained with vasopressin. The experiments differ in that in Knobil's experiments the monkeys were unanaesthetized but restrained, the extract injected was equivalent to only two porcine hypothalami, and the antiserum utilized for the immunoassays was developed using a highly purified simian growth hormone as antigen. Whether these differences in procedure explain the differences in response to extract or vasopressin remains to be determined.

RESPONSE OF PINEAL SYMPATHETIC NERVE PROCESSES AND ENDINGS TO ANGIOTENSIN

By DR. NICHOLAS M. PANAGIOTIS
Department of Anatomy, University of Utah College of Medicine, Salt Lake City, Utah
AND
DR. GERALD F. HUNGERFORD
University of Southern California School of Medicine, Los Angeles, California

IN the past, investigators have felt that the hypertensive properties of angiotensin II were due entirely to the peripheral actions of the compound[1–3]. Recent experimental evidence has suggested that in addition to the peripheral action on the muscle, a second mechanism exists which acts centrally. The experiments of Bickerton and Buckley[4], Buckley *et al.*[5], Laverty[6], Zimmerman[7], and Benelli *et al.*[8] have stimulated interest in a nerve-mediated influence of angiotensin. The purpose of this investigation was to study the morphological effects of angiotensin on sympathetic nerve processes and endings of the rat, with particular attention given to the synaptic vesicles and their contents.

Male rats of the Holtzman strain averaging 150 g at the onset of the experiment were selected for the present investigation. They were placed on purified diets with complete salts[9]. Tap water was given for drinking purposes.

The animals were placed in groups and treated as follows: twelve intact rats weighing 170 g at autopsy received 5 per cent glucose subcutaneously without angiotensin for 12 days and were considered as a control group. Six intact rats weighing 190 g at autopsy were given 6·0 gamma/day angiotensin II (kindly donated by Ciba, Ltd.) in 5 per cent glucose administered subcutaneously for 12 days. At autopsy, the animals were decapitated and the pineal glands quickly removed and fixed in 2 per cent osmium tetroxide. The tissues were dehydrated and embedded in the epoxy resin, 'Araldite', according to the methods described by Luft[10]. Thin sections of random samples of nerve processes and endings were then examined and studied with the RCA 'Emu-3G' microscope. Fig. 1 was prepared by selecting parallel electron micrographs and comparing the number of clear vesicles with those containing osmiophilic material in both the control and angiotensin-treated rats.

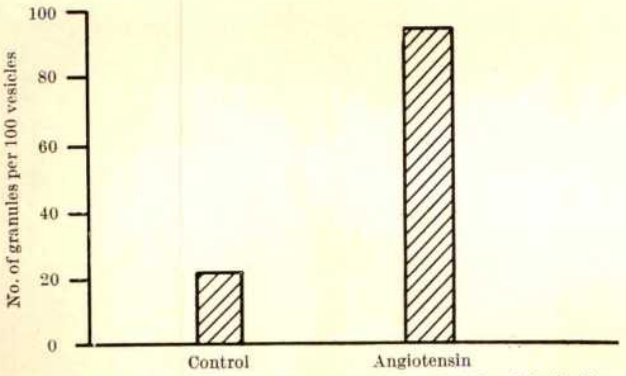

Fig. 1. Histogram comparing the number of granulated vesicles in the control and angiotensin-treated animals

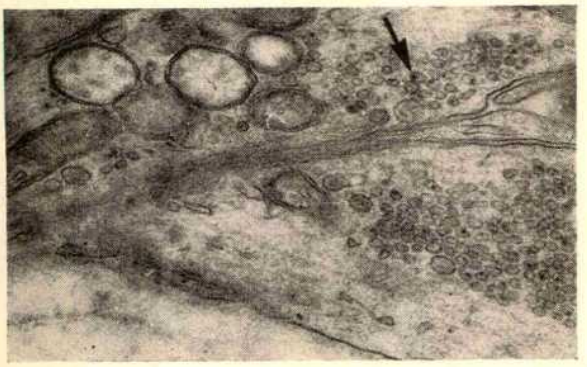

Fig. 2. Electron micrograph (× *c.* 18,000) of rat pineal gland showing a normal sympathetic nerve ending. Note the clear vesicles and vesicles containing small black (osmiophilic) granulated vesicles (arrow)

Angiotensin was administered subcutaneously in these experiments as this route of administration has been shown to be effective in reducing kidney pulse[11].

The results obtained were as follows.

Control. The nerve processes and nerve endings of the intact controls contained numerous vesicles exhibiting a heterogeneous morphology, some containing osmiophilic granules and some without. These synaptic vesicles have a definite limiting membrane and a mean diameter of 425 Å. Most of the vesicles have a clear centre, but some exhibit a dense osmium deposit about 210 Å in diameter (Fig. 2).

Angiotensin. Similar vesicles were observed in the angiotensin-treated animals; however, those containing osmiophilic granules were observed to be markedly increased when compared with sympathetic nerve endings of the control animals (Figs. 1–4).

Electron microscope studies thus established the presence of granular and agranular vesicles in many autonomic nerve endings and neurites. The granular vesicles of neurites have an average diameter of 320 Å. while those of the nerve endings are 580 Å. These granulated vesicles contain an electron-dense core 200–300 Å wide. The agranular vesicles have an average diameter of 520 Å (refs. 12–14). Recent evidence has strongly suggested that granulated vesicles contain norepinephrine[12,14]. These suggestions are based on the following circumstantial evidence: the morphological similarity of a limiting membrane and dense core observed in granulated vesicles and chromaffin cell granules[15]; the known concentration of norepinephrine in sympathetic nerves[16]; and the evidence from centrifugation studies of splenic nerve homogenates, showing that at least 20 per cent of norepinephrine is associated with "particles" somewhat similar to catecholamine containing granules from adrenal homogenates[17]. Further evidence has been presented by Wolfe *et al.*[14], who showed that circulating tritiated-norepinephrine (^{3}H-NE) was taken up into non-myelinated axons, that autonomic axons incorporating tritiated norepinephrine were adrenergic, and that the constant association of autoradiographic grains with granulated vesicles directly demonstrated the constant association of tritiated norepinephrine with granulated vesicles.

The pineal body was examined because of the richness of its sympathetic innervation[18], its known concentration of norepinephrine[19], the availability of electron microscopic descriptions of pineal autonomic nerves[13] and the

Fig. 3. Electron micrograph (× *c.* 50,000) of rat pineal gland showing sympathetic nerve ending following treatment with angiotensin. Note the marked increase in vesicles containing granules (arrows) when compared with Fig. 1

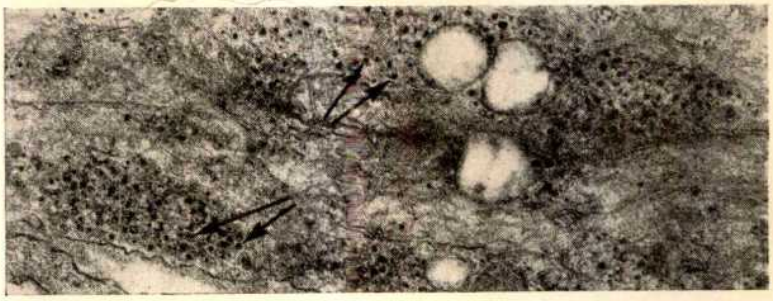

Fig. 4. Electron micrograph (× *c.* 31,000) of rat pineal gland showing sympathetic nerve processes following treatment with angiotensin. Note the marked increase in granulated vesicles (arrows)

demonstration of tritiated norepinephrine uptake in sympathetic axons of rat pineal gland[14].

Angiotensin is a humoral agent possessing powerful pressor properties. Its direct action on blood vessels has been demonstrated *in vivo* and *in vitro* and in a variety of preparations[1-3]. However, recent evidence has indicated that angiotensin may act centrally, stimulating the sympathetic nervous system. The results presented here (Figs. 1–4) would seem to support the hypothesis that angiotensin affects peripheral sympathetic transmission by promoting a greater output of noradrenaline[8]. Recent work by Bickerton and Buckley[4] and Buckley *et al.*[5] has demonstrated that angiotensin administered to the isolated perfused head of a dog caused neurogenic vasoconstriction in the trunk and limbs of the animal. Robertson and Ruben[20] reported that drugs which interfere with cholinergic transmission (ganglion blocking and anti-acetylcholine drugs as well as botulinum) are able to alter significantly the typical stimulation by angiotensin. Furthermore, Zimmerman[7] has observed that the vasopressor response to angiotensin administered extra-arterially to the perfused hindquarters of the dog was reduced significantly after acute sympathectomy. Similar results were obtained following ganglionic blockade with hexamethonium and cervical spinal transmission.

Beaulnes[21] investigated the positive inotropic and chronotropic actions of angiotensin on the isolated heart and concluded that they are at least partially due to a release of catecholamines. Similar conclusions were reached by Berry *et al.*[22] in perfusion studies of the dog. Feldberg and Lewis[23] have also reported an adrenaline-releasing effect of angiotensin on cat adrenal glands.

The results presented here would seem to provide evidence supporting the hypothesis that angiotensin, in addition to its peripheral action, may act centrally, stimulating the sympathetic nervous system. The granular vesicles of neurites and nerve endings were significantly increased in all animals treated with angiotensin. Therefore, it is possible that the pressor activities of angiotensin might be explained by the increase in adrenergic material in the endings of the sympathetic nerves. Further work is required in order to confirm that such a mechanism of action for angiotensin is possible.

USE OF NEUTRON ACTIVATION IN THE CHARACTERIZATION OF SMALL QUANTITIES OF NUCLEIC ACIDS

By DR. K. MURRAY and R. E. OFFORD

Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

ONE approach to the characterization of nucleic acids involves the examination of maps of enzymatic digests of these substances. Such maps are produced by the application of two of a large number of separating systems at right angles on paper. The oligonucleotide spots can then be located by, among other methods, ultra-violet absorption[1] (minimum quantity detectable 1–2 μg base/cm², that is, 0·1–0·2 μg phosphorus/cm²) or the molybdate test for phosphate[2] (sensitivity about 1 μg phosphate/cm²). If it is only possible to prepare minute quantities of starting material, or if the particular system in use is subject to overloading (see below), it is customary to label the nucleotides with either carbon-14 or phosphorus-32 during biosynthesis and to detect the spots by autoradiography. In this way extremely small quantities of nucleic acid can be examined. There are occasionally circumstances where it is wished to work with such small quantities but where biosynthetic labelling is difficult or impossible. This is particularly true of materials from the higher animals, including man.

This article describes a procedure for the location of oligonucleotide and other phosphorus-containing spots by neutron activation of the completed chromatogram and subsequent autoradiography. It is most unlikely that even those oligonucleotides which have not interacted with a neutron will remain in the original chemical form. The procedure resembles that described by Benson[3] in connexion with work on phospholipids, although in the present case a considerably stronger irradiation seems to be necessary to achieve the same sensitivity.

The particular application discussed here is the mapping of digests of DNA from higher animals by the method of Sanger, Brownlee and Barrell[4]. This method, although giving a considerably greater degree of resolution than most two-dimensional systems, has not previously been used on non-radioactive material because the system overloads if more than 200 μg of digest are used. Because neutron activation gives a sensitivity of the order of 10^{-2} μg of phosphorus/cm², it is adequate for the location of spots in digests of materials which are only available in quantities of this order.

The principle is that phosphorus-31 can be converted by thermal neutrons to phosphorus-32. Thus, in the neutron flux of a typical graphite reactor, the saturated specific activity at 10^{12} neutrons/cm²/sec is about 100 mc./g of phosphorus[5]. One-quarter of this activity can be obtained after irradiation at this flux for 7 days. There is no major component of paper with a similar response to irradiation and, provided that a few days are allowed for the decay of short-lived activities, phosphorus-32 remains as the predominant substance detectable by autoradiography. This is particularly so if a thin sheet of material is interposed between the chromatogram and the film (for example, another sheet of unexposed X-ray film) in order to filter out soft radiations from contaminating activities. It is desirable to keep the papers as clean as possible before irradiation. Moisture from the fingers in particular contains sufficient sodium to interfere by virtue of its conversion to sodium-24.

Preliminary experiments were carried out in the irradiation facility in *Bepo* (Atomic Energy Research Establishment, Harwell) at a thermal neutron flux of 7×10^{12} neutrons/cm²/sec. The operating temperature (about 150° C) and the high fast neutron and gamma fluxes in this facility made the paper extremely brittle and it was impossible to unwrap rolls of paper after irradiation. However, a surface concentration of adenosine triphosphate (ATP) equivalent to 4×10^{-2} μg of phosphorus/cm² could be detected. The experiments also served to test a variety of washing procedures and a number of different types of paper. Washing was found to make very little difference to the background, which was, incidentally, considerably worse with DEAE paper than with the normal cellulose grades. Damage to the paper did not vary greatly among the common commercial grades of chromatography paper, with the exception of DEAE-paper which was affected more than the unmodified forms. Cellulose acetate ('Oxoid') melted.

Subsequent irradiations were carried out in *Herald* (Atomic Weapons Research Establishment, Aldermaston), a water-moderated reactor with a graphite thermal neutron column. A flux of $2{\cdot}5 \times 10^{11}$ neutrons/cm²/sec was used in irradiations lasting about 2 weeks. The much lower temperature of the samples and/or relative lack of fast neutrons and gamma radiation resulted in the paper remaining in fairly good condition after this time.

In an experiment designed to test the method, a mixture of unlabelled calf thymus DNA (200 μg) (Sigma Chemical Company) and ^{32}P-labelled DNA from *Escherichia coli*[6] (5 μg; 3×10^5 c.p.m.) was denatured by heat treatment and was then digested with *Neurospora crassa* endonuclease[7]. (Nucleotide maps of digests made with this enzyme were closely similar to those made with pancreatic DNase[8] (Worthington Biochemical Corporation).) The method of Sanger *et al.*[4] has provided highly reproducible nucleotide maps when applied to endonuclease digests of several independent preparations of DNA from *E. coli*[3]. An autoradiograph was made of the DEAE-paper. After storage for about 12 months, when decay of phosphorus-32 was virtually complete, the DEAE-paper was cut into strips which were interleaved with aluminium foil, rolled up, and inserted in an aluminium can for neutron irradiation. Following irradiation in *Herald* as already described, the strips were carefully unrolled, attached to a sheet of Whatman 3*MM* paper with 'Sellotape', and autoradiographed through an additional sheet of X-ray film used as a screen. The two autoradiographs are compared in Fig. 1. The initial autoradiograph (Fig. 1*A*) shows only the nucleotides derived from *E. coli* DNA. After neutron activation, all the nucleotides were radioactive, but as there was almost fifty times more calf thymus DNA present the contribution from the nucleotides from *E. coli* DNA was negligible. Thus, the second autoradiograph (Fig. 1*B*) represents only the nucleotides derived from calf thymus DNA. The nucleotides occupied an area of 222 cm² (the darkened area of Fig. 1), indicating an average surface concentration of nucleotide on the DEAE-paper of about 1 μg/cm², which is equivalent to a surface concentration of phosphorus of about 0·1 μg/cm². However, appreciable losses of material occurred in the course of preparation of the digest owing to adsorption on glass and polythene surfaces; thus the actual average surface concentration of phosphorus is probably nearer 0·05 μg/cm². It thus seems quite reasonable to claim that some of the weaker spots on the autoradiograph shown in Fig. 1*B* represent a surface concentration of phosphorus of the order of 10^{-2} μg/cm².

Although most of the spots on the two autoradiographs are in identical positions, as would be expected for the products of an enzyme with a rather broad specificity, several distinct differences are readily apparent. These differences are given in Table 1; four of the nucleotides are present in the digest of *E. coli* DNA, but are essentially absent from the digest of calf thymus DNA, while a fifth nucleotide is considerably more abundant in the digest of calf thymus DNA than in that of *E. coli* DNA. The composition of these nucleotides was determined (after elution from DEAE-paper in a separate experiment) by digestion with snake venom phosphodiesterase[8]. The observed differences in nucleotides between the two DNA digests are consistent with the relative abundance of the dinucleotides found in a pancreatic DNase digest of calf thymus DNA by Sinsheimer[9], and with the nearest neighbour nucleotide frequencies determined by Josse, Kaiser and Kornberg[10]. On the basis of the relative frequencies of the dinucleotide sequences CpG and GpC, which are given in Table 2, it might be expected that the sequence pCpG could be found in the nucleotides that were present in the digest of *E. coli* DNA but absent from the digest of calf thymus DNA (that is, nucleotides 5, 7, 12 and 15 in Fig. 1).

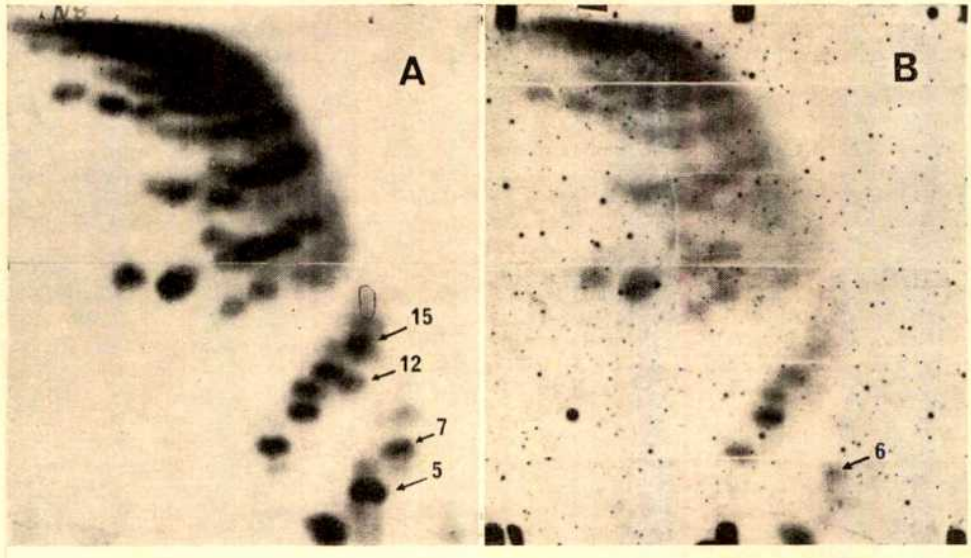

Fig. 1. Autoradiographs of the ionophoretogram of a DNase digest of a mixture of calf thymus DNA and *E. coli* DNA. *A*, Original autoradiograph of the nucleotides formed from phosphorus-32-labelled *E. coli* DNA. *B*, Autoradiograph made after a long period of storage for radioactive decay followed by neutron irradiation. The rectangular dark patches at the top and bottom of this autoradiograph are due to the activation of some component of pieces of 'Sellotape' that had remained on the DEAE-paper after the first autoradiograph. The base composition of numbered nucleotides is given in Table 1

Table 1. BASE COMPOSITION OF THE NUCLEOTIDES THAT WERE FOUND ONLY OR PREDOMINANTLY IN ONE OF THE NUCLEIC ACIDS CONTRIBUTING TO THE MIXED DIGEST

Nucleotide No.	Composition	*E. coli* DNA	Calf thymus DNA
5	CG	+	−
6	C_2T	(−)	+
7	C_2G	+	−
12	ACG	+	−
15	AC_2G	+	−

Table 2. NEAREST NEIGHBOUR FREQUENCIES OF THE CG DINUCLEOTIDES IN *E. coli* DNA AND CALF THYMUS DNA. THESE ARE VALUES PUBLISHED BY JOSSE *et al.* (ref. 10)

Dinucleotide	*E. coli* DNA	Calf thymus DNA
CpG	0·067	0·016
GpC	0·083	0·044

No other dinucleotide frequencies approach these two in the magnitude of the difference between the two species.

Thus, neutron activation of nuclease digests after two-dimensional ionophoretic separation may be used to obtain nucleotide maps on small quantities (100–200 μg) of nucleic acids from sources that cannot conveniently be labelled biosynthetically. This should facilitate a more detailed examination than has hitherto been possible of nucleic acids from large plants and higher animals (including the obvious example of tumour materials), as sufficient nucleic acid could usually be obtained from about 100 mg of tissue. Inclusion of an internal reference of phosphorus-32 labelled nucleic acid, involving the long delay for decay of its radioactivity, is not, of course, necessary in routine experiments. There seems little doubt that the method will be useful to amplify differences between nucleic acids which only differ slightly in base composition or nearest neighbour nucleotide frequency—this would be particularly so if more endonucleases of well-defined specificity became available. One enzyme that may prove valuable is spleen acid deoxyribonuclease[11]. The utility of the procedure as a fingerprinting method for nucleic acids is being investigated, and the method is also being applied in investigations of the specificity of association of different histone fractions with DNA in native deoxyribonucleoproteins. Neutron activation after ionophoresis or paper chromatography may also find limited application in protein chemistry for detection of amino-acids or peptides that contain sulphur. Although, unlike most methods of detection, it is equally applicable to compounds in which the sulphur is fully oxidized, it is in all cases a less sensitive method than for phosphorus. An additional application is the detection of serine or threonine phosphate; the method has in fact proved useful for confirmation of the presence of serine phosphate in partial acid hydrolysates of histones[12].

We thank Dr. A. Kornberg, who directed our attention to the possibility of using neutron activation for the examination of nuclease digests of unlabelled nucleic acids, and Dr. I. R. Lehman for a generous gift of *Neurospora crassa* endonuclease. We also thank Mr. M. Whiting for arranging the irradiations in *Bepo*, and Dr. D. H. Brown and his colleagues for including our materials in their schedule of work.

N-FORMYL-METHIONYL-*s*RIBONUCLEIC ACID AND CHAIN INITIATION IN PROTEIN BIOSYNTHESIS

POLYPEPTIDE SYNTHESIS DIRECTED BY A BACTERIOPHAGE RIBONUCLEIC ACID IN A CELL-FREE SYSTEM

By DR. B. F. C. CLARK and DR. K. A. MARCKER
Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

THE blocking of the amino group of methionine in *N*-formyl-methionyl-*s*RNA[1] suggested that this aminoacyl-*s*RNA might act as an initiator of polypeptide chains. Experimental evidence in support of this idea has been found in bacterial cells[2–5]. Using synthetic polyribonucleotides as messengers in cell-free bacterial systems the specificity for placing methionine in the N-terminal positions of the growing polypeptide chains is carried by a methionyl-*s*RNA which is distinguished by its ability to become formylated[3]. We have now confirmed this finding, using bacteriophage RNA as a messenger in the cell-free system. We have also shown that the formyl group plays no part in locating the methionine residue at the N-terminus; its role apparently consists in increasing the rate of polypeptide chain synthesis.

Before describing our results we wish to recapitulate some of the previous findings relating to this system. The formylation of Met-*s*RNA occurs after methionine has become attached to its specific *s*RNA[1] and is catalysed by an enzyme distinct from Met-*s*RNA synthetase[6]. *s*RNA from *Escherichia coli* contains two methionine-accepting species only one of which, Met-$sRNA_F$, could be formylated[3]. The reactions leading to the formation of the formylated species, F-Met-$sRNA_F$, are summarized in Fig. 1.

The role of F-Met-*s*RNA as an initiator of protein synthesis, at least in bacteria, was first confirmed when *N*-formyl-methionine was found to be incorporated into nascent proteins made in a cell-free system directed by bacteriophage RNA[4,5]. Using a cell-free system directed by poly UG and poly UAG and fractionated Met-*s*RNA we found that Met-$sRNA_M$, the species which could not be formylated, responded only to poly UAG, whereas Met-$sRNA_F$ responded to both polymers. The interesting point was that the actual formylation of Met-$sRNA_F$ made no difference to the results: when the cell-free system was assembled so as to avoid formylation[3], the methionine attached to Met-$sRNA_F$ became incorporated almost exclusively into N-terminal positions of the newly synthesized chains, whereas methionine attached to Met-$sRNA_M$ became incorporated into internal positions[3]. We now report similar findings using bacteriophage RNA to direct polypeptide chain synthesis in a cell-free system containing negligible transformylase activity.

Fig. 2 shows an autoradiogram obtained from a chymotryptic digest of the polypeptide made in the cell-free system when *mu*2 bacteriophage RNA was used as a messenger. Peptides A and B were formed only when Met-$sRNA_M$ was used as a source of methionine. On pronase digestion both liberated methionine. No change in mobilities was seen on mild acidic hydrolysis. The use of F-Met-$sRNA_F$ yielded two peptides, F_1 and F_2. When F_1 was treated with pronase, free formyl-methionine was liberated together with a dipeptide which was identified

$$\text{Met} + s\text{RNA}^{(M,F)} \xrightarrow[\text{Met-}s\text{RNA synthetase}]{\text{ATP}} \begin{matrix}\text{Met-}s\text{RNA}_M\ (\sim 30\ \text{per cent}) \\ + \\ \text{Met-}s\text{RNA}_F\ (\sim 70\ \text{per cent})\end{matrix} \xrightarrow[\text{Met-}s\text{RNA transformylase}]{\text{Formyl-THF}} \text{F-Met-}s\text{RNA}_F$$

Fig. 1. Formyl-THF represents 10-formyl tetrahydrofolate, Met-sRNA$_M$ is Met-sRNA$_1$ of ref. 3, and Met-sRNA$_F$ is Met-sRNA$_2$ of ref. 3

as F-Met-Ala. After the same treatment, F_2 gave free formyl-methionine and a dipeptide which was tentatively identified as F-Met-Ser. In both cases free formyl-methionine was also observed, probably coming from further splitting of the respective dipeptides, because both liberated formyl-methionine on further incubation with pronase. The appearance of two different formyl-methionine-containing peptides in the chymotryptic digest of the polypeptide produced under the direction of the phage RNA suggests that at least two different proteins were synthesized under such conditions.

When unformylated Met-sRNA$_F$ was used as a source of methionine, two peptides were liberated (M_2 in rather low and variable yield compared with M_1) by chymotryptic digestion. On pronase treatment both liberated free methionine. When peptide F_1 was subjected to a very mild acidic hydrolysis to remove the formyl group (0·2 M hydrochloric acid : dioxan as 1 : 1 v/v for 24 h at room temperature) it gave a compound having a mobility identical with that of M_1. Peptide F_2 subjected to the same treatment gave a peptide having a mobility identical with that of M_2. Peptides F_1 and M_1 after limited acidic hydrolysis (6 N hydrochloric acid for 30 min at 100° C) gave rise to peptides which were identical on ionophoresis at pH 6·5. Peptides F_2 and M_2 after the same treatment yielded mainly free methionine presumably because the next amino-acid in both cases was serine. Thus we concluded that peptide F_1 corresponded to peptide M_1, and peptide F_2 probably to peptide M_2—the only difference between the respective peptides being the presence of the formyl group on the N-terminal methionine of F_1 and F_2. End-group determinations using a modification of the procedure developed by Edman[3] on the product formed when Met-sRNA$_M$ was used as a source of radioactive label revealed no N-terminal methionine. Peptides A and B must therefore be internal peptides. End-group determinations on the product formed when Met-sRNA$_F$ was used revealed that methionine was in an N-terminal position.

When F-Met-sRNA or the means of formylation are added to a cell-free system deficient in transformylase activity the rate and efficiency of the poly UG or poly UAG-directed incorporation of methionine increase[2,3]. This effect has now been examined in more detail by using the bacteriophage RNA as messenger. The results are shown in Fig. 3, where the incorporation of methionine is compared with the incorporation of leucine and valine. In the presence of F-Met-sRNA or 10-formyl-tetrahydrofolic acid, a stimulation (about four-fold) of protein biosynthesis occurs in the first few minutes of the incubation as indicated by the incorporation of the three amino-acids. Because the rate of formation of the first peptide bond is probably the rate-limiting step in the synthesis of proteins, this may be the step affected by the presence of the formylated Met-sRNA$_F$.

It is an attractive idea that F-Met-sRNA$_F$ because of its similarity with a peptidyl-sRNA (ref. 8) may directly enter the peptidyl-sRNA site on the ribosome, thereby initiating protein biosynthesis. This theory emphasizes the formylation of Met-sRNA, and allocates a critical function of the formyl-donor system in chain initiation. According to Noll[9], such a situation would permit the control of protein biosynthesis at the level of chain initiation by regulating the transformylase reaction. Contrary to his proposal, our work shows that the Met-sRNA which can be formylated has a specific structure, fitting directly into the peptidyl-sRNA site on the ribosome, whatever the state of formylation. Bretscher and Marcker's observations[10] point to the same conclusions. Thus chain initiation would occur whether or not the α-amino group of methionine is blocked. Formylation of the Met-sRNA possibly increases the rate of protein synthesis.

F-Met-sRNA has also been demonstrated in yeast, suggesting that the mechanism of chain initiation is the

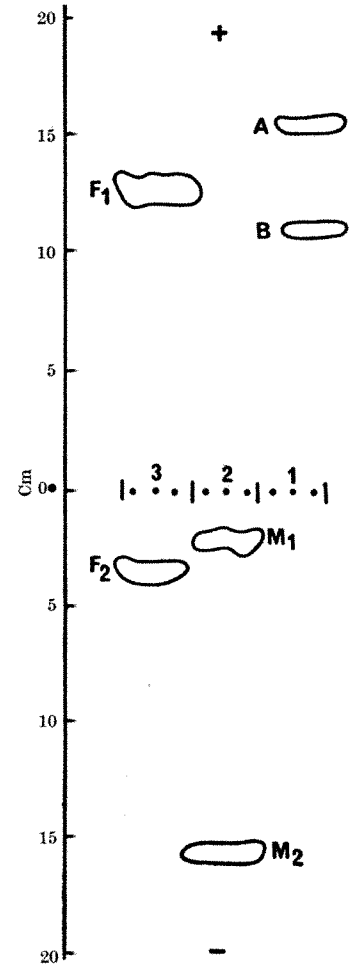

Fig. 2. Chymotryptic digestion of the polypeptide formed during incubation of an *E. coli* cell-free system with fractionated ^{35}S-Met-sRNA and *mu*2 phage RNA. The RNA was prepared from intact phage particles (a gift from Dr. G. L. Brown) by the method of Boedtker and Stumpp (ref. 7). The reaction mixture (0·5 ml.) contained 0·05 M *tris*-hydrochloric acid pH 7·4, 0·05 M ammonium acetate, 0·01 M magnesium acetate, 0·001 M adenosine triphosphate, 0·0002 M guanosine triphosphate, 0·004 M phosphoenolpyruvate, 5 μg pyruvate kinase, 0·01 M 2-mercaptoethanol, 0·005 M ^{12}C-methionine and 0·0002 M of nineteen other ^{12}C-amino-acids, 38·2 A_{260} units of MRE 600 ribosomes, 0·72 mg of supernatant protein free of formyl-donor from a DEAE-column, 8 A_{260} units unfractionated *E. coli*-sRNA, 200 μg of the phage RNA and either 3 A_{260} units of ^{35}S-Met-sRNA$_M$ (300 μμmoles ^{35}S-Met) or 1·9 A_{260} units of ^{35}S-Met-sRNA$_F$ (305 μμmoles of ^{35}S-Met) or 1·9 A_{260} units of F-^{35}S-Met-sRNA$_F$ (310 μμmoles of ^{35}S-Met)

After the reaction mixture had been incubated at 37° C for 20 min, EDTA at pH 7·0 was added to give a concentration of 0·05 M to attain the conditions for a further incubation of 10 min in the presence of 100 μg pancreatic RNase (five times crystallized, Calbiochem). The proteins were then precipitated with 10 per cent trichloroacetic acid (TCA) and the precipitate was washed five times with 5 per cent TCA containing 3 per cent casamino acids, twice with ethanol : ether (1 : 1 v/v) and finally dried with ether. Digestions with α-chymotrypsin (three-times crystallized, Worthington Biochemical Corporation) were carried out in 1 per cent ammonium bicarbonate (enzyme/protein = 1/25) at 37° C for 15 h. After the digestions the solutions of solubilized material were concentrated to permit their application to Whatman 3*MM* paper for electrophoresis at pH 6·5 for 2 h at 3 kV. The numbers refer to the applications of products from ^{35}S-Met-sRNA$_M$ at 1, ^{35}S-Met-sRNA$_F$ at 2, and F-^{35}S-Met-sRNA$_F$ at 3. A_1, B_1, M_1 and M_2 refer to ^{35}S-methionine-containing peptides. F_1 and F_2 refer to ^{35}S-formyl-methionine-containing peptides

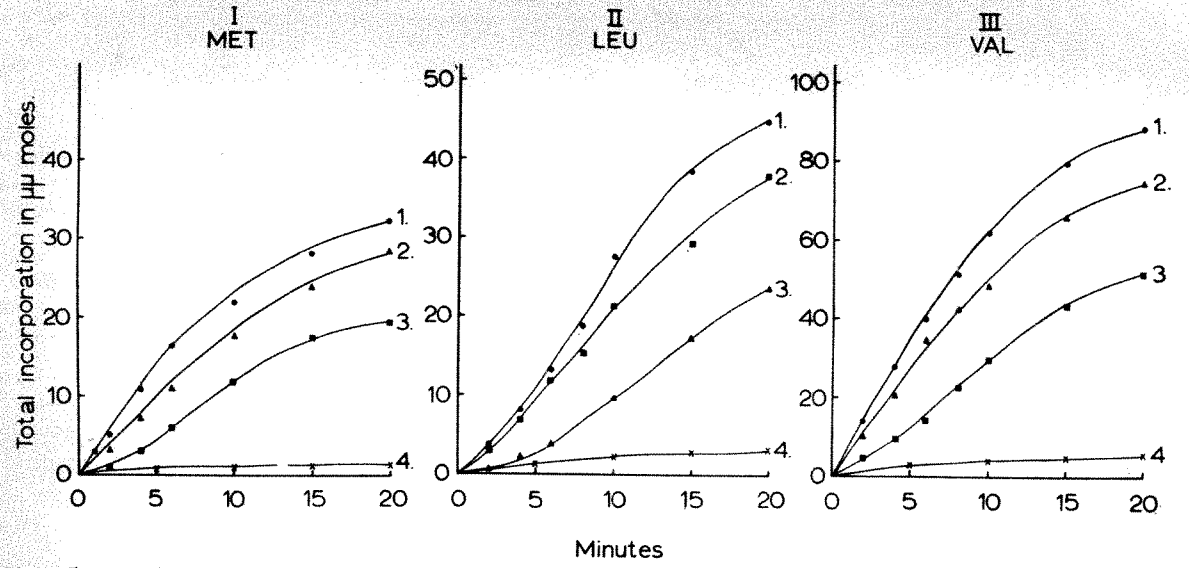

Fig. 3. Incorporation of ^{35}S-methionine, ^{14}C-leucine and ^{14}C-valine from unfractionated *s*RNA into polypeptide in a cell-free system containing no transformylase activity. The buffer and energy-providing components of the system (0·25 ml.) were the same as those described in Fig. 2. In addition the incubation mixture contained 0·0002 M of nineteen other ^{12}C-amino-acids, 22·5 A_{259} units of MRE 600 ribosomes, 0·36 mg of supernatant protein prepared as for Fig. 2, 5 A_{259} units of the charged *s*RNA and 100 μg of the phage RNA. All added *s*RNA preparations were charged in the presence of nineteen other ^{12}C-amino-acids. At the indicated time intervals during incubation at 30° C, 25 μl. samples were removed and added to tubes containing 100 μl. each of 0·5 per cent solutions of bovine serum albumin. The polypeptide product was precipitated in 5 per cent TCA and the suspended precipitate heated at 90 per cent for 15 min before being collected on a cellulose acetate filter for counting in a Nuclear Chicago thin-window gas-flow counter. The curves represent conditions in:
(I) For the addition of ^{35}S-Met-*s*RNA: (1) with 260 μμmoles of ^{35}S-Met-*s*RNA containing F^{35} S-Met-*s*RNA; (2) with 245 μμmoles of non-formylated ^{35}S-Met-*s*RNA but with the addition of 0·1 μmole of 10-formyl-THF; (3) with 245 μμmoles of non-formylated ^{35}S-Met-*s*RNA; (4) as for (3) but without the addition of the phage RNA
(II) For the addition of ^{14}C-Leu-*s*RNA: (1) with 131 μμmoles of ^{14}C-Leu-*s*RNA containing cold F-Met-*s*RNA; (2) with 141 μμmoles of ^{14}C-Leu *s*RNA containing cold non-formylated Met-*s*RNA but with the addition of 0·1 μmole 10-formyl-THF; (3) with 141 μμmoles of ^{14}C-Leu-*s*RNA containing cold non-formylated Met-*s*RNA; (4) as for (3) but without the addition of the phage RNA
(III) For the addition of ^{14}C-Val-*s*RNA: (1) with 238 μμmoles of ^{14}C-Val-*s*RNA containing cold F-Met-*s*RNA; (2) with 232 μμmoles of ^{14}C-Val-*s*RNA containing cold non-formylated Met-*s*RNA but with the addition of 0·1 μmole 10-formyl-THF; (3) with 232 μμmoles of ^{14}C-Val-*s*RNA containing cold non-formylated Met-*s*RNA; (4) as for (3) but without the addition of the phage RNA. In this experiment 18·5 A_{259} units of a different batch of MRE 600 ribosomes were used

same as in *E. coli*. On the other hand, we have so far failed to demonstrate F-Met-*s*RNA or other blocked aminoacyl-*s*RNA in mammalian systems.

We thank Dr. M. F. Perutz for his helpful suggestions about the arrangement of this manuscript.

POLYPEPTIDYL-*s*RIBONUCLEIC ACID AND AMINO-ACYL-*s*RIBONUCLEIC ACID BINDING SITES ON RIBOSOMES

By M. S. BRETSCHER and Dr. K. A. MARCKER
Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

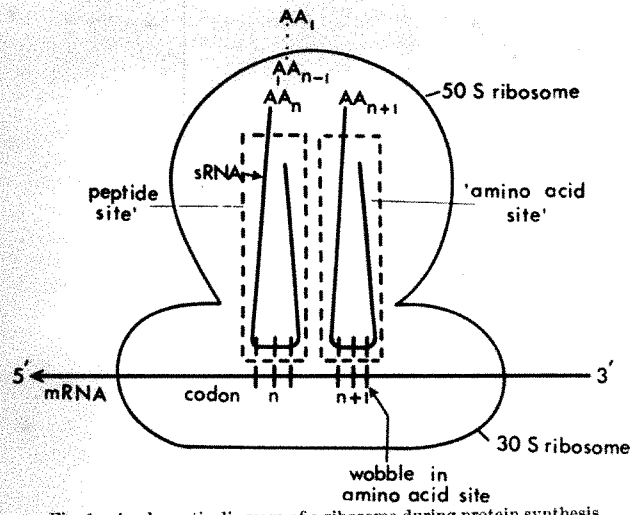
Polypeptidyl-*s*RNA and amino-acyl-*s*RNA are bound to ribosomes in the presence of a messenger RNA (*m*RNA). We shall show here that the methionyl-RNA from *Escherichia coli* which can be formylated binds to the polypeptidyl-*s*RNA site on the ribosome, while the other methionyl-*s*RNA from *E. coli* binds to a different site, presumably the amino-acyl-*s*RNA binding site. This has been ascertained by examining the sensitivity of these methionyl-*s*RNA species to the antibiotic puromycin when bound to ribosomes.

Polypeptide chain synthesis occurs on ribosomes[1]. The detailed reactions are unresolved. It is clear, however, that the two reacting species concerned with the addition of one amino-acid residue to the growing polypeptide chain are the incoming amino-acyl-*s*RNA (ref. 2) and the growing polypeptidyl-*s*RNA (ref. 3). At least two enzymes catalyse the overall process[4], which also requires GTP* (ref. 5), *m*RNA (ref. 6) and various inorganic ions. The point here is that at any moment there must be two ribosomal sites, one capable of binding the existing polypeptidyl-*s*RNA and the other binding the correct incoming amino-acyl-*s*RNA, as directed by the *m*RNA. It is not unlikely that these two sites may have different properties (Fig. 1).

In the presence of a trinucleotide *m*RNA ribosomes bind a specific amino-acyl-*s*RNA (ref. 7); this interaction, which has been used to decipher many of the sixty-four triplets[8], occurs between the amino-acyl-*s*RNA and the trinucleotide, probably in the amino-acyl-*s*RNA binding site (the "amino-acid site") on ribosomes. One of its characteristics is the high level of magnesium ion required to obtain a stable complex (about 0·02–0·03 M Mg^{++}). Another feature is a lack of complete specificity in the recognition between the anticodon of the *s*RNA and the last nucleotide (at the 3′-OH end) of the trinucleotide, which is reflected in the form of degeneracy of the genetic code[8].

Two species of methionyl-*s*RNA exist in *E. coli*, one of which can be formylated both *in vivo* and *in vitro*[9]. The methionyl-*s*RNA which cannot be formylated (met-

* *Abbreviations:* GTP, Guanosine 5′ triphosphate; poly U, poly-uridylic acid; poly A, polyadenylic acid.



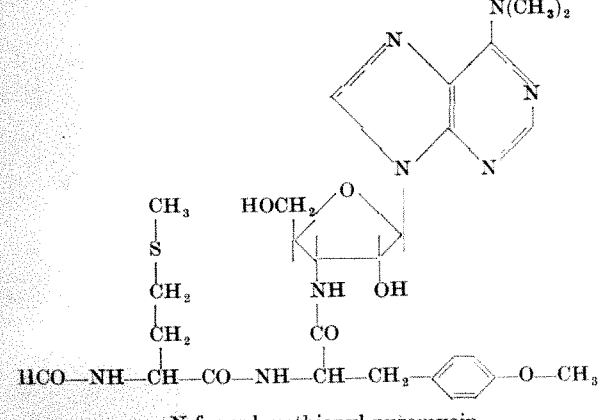


Fig. 1. A schematic diagram of a ribosome during protein synthesis

$sRNA_M$) has optimal binding conditions similar to most other amino-acyl-*s*RNAs; it binds well to ribosomes in the presence of the trinucleotide AUG in 0·02–0·03 M Mg^{++}. The methionyl-*s*RNA which can be formylated (met-$sRNA_F$), whether formylated or not, binds optimally to ribosomes in the presence of AUG at about 0·01 M Mg^{++} (ref. 10). This *s*RNA species is also bound well by GUG, UUG and less well by CUG (ref. 10), which indicates a lack of specificity in the first nucleotide residue of the trinucleotide (at the 5′-OH end). Furthermore, this met-$sRNA_F$, whether formylated or not, acts as an initiator of polypeptide chain synthesis *in vitro*[10].

We made use of the antibiotic puromycin which resembles the amino-acid of an amino-acyl-*s*RNA (ref. 11). Puromycin inhibits protein synthesis by substituting for an amino-acyl-*s*RNA and displacing the polypeptide from the peptidyl-*s*RNA as polypeptidyl-puromycin[12]. It probably enters the ribosomal structure by way of the amino-acid site and reacts with the polypeptidyl-*s*RNA bound in the polypeptidyl-*s*RNA binding site (the "peptide site").

We find that formyl-met-$sRNA_F$ and met-$sRNA_F$ are both sensitive to puromycin when bound to ribosomes with the triplet AUG. Met-$sRNA_M$ is comparatively insensitive to puromycin under identical conditions. This is taken to imply that met-$sRNA_F$, whether formylated or not, binds to the peptide site on a ribosome, while met-$sRNA_M$ binds to the amino-acid site. The product of the ribosomal reaction between formyl-met-$sRNA_F$ and puromycin is formyl-methionyl-puromycin. The product of the ribosomal reaction between met-$sRNA_F$ and puromycin is methionyl-puromycin. In a further experiment both species of methionyl-*s*RNA have been acetylated chemically. Acetyl-met-$sRNA_F$ is sensitive to puromycin yielding acetyl-methionyl-puromycin, while acetyl-met-$sRNA_M$ is comparatively insensitive to puromycin.

N-formyl-methionyl-puromycin

Our results indicate that formyl-met-$sRNA_F$ acts as an initiator of polypeptide chain synthesis by virtue of its affinity for the ribosomal site which is specific for polypeptidyl-*s*RNA. This specificity lies in the $sRNA_F$.

Ribosomes were isolated from *Escherichia coli* strain *B* (ref. 13) and washed twice in 1·0 M potassium chloride containing 0·03 M magnesium acetate in 0·02 M *tris*-hydrochloric acid, *p*H 7·5. *s*RNA from *E. coli* strain *B*, fractionated by countercurrent distribution to separate the two methionyl-*s*RNA species, was generally provided by Dr. B. F. C. Clark[10]. The met-$sRNA_F$ is uncontaminated with met-$sRNA_M$ (less than 1 per cent). The met-$sRNA_M$ contains about 8 per cent met-$sRNA_F$, determined by its ability to accept formyl groups. Both peaks of methionyl-*s*RNA were charged with ^{35}S-L-methionine of high specific activity (1,800 mc./mmole) (ref. 10), using an *E. coli* supernatant fraction free of formyl donor. For some experiments the met-$sRNA_F$ was formylated in the presence of 10-formyl tetrahydrofolate[14]. These *s*RNA fractions are the same as those used by Clark and Marcker[15]. Acetylation of both met-*s*RNAs was carried out with acetic anhydride[16]. It was found after hydrolysis at *p*H 10 and subsequent electrophoresis at *p*H 3·5 that all the radioactivity released from the *s*RNA co-electrophoresed with synthetic acetyl-methionine. The specific activities of all *s*RNA preparations were very similar, being about 4–7 × 10^6 d.p.m./mg *s*RNA. ApUpG was prepared from ApU using polynucleotide phosphorylase, GDP, and *T*1 takadiastase diesterase. The 3′-phosphate was removed with alkaline phosphatase. Puromycin dihydrochloride was purchased from Nutritional Biochemicals and was neutralized before use.

Table 1 shows the binding characteristics of the ribosome preparation used in Figs. 2–6. Formyl-met-$sRNA_F$ and met-$sRNA_F$ are both bound well in 0·01 M magnesium ions, and met-$sRNA_M$ in 0·02 M magnesium ions. In each case some 70 per cent of the added labelled *s*RNA is bound in the presence of AUG; this high level of binding is due to the excess of ribosomes used.

Figs. 2 and 3 show the rate of appearance of acid-soluble label (that is, material free from *s*RNA) when the ribosomes are incubated with ^{35}S-formyl-met-$sRNA_F$ and met-$sRNA_F$, respectively in the presence of puromycin. The initial rate of reaction in each case is stimulated some five-fold by the addition of AUG and is strongly dependent on the presence of both ribosomes and puromycin. The presence of the formyl group on the met-$sRNA_F$ increases the initial rate of reaction some five-fold.

In order to compare met-$sRNA_F$ and met-$sRNA_M$ in their sensitivity to puromycin, met-$sRNA_F$ has been incubated in 0·02 M Mg^{++} to show that higher levels of magnesium do not prevent the reaction observed in Fig. 3. Figs. 4 and 5 show the rates of appearance of acid-soluble label when met-$sRNA_F$ and met-$sRNA_M$ are incubated in the presence of puromycin, AUG and ribosomes. The label in met-$sRNA_F$ becomes acid-soluble at a rate similar to that shown in Fig. 3. In contrast, met-$sRNA_M$ has a slow rate of reaction stimulated by AUG. The difference in the two rates of reaction is about ten-fold. At least part of the observed reaction of met-$sRNA_M$ arises from the small contamination (about 8 per cent) of met-$sRNA_F$ in this *s*RNA.

Table 1

*s*RNA species	Mg^{++} molarity	C.p.m. bound to ribosomes −AUG	C.p.m. bound to ribosomes +AUG	Total c.p.m. added
(1) met-$sRNA_M$	0·01	1,840	3,770	11,000
(2) met-$sRNA_M$	0·02	2,200	8,270	11,000
(3) met-$sRNA_F$	0·01	1,600	8,080	11,000
(4) formyl-met-$sRNA_F$	0·01	2,370	11,200	13,500

Each reaction mixture (0·025 ml.) contained 0·2 mg ribosomes in 0·10 M *tris*-hydrochloric acid *p*H 7·1, 0·05 M ammonium chloride and magnesium acetate as indicated. The trinucleotide AUG was added, where indicated, at a concentration of 4 A_{260} units/ml. After incubation at 30° C for 10 min, samples were diluted and filtered on a 'Millipore' filter (ref. 7) and washed in the same buffer as that in which they were incubated. The filters were dried and counted in a scintillation counter with an efficiency of about 70 per cent. The data shown are the averages of duplicate samples.

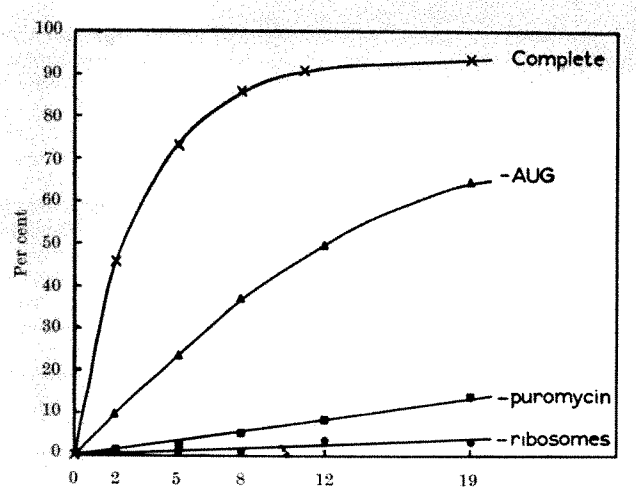

Fig. 2. The appearance of acid-soluble label with ^{35}S-formyl-met-sRNA$_F$. ^{35}S-formyl-met-sRNA$_F$ was incubated in 0·1 M *tris*-hydrochloric acid (*p*H 7·1) containing 0·010 M $MgAc_2$, 0·05 M ammonium chloride, 0·8 mM puromycin, 4 A_{260} units/ml. of the trinucleotide AUG and 8 mg/ml. ribosomes. Equal portions of the reaction mixture (0·02 ml.) were withdrawn at 0 min and at the times indicated and blown into 0·2 ml. of a solution at 0° C of 0·05 M potassium cacodylate *p*H 6·8 containing 0·01 M $MgAc_2$ and 1·5 mg/ml. bovine plasma albumin. 0·2 ml. 5 per cent perchloric acid were added; the precipitate was removed by centrifugation and the supernatant plated out on to a strip (3 cm × 4 cm) of Whatman 3 *MM* paper. This was dried, neutralized in ammonia vapour, dried and counted in a scintillation counter with an efficiency of 60 per cent. From each sample has been subtracted a small (less than 5 per cent) 0 min blank value. The total acid-precipitable material at 0 min was measured by dissolving that precipitate in 1 M ammonium hydroxide, plating this out on paper and counting as already described. The total acid-precipitable material at 0 min was 6,050 c.p.m. The effect of omitting either puromycin or AUG or ribosomes is shown

To determine what the products of reaction were, the ethanol-soluble components of incubation mixtures containing either ^{35}S-formyl-met-sRNA$_F$ or ^{35}S-met-sRNA$_F$ were subjected to electrophoresis at *p*H 3·5. An autoradiograph of the paper sheet is shown in Fig. 6. The principal product of the reaction between formyl-met-sRNA$_F$ and puromycin (sample 1, FMP) has a mobility similar to the marker formyl-methionyl-adenosine (FMA) (as would be expected of formyl-methionyl-puromycin). This labelled material was eluted and shown to co-electrophorese with chemically synthesized formyl-methionyl-puromycin, at *p*H's 1·9, 3·5 and 5·0. It is quantitatively adsorbed to 'Norite' suggesting that the formyl-methionine is attached to an aromatic base; it is not sensitive to dilute alkali (as formyl-methionyl-adenosine is), but is degraded by dilute acidic hydrolysis (0·2 M hydrochloric acid in methanol at 37° C for 90 min) yielding a compound that moves like synthetic methionyl-puromycin at *p*H's 1·9 and 3·5. We conclude that this product is formyl-methionyl-puromycin. In the absence of puromycin, formyl-met-sRNA$_F$ gives rise to a faint, unidentified band with a mobility lower than methionine (sample 3).

^{35}S met-sRNA$_F$ when bound to ribosomes in the presence of puromycin gives rise to an increase (some three-fold over the control, sample 6) of material in the methionine band (sample 4, M). Its identity with methionine (or its sulphoxide) has been checked by co-electrophoresis with authentic markers at *p*H's 1·9 and 3·5. The faint band observed in sample 4 (MP) with a mobility between methionyl-adenosine (MA) and formyl-methionyl-adenosine has been identified as methionyl-puromycin by its co-electrophoresis with synthetic methionyl-puromycin at *p*H's 1·9, 3·5 and 5·0. It is adsorbed to 'Norite' and is indistinguishable from deformylated ^{35}S-formyl-methionyl-puromycin. Both the ^{35}S-methionyl-puromycin formed from met-sRNA$_F$ and that obtained by deformylation of formyl-methionyl-puromycin appear to be unstable at low *p*H's (about *p*H 2·0), especially on elution from paper. Both give rise to two other unidentified bands on electrophoresis at *p*H 3·5, one of which is probably methionyl-0-methyl-tyrosine. The appearance of free methionine was found to be due to contamination of the ribosomes used in Fig. 6 by an amino-peptidase[17]. Another ribosome preparation which was virtually free of amino-peptidase activity yields predominantly methionyl-puromycin as the product of reaction between met-sRNA$_F$ and puromycin (Fig. 7). We therefore conclude that methionyl-sRNA$_F$, whether formylated or not, is sensitive to puromycin when bound to ribosomes, yielding the acyl-puromycin derivative.

In Figs. 8 and 9 chemically acetylated met-sRNA$_F$ and met-sRNA$_M$ have been tested for their sensitivity to puromycin. Both sRNAs were tested in 0·01 M Mg^{++}; the ribosome preparation used here was prepared as for earlier experiments but was not as active with formyl-met-sRNA$_F$. The rate of reaction of the acetyl-met-sRNA$_F$ is some twelve-fold greater than that of acetyl-met-sRNA$_M$. The product of the reaction of acetyl-met-sRNA$_F$ and puromycin has electrophoretic properties similar to formyl-methionyl-puromycin and is therefore assumed to be acetyl-methionyl-puromycin.

When puromycin is present in an incubation mixture in which poly *A* directs the synthesis of polylysine, the principal products observed are the oligolysyl-puro-

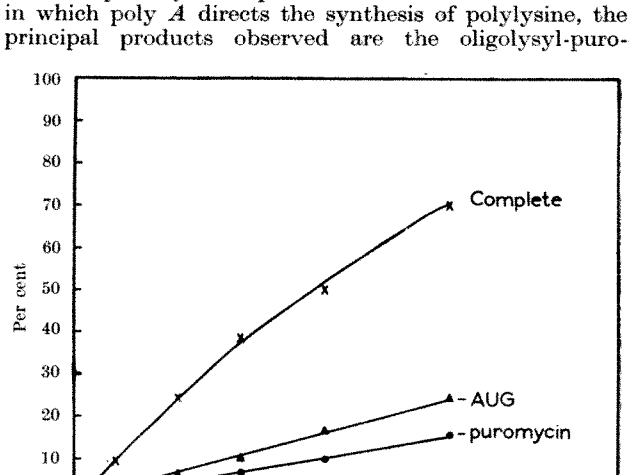

Fig. 3. The appearance of acid-soluble label with ^{35}S-met-sRNA$_F$. The conditions used were the same as in Fig. 2 except that 10^{-4} M L-methionine was present during the incubation. The total acid-precipitable material at 0 min was 5,700 c.p.m.

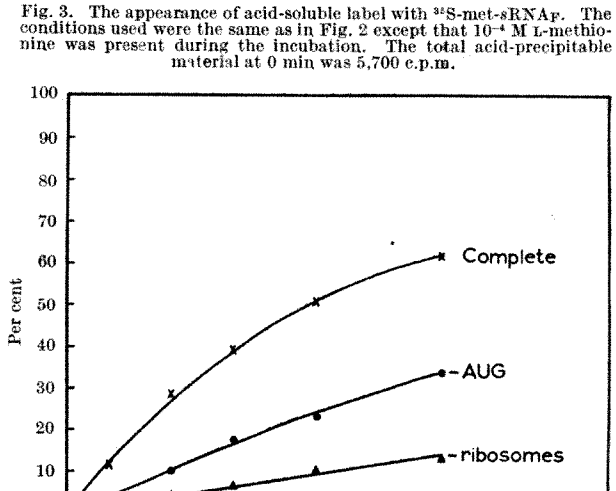

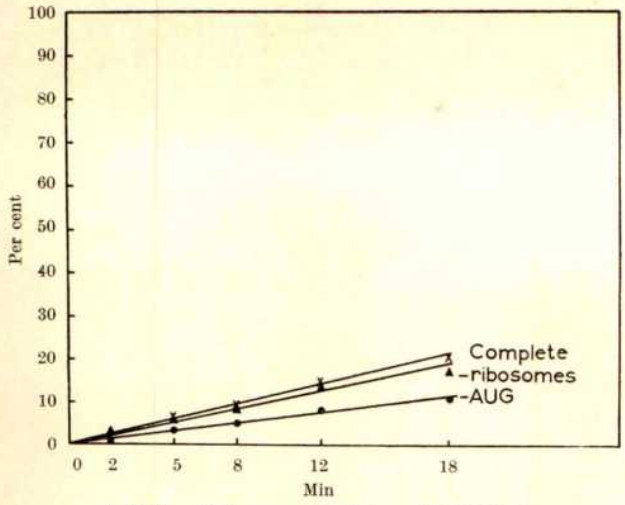

Fig. 4. The appearance of acid-soluble label with ^{35}S-met-sRNA$_F$. The conditions used were the same as in Fig. 3 except that the incubation was carried out in 0·02 M $MgAc_2$ and in 0·1 M potassium cacodylate *p*H 6·8 (instead of *tris*-hydrochloric acid, *p*H 7·1). The total acid-precipitable material at 0 min was 9,100 c.p.m.

met-$sRNA_M$, AUG, puromycin, ribosomes in 0·02 M Mg^{++}

Fig. 5. The appearance of acid-soluble label with ^{35}S-met-$sRNA_M$. The conditions used were the same as in Fig. 4. The total acid-precipitable material at 0 min was 8,900 c.p.m.

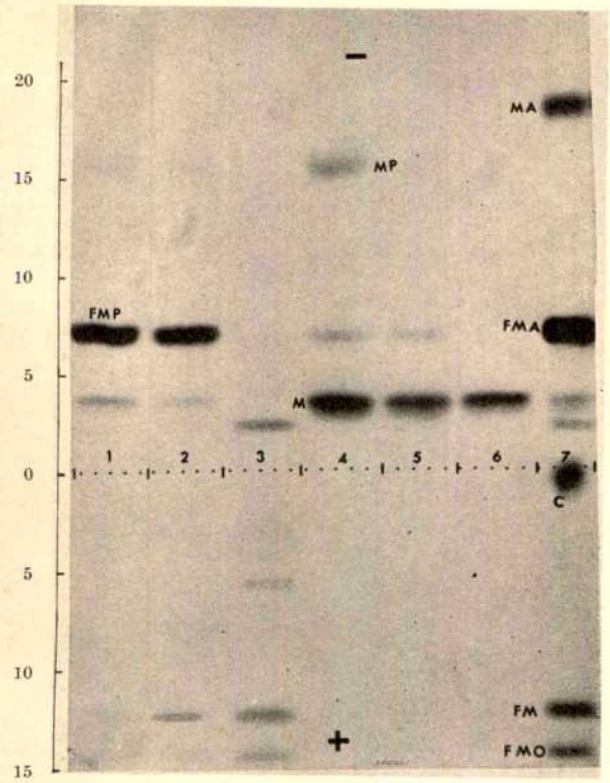

Fig. 6. Electrophoresis of reaction products at *p*H 3·5. Incubations (0·05 ml.) were carried out at 30° C for 20 min in 0·10 M potassium cacodylate *p*H 6·8 (instead of *tris*-hydrochloric acid *p*H 7·1), but otherwise as described under Fig. 3. After incubation 0·12 ml. ethanol was added to each sample, the precipitate removed, the ethanolic phase dried down and subjected to high-voltage electrophoresis on Whatman 3 *MM* paper at *p*H 3·5 (50 min at 50 V/cm). The paper was dried and left to autoradiograph with commercial X-ray paper for 4 days

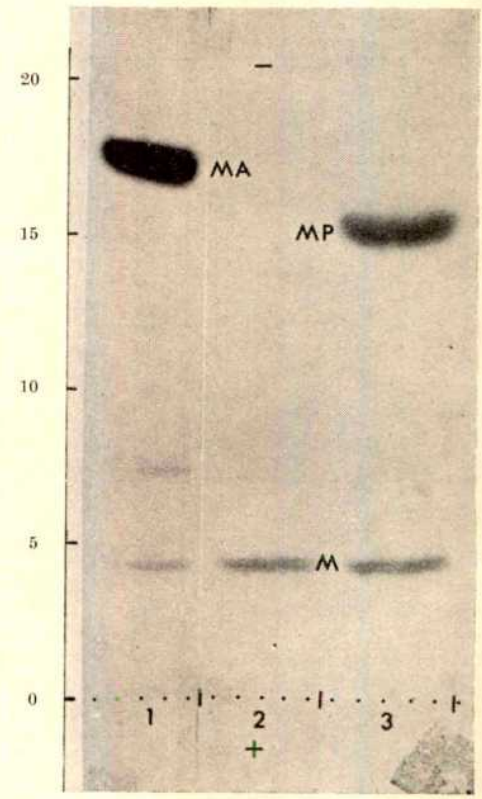
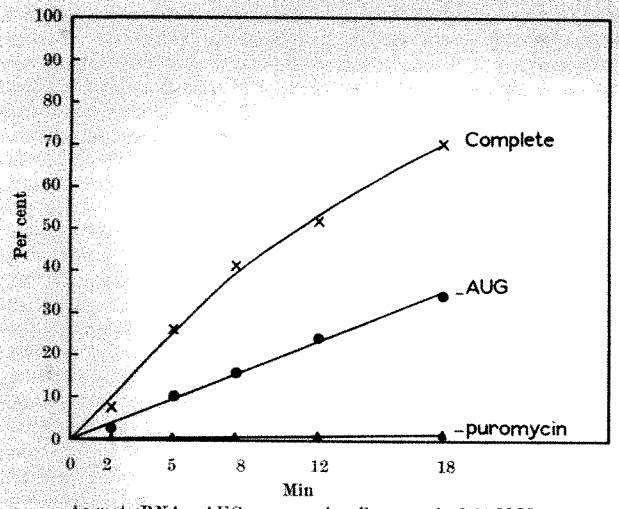
Samples: (1) Complete reaction mixture using ^{35}S-formyl-met-$sRNA_F$. (2) As in sample (1) but with the omission of AUG. (3) As in sample (1) but with the omission of puromycin. (4) Complete reaction mixture using met-$sRNA_F$. (5) As in sample (4) but with the omission of AUG. (6) As in sample (4) but with the omission of puromycin. (7) This contains a pancreatic ribonuclease digest of partially formylated ^{35}S-met-*s*RNA as markers. Spots are labelled as follows: methionyl-adenosine (MA), formyl-methionyl-adenosine (FMA), methionine (M), formyl-methionyl-puromycin (FMP), methionyl-puromycin (MP), a contaminating spot picked up after electrophoresis (C), formyl-methionine (FM) and formyl-methionine sulphoxide (FMO)

A scale in centimetres is shown on the left. The radioactivity in the methionine bands in samples 4 and 6 is about 3 : 1

mycins[12]. It is also known that polyphenylalanyl-*s*RNA and polylysyl-*s*RNA are sensitive to puromycin when bound with poly U and poly A, respectively[18]. Probably only a polypeptidyl-*s*RNA which is bound in the peptide site can react with puromycin. The puromycin, on the other hand, is bound in the same environment as the amino-acyl-adenosine group of amino-acyl-*s*RNA in the amino-acid site before reaction. Ribosomes may contain enzyme systems capable of transferring a peptidyl-*s*RNA from the amino-acid site to the peptide site, but in the experimental system described here such transfer may be inefficient, because only a trinucleotide is used as *m*RNA. In the earlier experiments carried out with polypeptidyl-*s*RNAs and polynucleotide messenger, motion of the polypeptidyl-*s*RNAs between the amino-acid and peptide sites may possibly have occurred.

Our experiments indicate that $sRNA_F$ recognizes the peptide site in preference to the amino-acid site irrespective of the presence or absence of the formyl group, and that therefore the $sRNA_F$ possesses some special feature.





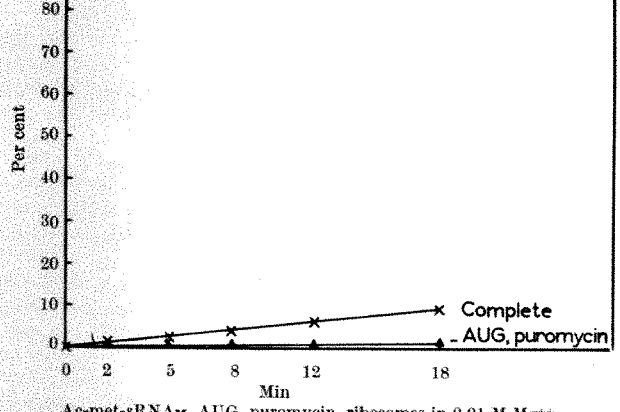


Fig. 7. Electrophoresis of reaction mixtures using met-$sRNA_F$. The experiment was as in Fig. 6. *Samples:* (1) Methionyl-adenosine from methionyl-*s*RNA. (2) Complete reaction mixture but with the omission of puromycin. (3) Complete reaction mixture

This preference for the peptide site confers on it its special function as an initiator of polypeptide chain synthesis because, whether formylated or not, this $sRNA_F$ acts as an initiator of polypeptide synthesis *in vitro*[10,15]. The specificity for binding to the peptide site and hence its ability to act as a chain initiator must reside in the $sRNA_F$. The presence of a blocked amino group does not appear to be sufficient to place an *s*RNA into the peptide site because acetyl-met-$sRNA_M$ is insensitive to puromycin under conditions where acetyl-met-$sRNA_F$ is sensitive. The presence of a formyl group on met-$sRNA_F$ simply serves to increase the rate of reaction with puromycin and thus the rate of formation of the first peptide bond. This has also been shown with the *mu*2 phage RNA in the *in vitro* system[15].

Ac-met-$sRNA_F$, AUG, puromycin, ribosomes in 0·01 M Mg^{++}

Fig. 8. The appearance of acid-soluble label with acetyl-met-$sRNA_F$. The conditions used are the same as in Fig. 6. The total acid-precipitable material at 0 min was 11,600 c.p.m.

Ac-met-$sRNA_M$, AUG, puromycin, ribosomes in 0·01 M Mg^{++}

Fig. 9. The appearance of acid-soluble label with acetyl-met-$sRNA_M$. The conditions used were the same as in Fig. 6. The total acid-precipitable material at 0 min was 9,000 c.p.m.

There may exist some subtle change in *s*RNA conformations which allows other *s*RNAs to be transferred from the amino-acid to the peptide site during protein synthesis. Whether the reversible conformation changes in *s*RNA which have recently been observed[19] are associated with different types of binding affinities is not known. The specificity of *s*RNA recognition by the *m*RNA should not be greater in the peptide site than in the amino-acid site. The binding properties of met-$sRNA_F$ suggest that the first base in the codon is either not recognized at all in the peptide site, or that A may be equivalent to G. The codon-*s*RNA relationships explored so far have, in the main, dealt with recognition in the amino-acid site. We would expect that a similar, although less specific, codon-*s*RNA recognition exists in the peptide site.

The ability to place an *s*RNA into either of two ribosomal sites, together with an assay for which site the *s*RNA is in, should be a useful tool for gaining a better understanding of ribosomal reactions. The experimental approach described here also provides a direct assay for polypeptide chain initiators.

We thank Dr. B. F. C. Clark for the generous gifts of fractionated *s*RNA species.

NUCLEIC ACID OF INFLUENZA VIRUS

By PATRICIA DAVIES and DR. R. D. BARRY

Department of Pathology, University of Cambridge

THE isolation of infective ribonucleic acid (RNA) from tobacco mosaic virus (TMV) in 1956, by extracting the virus with either phenol[1] or sodium dodecyl sulphate[2], suggested that hereditary functions were not the exclusive property of deoxyribonucleic acid (DNA). The importance of RNA as genetic material was firmly established during the next 5-year period, when infectious material was isolated from a large number of structurally simple animal and plant viruses[3]. In these investigations, extraction of infectious RNA was based mainly on the phenol method of Gierer and Schramm[1] and the activity of the RNA was invariably destroyed by treatment with ribonuclease (RNase).

Detailed physico-chemical investigations of TMV-RNA showed that the molecular weight of the infectious RNA was about 2×10^6, and that each infectious molecule represented the complete nucleic acid complement of the virus particle[4–6].

Recently, improved extraction methods have been devised in which a combination of phenol and detergents together with RNase inhibitors is used. The nucleic acid of several larger RNA viruses has been isolated by

such methods, and shown to be of high molecular weight, as calculated from the sedimentation coefficient (*S* value)[10–13]. Tests for infectivity were not carried out, but the calculated size of the extracted material is consistent with the idea that each virus particle contains only one molecule of RNA. Listed in Table 1 are some *S* values obtained from a number of RNA viruses, together with estimates of their molecular weights.

Table 1

Virus	Sedimentation coefficient of RNA (*S*)	Mol. wt. of RNA	Reference
Polio	37	2×10^6	7
Foot and mouth disease	37	3×10^6	8
Mouse encephalitis	27·5	2×10^6	9
Newcastle disease	57	$7{\cdot}5 \times 10^6$	10
Rous sarcoma	64	$9{\cdot}5 \times 10^6$	11
Rauscher	73, 74	13×10^6	12, 13

Influenza virus has an RNA content of about 0·75 per cent–1 per cent[14,15]. The estimated molecular weight of this RNA is 2×10^6 (ref. 16). Many attempts have been made to isolate the RNA from influenza virus in an infectious form, either from whole virus or from virus-infected cells. The results reported are confusing and contradictory, as can be seen from Table 2. As there is no general agreement between these reports, it is still uncertain whether the various extraction methods used succeed in isolating the RNA from influenza virus in its naturally occurring state. Furthermore, virtually no physico-chemical data are available concerning the nature of the nucleic acid. There is some genetic evidence that the RNA may exist in the intact virus particle as several separate pieces[26]. On the other hand, if the RNA is a single large molecule, as is the case for other RNA viruses, the confusion apparent in Table 2 might reflect the inadequacies of the extraction procedures used. The purpose of the experiments described in this article was to investigate this problem further, in an attempt to determine the size and nature of the RNA of influenza viruses.

The influenza A_2 strain *A*/Singapore/1/57 was used throughout. It was prepared as follows:

Eleven-day-old embryonated eggs were inoculated with 0·1 ml. of infected allantoic fluid diluted 10^{-6}, incubated at 37° C for 36 h and then collected. For unlabelled virus, yields of allantoic fluid were obtained from two separate batches of 5,000 eggs. To obtain virus labelled with phosphorus-32, batches of twelve eggs were inoculated with 0·4 mc. of phosphorus-32 (as phosphate buffer) per egg, 24 h before virus infection.

Both labelled and unlabelled virus was purified in the same way. Freshly washed fowl red cells were added to the allantoic fluid to a final concentration of 0·5 per cent and kept at 4° C for 1 h with occasional shaking. The red cells were deposited by centrifugation and washed once in ice-cold phosphate buffered saline. Virus was eluted by stirring the red cells in 0·9 per cent sodium chloride at 37° C for 2 h. The eluate was then treated with 5 μg/ml. DNase and 5 μg/ml. RNase for 20 min at 37° C and immediately centrifuged on a linear 15–60 per cent sucrose density gradient at 20,000 r.p.m. for 1 h in a Spinco *SW*25 rotor. 3 ml. fractions were collected through a hole pierced in the bottom of the centrifuge tube. 0·1 ml. amounts of each fraction were used to measure haemagglutinin content and an equal amount was used for radioactivity measurements. The level of radioactivity was counted in a Packard 'Tricarb' liquid scintillation counter, series 4,000. The scintillation fluid used was prepared according to Bray[27].

The results of a typical experiment using labelled virus are shown in Fig. 1. Most of the virus present was confined to fractions 12, 13 and 14 of the gradient. Most of the phosphorus-32, on the other hand, was found at the top of the gradient. However, considerable radioactivity was associated with the virus. From any such gradient, only the two or three fractions (such as Nos. 12, 13 and 14 in Fig. 1) in which the haemagglutinin peak occurred were kept and processed further. These fractions were pooled and dialysed overnight at 4° C against 0·9 per cent sodium chloride. The dialysed virus was then deposited by centrifugation at 20,000 r.p.m. for 1 h in a Spinco model *L* ultracentrifuge; the pellet was resuspended in a small volume of 0·1 M sodium chloride–0·001 M ethylenediamine tetraacetate (EDTA) and the resulting suspension was treated for 1 min with an M.S.E. ultrasonic disintegrator. This treatment breaks apart any aggregates of virus caused by centrifugation but has no effect on the biological properties of influenza virus.

Extraction of RNA was carried out in the following way. Sodium dodecyl sulphate (SDS) was added to the purified virus preparation to give a final concentration of 1 per cent. The virus was then deproteinized by the addition of an equal volume of water-saturated, freshly redistilled phenol, *p*H 7·5. Extraction with phenol was carried out in two ways: (1) all extractions performed at 4° C; (2) the first phenol extraction performed at 52° C, then all subsequent extractions at 4° C. Identical results were obtained in both cases.

The aqueous and phenol phases were separated by centrifugation and the aqueous phase re-extracted with phenol until all traces of an interface had disappeared. RNA was precipitated from aqueous phase by addition of 2·5 volumes of absolute alcohol and 0·1 volumes of 20 per cent sodium acetate, the mixture then being stored at −20° C for at least 2 h. The precipitate was washed twice with absolute alcohol, once with ether and resuspended in 0·5–1 ml. of 0·01 M acetate buffer *p*H 5·3, containing 0·1 M sodium chloride and 0·001 M EDTA. The last traces of ether were blown off with compressed nitrogen.

A batch of unlabelled influenza virus, consisting of 100 mg of purified virus, was subjected to the extraction procedure outlined here. A total of 630 μg of nucleic acid was recovered; the ultra-violet absorption spectrum of this material is shown in Fig. 2.

A diphenylamine test for deoxyribose was negative. To investigate the physical nature of this RNA, about 30 μg was layered on to a 5–20 per cent linear sucrose density gradient and centrifuged at 37,000 r.p.m. for 3 h in a Spinco rotor *SW* 39. A second sample of the same RNA was treated with RNase (0·5 μg/ml.) for 30 min

Table 2

Virus	Extraction procedure	Result of infectivity test	Properties of extracted material	Reference
Fowl plague	Phenol	−ve	Heterogeneous in size 8–14*S*	17, 18
MEL, WSE, NEURO-WS, LEE, NDV	Cold phenol	−ve		19
Influenza *T*	Ether, cold phenol	+ve	Orcinol +ve; amino-acid −ve	20
Influenza/A_2/Sing.	Ether, cold phenol	−ve	Typical nucleic acid spectrum. Susceptible to RNase	21
Influenza *A*	EDTA, ether, cold phenol	+ve	Typical nucleic acid spectrum. Susceptible to RNase	22, 23
Influenza	Chloroform, cold phenol	+ve	Susceptible to RNase and immune gamma globulin	24
Influenza	Sodium deoxycholate, phenol at various temperatures	not tested	Largest sedimentation coefficient = 11. Single stranded RNA	25

at room temperature, before centrifugation. The distribution of nucleic acid in the fractionated gradients was determined by optical density measurements. The results are shown in Fig. 3. Most of the untreated RNA banded in a single broad peak rather less than half way down the tube. The remainder was diffusely scattered throughout the low-density region of the gradient. The RNA was completely degraded by pretreatment with RNase. Those samples which contained the untreated RNA peak (fractions 12–16) were pooled, the RNA reprecipitated with alcohol and sodium acetate and redissolved in 1 ml. acetate buffer for analysis in the analytical ultracentrifuge. During centrifugation the RNA began to break down, making an accurate estimation of the *S* coefficient difficult. However, an average value was calculated to be 16*S*.

In this experiment, it took a fortnight to purify and to concentrate virus from about 100 l. of infected allantoic fluid. It seemed likely that the low *S* value obtained arose from breakdown of larger molecules during this lengthy process. However, by using much smaller quantities of phosphorus-32 labelled virus, the time involved in purification and extraction could be reduced to 24 h.

Several separate batches of phosphorus-32 labelled virus were prepared and the RNA extracted. Fig. 4 shows a typical sedimentation pattern for phosphorus-32-labelled RNA. Two distinct components were present. Pre-treatment with RNase converted all the RNA to slowly sedimenting material. It can be seen that about 57 per cent of the radioactivity bands in the faster sedimenting peak–fractions 17–21 of the gradient. This is considered to be intact virus RNA; the remainder of the radioactivity is distributed at the top of the gradient and is presumably RNA which has been degraded during the extraction process. This figure of 57 per cent compares well with the data of Duesberg and Robinson[10], who found that a maximum of only 21 per cent of NDV-RNA bands in the faster sedimenting peak. Identical results have been obtained using several different batches of phosphorus-32-labelled virus. By comparing the sedimentation rate of virus RNA with that of chick embryo fibroblast RNA spun under identical conditions, it can be seen that the faster sedimenting component of the influenza virus RNA coincides exactly with the 18*S* ribosomal RNA component. This is shown in Fig. 5. The fact that the majority of influenza RNA forms a band in the leading peak, and that this peak is homogeneous in nature, suggests that the bulk of the virus RNA has been extracted in an undegraded state.

To test the possibility that the extraction method itself was breaking down what was really a high molecular

weight RNA into regular pieces having an approximate *S* value of 18, the nucleic acid of TMV was extracted and examined in the same way. Purified TMV (17 mg) was extracted, and 342 μg of RNA were obtained. Analysis in the analytical ultracentrifuge of a 50 μg/ml. solution in acetate buffer *p*H 5·3, 0·10 M sodium chloride, and 0·001 M EDTA gave a sharp boundary, and an *S* value of 31 was calculated from the densitometer tracing. This value corresponds exactly with that obtained by Spirin[28] and indicates that an undegraded molecule of molecular weight 2×10^6 has been obtained. The successful isolation of TMV-RNA by the combined phenol-SDS extraction method suggests that the homogeneous 18*S* material extracted from influenza virus is actually the RNA as it occurs in the intact particle.

It is generally agreed[28] that 18*S* ribosomal RNA has a molecular weight of about 500,000. As the extracted nucleic acid of influenza virus is about the same size, it seems that four such molecules would be required to provide a full molecular weight complement of 2×10^6.

From a consideration of the genetics of influenza virus, and the existence of incomplete virus, Hirst[26] has developed a case for the existence of separate pieces of RNA in the intact influenza virus particle. Similarly, experiments on the multiplicity reactivation of this virus[29] indicate that there could be six separate functional pieces. The experi-

ments reported here support the idea that the nucleic acid influenza virus occurs in separate pieces, and because the virus RNA appears to be of similar size to ribosomal RNA, there is the possibility that it is a variety of ribosomal RNA. In support of this idea is the fact that the synthesis of both virus RNA[30] and ribosomal RNA[31] occurs in the nucleus of the cell. Furthermore, inhibition of the synthesis of both types of RNA by actinomycin *D*[32,33] suggests that they are both made on a DNA template.

Despite the homogeneity of the extracted influenza RNA, there is still a chance that it represents broken-down molecules. Burgi *et al.*[34] have recently described preferred breakage points in the DNA molecule of *T5* bacteriophage, when subjected to shear. The effect of such shearing is to produce two or three pieces of different size, which can be readily distinguished as separate bands in a sucrose density gradient. Unless influenza RNA has three preferred breakage points, evenly distributed along the length of a single molecule, any random breakdown of virus RNA should be detectable in a sucrose gradient. Thus, the results reported here suggest that RNA occurs in the intact influenza particle in pieces with molecular weight of about 500,000.

The assistance of Major L. Kent and Mr. F. Belton of the Microbiological Research Establishment, Porton, in the large-scale production of influenza virus is gratefully acknowledged. We are also indebted to Mr. M. Rees of the Agricultural Research Council Virus Research Unit, Huntingdon Road, Cambridge, for a gift of purified TMV. One of us (P. D.) was supported by a grant from the Medical Research Council.

The action of DMBA seems to be related to the presence of corticosterone in the adrenal, and it has been suggested that the induction of necrosis is dependent on synthesis of this hormone[3]. Currie *et al.*[4] reported that 2-methyl-1,2-*bis*-(3-pyridyl)-1-propanone (metyrapone), which inhibits 11β hydroxylation and therefore interferes with the synthesis of cortisol and corticosterone[5], protected the adrenal glands from DMBA. Dao and Tanaka[6], in addition to confirming this finding, showed that 3-methylcholanthrene, which also inhibits corticosterone synthesis[7], also had a protective action, and furthermore, that a number of other polycyclic hydrocarbons—including DMBA itself in a small dose—were also effective[8]. Recently Wattenberg and Leong[9] reported that substances such as phenothiazine, which enhance detoxification mechanisms of polycyclic hydrocarbons non-specifically, can protect the adrenal gland from DMBA. Protection may have been achieved by speeding up the removal of DMBA from the body, but, on the other hand, it has been known for some time that DMBA, like other carcinogenic polycyclic hydrocarbons, can be metabolized by the rat and it is possible that DMBA exerts its action only after conversion to an active derivative[10].

We have investigated the effect of impairment of liver function by carbon tetrachloride and by partial hepatectomy on DMBA-induced adrenal necrosis.

Female Sprague–Dawley rats were obtained commercially at 40 ± 1 days of age from Oxford Laboratory Animal Colonies, Oxford. In the first experiment, groups of rats (see Table 1) were treated intraperitoneally with carbon tetrachloride (0·3 ml. of a 50 per cent v/v solution in olive oil) or olive oil alone when 49 ± 1 days old. In the second experiment, partial hepatectomy was performed under ether anaesthesia. The median and left lateral lobes of the liver were excised after the method of Higgins and Anderson[11]—from our previous experience about 65 per cent of the liver is removed. Control groups included sham hepatectomy and unilateral nephrectomy (see Table 3). DMBA in 15 per cent lipid emulsion (3 mg in 0·6 ml. emulsion) was injected intra[illegible] 24 h after treatment with carbon tet[illegible] operation. In control groups [illegible] emulsion containing no [illegible] stunning 3 days af[illegible] were removed [illegible] formaldehyde. [illegible] were similarl[illegible]

laris); + +, focal necrosis; + + +, severe necrosis involving > 90 per cent of the zona fasciculata and zona reticularis. On no occasion was there disagreement on categorization, and in almost all cases the two adrenals from the same rat showed the same histology. In the rats treated with carbon tetrachloride, liver damage was also assessed independently without knowledge of the previous treatment. Eighty-five to ninety per cent of the rats treated with carbon tetrachloride developed centrilobular liver necrosis (Fig. 1).

Carbon tetrachloride. The results for the first experiment are summarized in Table 1. The majority of adrenal glands in rats given DMBA 24 h after carbon tetrachloride showed little or no damage. For ease of comparison we have grouped together the glands showing massive necrosis (+ + and + + +); the glands in the other grades (− and +) show little or no damage (Table 2). Pretreatment of rats with carbon tetrachloride gives a high degree of adrenal protection against DMBA; in four of the seven rats in which carbon tetrachloride did not do so, only minimal liver damage had been produced. Adrenal necrosis was not seen in rats given only carbon tetrachloride. There was no histological difference between the livers of rats treated with both carbon tetrachloride and DMBA and those of the animals given only carbon tetrachloride.

Table 1. EFFECT OF CARBON TETRACHLORIDE ON ADRENAL NECROSIS INDUCED BY DMBA

Group	Pretreatment—intraperitoneal injection of	Challenge (intravenous)	No. of rats	No. rats surviving expt.	Adrenal grading −	+	+ +	+ + +

[illegible]ARTIAL HEPATECTOMY ON DMBA-INDUCED ADRENAL NECROSIS

that in this group—as also after sham hepatectomy—DMBA caused massive adrenal necrosis in all the rats. Eight out of ten rats given only DMBA (group 4) developed adrenal necrosis: this is in accord with our previous experience that 3 mg DMBA causes massive adrenal necrosis in 70–80 per cent of the rats.

It is quite clear that when liver function is impaired either by the treatment with carbon tetrachloride or by partial hepatectomy the adrenal glands are protected from the action of DMBA. It seems likely that DMBA is metabolized in the liver to a derivative that is adrenocorticolytic. Boyland, Sims and Huggins[10] have shown not only that DMBA can be metabolized by rats but also that the derivative 7-hydroxymethyl-12-methylbenz(*a*)-anthracene (American terminology), given in smaller doses than DMBA, produces severe adrenal necrosis. Metyrapone, which inhibits the adrenal enzyme 11β-hydroxylase, protects the adrenals[4], and it is possible that it may also act on liver hydroxylases, thereby preventing the metabolism of DMBA.

The interval between administration of carbon tetrachloride and the challenge with DMBA is important: with the dose used by us, treatment with carbon tetrachloride 24 h before DMBA gives the highest degree of protection. Tanaka and Dao[12] recently reported that carbon tetrachloride has no effect on DMBA-induced adrenal necrosis. In our earlier experiments, with doses of carbon tetrachloride similar to those used by these workers and a similar vehicle (mineral oil), we found little or no liver damage and no evidence of adrenal protection.

The 'stress' of treatment with carbon tetrachloride or of partial hepatectomy is likely to cause increased production and secretion of corticosterone and, furthermore, if DMBA is metabolized less efficiently because of impaired liver function, the adrenal glands will be exposed to circulating DMBA for longer than controls. Despite these two factors—which might be expected to cause a greater incidence of adrenal necrosis—the adrenal glands are protected from the action of DMBA. This is all the more remarkable because operative stress, as in the sham hepatectomy and nephrectomy groups, apparently increases the susceptibility of the adrenal glands to DMBA.

Thus, in summary, pretreatment of female Sprague–Dawley rats with 0·3 ml. of a 50 per cent v/v solution of carbon tetrachloride in olive oil intraperitoneally 24 h before challenge with DMBA protected the adrenal glands from the necrotizing effect of DMBA. This dose of carbon tetrachloride caused centrilobular necrosis of the liver in 85–90 per cent of the rats. Protection was also achieved by partial hepatectomy 24 h before challenge with DMBA. It is concluded that DMBA itself is not adrenocorticolytic and that it is metabolized in the liver to a substance that causes massive adrenal necrosis.

This work was supported by a grant to one of us (A. R. C.) from the Scottish Hospital Endowments Research Trust. DMBA in 15 per cent lipid emulsion was prepared by Dr. Paul Schurr (The Upjohn Co., Kalamazoo, Michigan) and was the generous gift of Prof. C. Huggins. We thank Mrs. M. Inglis and Mr. G. Milne for their assistance in this work.

DEFICITS IN PRIMITIVE PERCEPTUAL AND THINKING SKILLS IN SCHIZOPHRENIA

By Dr. VERNON HAMILTON
Department of Psychology, University of Reading

Traditionally, though not perhaps with complete justification, the diagnosis of the complex of conditions known as schizophrenia has been the responsibility of the medical speciality of psychiatry. While logical doubts remain whether this condition of psychological abnormalities is classifiable as an illness in the sense that anaemia or tuberculosis is an illness, the major treatment of choice has been for at least 30 years a variety of medically prescribed biochemical or electrical agents. This direction of responsibility, interest and treatment has derived basic support not only from the history of medicine but from a variety of genetical assumptions founded on a variety of evidence concerning the familial incidence of the condition, thus leading to specific as well as general assumptions concerning the physiological or neurological origin of schizophrenia.

By contrast, in a recent article Huxley, Mayr and Osmond[1] have made a case for considering the solution of the problem of schizophrenic behaviour as a wide interdisciplinary concern to which *inter alia* biochemistry and psychology may be expected to make valid contributions. Baldessarini and Snyder[2] have appropriately taken issue with Huxley *et al.* on the degree of incautious certainty with which the latter have put forward their views (*a*) concerning the genetical determination of schizophrenia and (*b*) concerning the mechanisms of genetical transmission. It is not my purpose to enter what is primarily a geneticist's province. From the psychological point of view it is less important to know that biochemical or morphological mechanisms may be genetically determined by one form of transmission or another, or even that these mechanisms may determine early abnormal developmental trends in children, than that behavioural predispositions to develop one or the other form of what is termed schizophrenia may originate early in life, and that the start of schizophrenic processes may be found in inadequacies and idiosyncrasies of perception and thought which have their roots in this early stage of individual development. This hypothesis, so far still not proved, ceased to be original a long time ago: one only has to cite the somewhat unpopular psycho-analytic theory concerning inadequate ego processes, reality testing and ill-defined and permeable ego boundaries, which in terms of this particular theory usually develop in early childhood. While this and other aspects of psycho-analytic theory have been castigated for lack of precision, for their fancifulness and untestability, testable alternative propositions concerning the possible early developmental roots of schizophrenic forms of behaviour have been slow in coming forward. There seem to have been six main

reasons for this omission. In the first place, psychiatry appears to have been rather jealous of its traditional position with respect to a human condition which has been classified as an illness, and has frequently been reluctant to invite the co-operation of non-medical personnel in the study of all the so-called mental illnesses. Secondly, and largely because of this, psychological hypotheses, both relevant and testable, concerning the genesis of schizophrenic perception and thought are only rarely formulated and even less frequently submitted to tests of falsification. Thirdly, a fully developed condition of schizophrenic behaviour in many cases rules out those types of experimental psychological investigations which require alert, rational and sometimes prolonged participation by the patient. Fourthly, the condition of schizophrenia, despite many attempts at meaningful sub-classification, and despite considerable evidence concerning the heterogeneous nature of its individual characteristics, frequently continues to be conceptualized as an internally consistent, homogeneous state. Fifthly, because the diagnosis of the condition of schizophrenia is made in most cases on overt behavioural, that is to say phenotypical grounds, its diagnosis is subject to the notorious errors of the unreliability and invalidity of subjective inspection, and furthermore the eclectic psychiatric definition itself of the condition contains more than the suspicion of a tautological error. Finally, the clinician as well as the experimental psychologist is faced in the patient with the end result of a long developmental history and not usually with the early stages of the abnormal processes. Under these conditions the testing of explanatory hypotheses is patently not appropriate because it would depend excessively on retrospective inference, while the required experimentally controlled longitudinal studies of a sufficiently large sample of children beginning at an early age have not yet been undertaken. Yet this degree of persistence will eventually be required in order to say whether a state of disordered perception and thinking in a fully developed schizophrenic condition represents the outcome of an early state of maldevelopment which has been continuous and of increasing implication for maladaptation of the individual, or whether the abnormal end state represents the outcome of an inhibition of culturally normal and acceptable processes and functions possibly as the result of a single traumatic experience or a series of such experiences, or whether a conjunction of both possibilities must be considered. Any investigation, therefore, showing deficits of rather basic skills of perception and thought in schizophrenia is subject to this important limitation.

It is commonly agreed that there are three major deficits in people diagnosed and classified as representing schizophrenic states: disorders of cognition, impoverishment of affect and diminution of motivation and motility. At present psychological theory based on experimentation is best qualified to offer models of explanation in the field of cognition. These models may be at different genotypical levels: they may be in terms of a restricted environmental field being available to a schizophrenic from which to draw appropriate cues for perception and thought, or they may concentrate on unusual or excessive use of cues giving rise to cognitive over-inclusion (see, for example, ref. 3). Alternatively, a more general model may be based on a reinforcement-type of learning theory, in which, for reasons as yet inadequately understood—but possibly through anxiety reduction—culturally inappropriate behaviour will be rewarded with progressive frequency (see, for example, ref. 4).

From 1959 until 1963 I was engaged in studying the effects of a variety of rehabilitation techniques and re-activating and re-motivating devices which might lead to an increase in the discharge rate and in the re-integration into the general social and occupational environment of schizophrenics who had been hospitalized for many years[5–7]. In the process of observing the patients concerned while engaged in actual or quasi-industrial assembly tasks, and while observing them and listening to them during the associated periods of group discussions, it was possible to obtain many examples of the operation of delusional, irrational and inconsequential thinking. In the present case this observational evidence suggested, because of its lack of everyday logic, because of the primitiveness of its cause and effect thinking (quite apart from the content of any delusional verbalizations), that it might be possible to find in schizophrenics evidence of an impairment at levels of thinking operations which are usually fully established in children of about 11 years of age possessing normal intelligence*. The kind of processes which were thought to be impaired were a sample of those cognitive skills which Piaget and his Geneva school of developmental psychology consider to occupy a fairly lowly and early, though essential, position in the hierarchical development of adult rational thought and perception. The aim of brevity of exposition forbids an account here of Piaget's conceptualizations concerning the development of propositional, logical thinking operations by way of earlier and developmentally more primitive stages of so-termed "sensori-motor, pre-operational, intuitive and concrete thinking". Apart from the many books and monographs by Piaget and his associates, eminently readable summaries of the relevant theories are available[8–10]. While Piaget's own work and particularly his earlier studies have been criticized because of an absence of experimental controls, a number of English workers have more recently produced experimental evidence that the hierarchical conception of the development of more and more complex, abstract and analytical thinking operations appears to be generally valid[11–15]. This means *inter alia* that children who on educational grounds are considered retarded and who also have a low intelligence quotient do not perform at the level of more normal children with tasks requiring abstraction, generalization or hypothetico-deductive forms of reasoning, and furthermore that children capable of logical/deductive operations are capable of them by virtue of the fact that developmentally earlier and more basic operations have been successfully assimilated. If it is held that delusional and other thinking abnormalities in schizophrenia suggest a breakdown of higher level logic in relation to certain events or situations impinging on an individual, it becomes relevant to enquire if lower level cognitive skills have remained unimpaired. Such an enquiry would involve the application of certain tasks under standard conditions which, according to Piaget's theories, are said to reflect the availability of such lower level skills.

In the experiment reported here, three cognitive skills usually fully or near fully developed in children of 11 years of age were selected to test the hypothesis that pre-operational, pre-logical thinking and perception are impaired in patients diagnosed as schizophrenic. The skills chosen were those of conservation of quantity and volume, the skill of seriation, and knowledge of parameters entering into perspective which requires both the skills of conservation and of seriation. In a task aimed at the availability of the conservation skill, subjects are required to make a comparison statement about quantities or volumes objectively equal in size or amount despite the presence of misleading spatial arrangements or distributions. Two tasks were given to test the availability of this ability. In the first, the investigator counted out two heaps of twelve dried beans from a jar and in the presence of the subject laid out the beans in two rows, 1 in. apart in one row and roughly 3 in. apart in the other row. To obtain a maximum score, subjects had to state without qualification that there were the same number of beans in each row. For the second conservation task, subjects were presented with two glass beakers filled to the same level with dried beans, pointing out that both beakers contained the same amount of

* This possibility was also suggested by, for example, Freeman *et al.*[16].

beans. The amount of beans in the first and then the second of these containers was then poured into two or more taller or shorter, narrower or wider glass beakers in a standard procedure. To obtain the maximum score subjects had to state without qualification that the amounts being compared were equal despite their varied distribution, difference of levels in glasses, number of glasses and apparent differences in volume.

The skill of seriation consists at its lower levels of the ability to order a set of material according to some principle of classification, which in the present investigation was order of size of randomly presented objects. Here, subjects were required to place ten differently coloured sticks 1 cm square varying in length from 1 to 10 cm, in order of size on a board with a straight horizontal bar to provide a level base for the series, after first indicating verbally and by pointing the order in which the sticks ought to be placed. For a fully adequate performance obtaining maximum score, anticipation and construction of the series had to be correct in detail without overt trials.

Knowledge of perspective requires availability of the knowledge that removal in distance does not affect the actual size of the object removed, only its apparent size. It also requires the ability to be aware of and profit from ordering of stimuli according to real or apparent size. For the assessment of present awareness of parameters operating in perspective, subjects were presented with a perspective drawing of a "Stately Home . . . with a long drive leading from the gate to the house . . .", as well as three sets of eight cardboard cut-outs shaped and painted to represent trees, which had to be placed ". . . at marked points along the drive as they would appear to us as we look from the gate along the drive to the house . . .". The trees were proportional in size to the perspective angle of the lines representing the drive in the drawing. Subjects received no further instructions and were thus free to use the same size trees for all positions or any combination of sizes in distance reducing or non-reducing series, placed in the true vertical position or perpendicular to the line demarcating the pathway. To obtain maximum score for this task, subjects had to place the cut-outs in the true vertical, size reducing series in correct sequence.

The system of scoring adopted here was simple and objective: 3 for a fully correct response, 1 for an incorrect response or a number of errors exceeding an operationally defined maximum, 2 for an intermediate response. It is indeed a rough-and-ready scoring system, though it is of a type frequently applied to the scoring of intelligence test items. For subsequent analysis responses were appropriately classified according to the degree to which the underlying cognitive principle was differentially present, where fully correct responses indicated presence of the full principle, and incorrect responses no principle present.

The investigation was carried out on an experimental group of twenty-five clinically diagnosed non-paranoid schizophrenic men aged 32–48 years ($\bar{X}$ = 40·8), detained in hospital 1–20 years ($\bar{X}$ = 11·9), with progressive matrices intelligence quotients 74–133 ($\bar{X}$ = 95·3) who participated in the conservation and seriation experiments only. A second group of ten schizophrenic men who participated only in the perspective experiment possessed the following basic characteristics: age 26–49 ($\bar{X}$ = 41·8), intelligence quotients 81–115 ($\bar{X}$ = 95·6), hospitalization 1–24 years ($\bar{X}$ = 9·1). The patients were receiving various maintenance doses of a variety of tranquillizers and almost all were employed either in rehabilitation workshops or on hospital service duties. The control group consisted of twenty secondary modern school boys aged 11·5–12·8 years ($\bar{X}$ = 12·2) with Moray House verbal reasoning quotients of 82–112 ($\bar{X}$ = 95·2), selected on the basis of their availability in relation to the school time-table.

The results of the investigation are shown in Fig. 1. They indicate that the skills pertaining particularly to conservation and knowledge of perspective parameters are impaired in the schizophrenic subjects compared with the much younger children, although the groups were well equated in terms of performance on (albeit different) intelligence tests. The statistical probability of the differences was assessed by χ^2 tests comparing for both groups the availability and non-availability of the full principle of the skill. For conservation $\chi^2 = 4{\cdot}06$, $P < 0{\cdot}05$; for seriation $\chi^2 = 0{\cdot}13$, not significant; for perspective $\chi^2 = 1{\cdot}27$, $P < 0{\cdot}001$. The main reason for the non-significant difference for seriation appeared to be the greater haste of the sample of children which led them into errors, which were scored as such, but which were in almost all cases quickly corrected on second inspection by the subjects themselves. A similar, though slightly smoothed pattern of differences was obtained, when comparing the control group performance with that of a sub-sample of the schizophrenic group, none of whom had an intelligence quotient lower than any intelligence quotient in the control group. Furthermore, when considering a schizophrenic sub-sample consisting only of subjects with an intelligence quotient of 100 or more, the sample of children still performed better. Additional evidence concerning the relationship between the skills assessed here and the status of schizophrenia was present when comparing the performance of schizophrenic subgroups with high and low ratings on a rating scale aimed at obtaining an index of degree of impairment or "illness" using consistent and relatively objective rating criteria[5]. This comparison showed that patients with the greater amount of clinical impairment produced less frequently a fully or partially adequate reply to the test questions in the conservation and seriation tasks. None of the differences, however, was statistically significant. This analysis could be carried out only in respect of patients belonging to the larger group on whom, furthermore, knowledge of perspective was not assessed.

It is clear that these findings provide no evidence concerning their possible role in the development of schizophrenic perception and thinking, or whether deficiencies in these cognitive skills antedate or post-date the incidence of the diagnosed condition. Without further careful investigations it is also not possible to exclude the possibility that the obtained deficits are the result of faulty verbalization, idiosyncratic interpretation of the task instructions or temporary psychotic pre-occupation. Close observation of the subjects, however, suggests that these explanations are less plausible than the conclusion that the patient sample had real difficulties with the tasks, and that their performance indicates deficiencies in

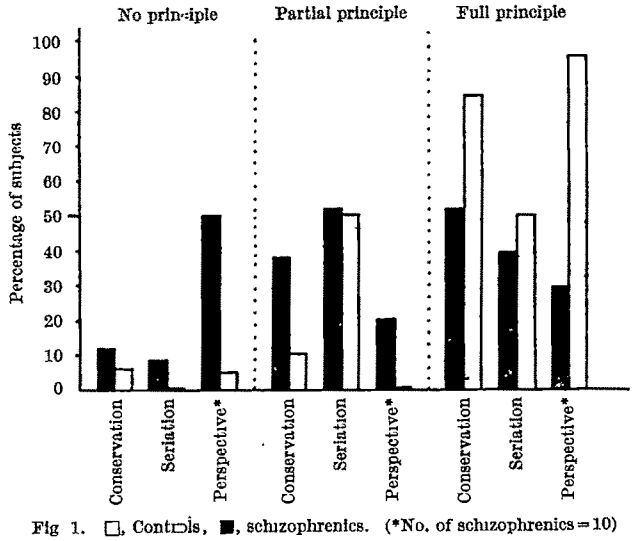

Fig 1. □, Controls, ■, schizophrenics. (*No. of schizophrenics = 10)

primitive reasoning and perceptual skills the intactness of which is usually considered an essential pre-requisite for higher level adult cognitive capacities. Given the presence of such deficits and their exacerbation with more severe psychological abnormality, their relationship to all kinds of aspects of schizophrenic behaviour will have to be more extensively investigated.

Contrary to the impression conveyed by Huxley *et al.*[1], it is not at all easy to make a psychological differential diagnosis between neurosis, psychosis and normality, partly for reasons given earlier and partly because the development of experiment-derived psychological tests and techniques of sufficient sensitivity, reliability, validity and relevance has been seriously retarded. One of the main reasons for this has been the lack of research funds in sufficient amounts and of sufficient duration to attract the experienced investigator most likely to make a breakthrough contribution. In parenthesis it might be added that the references cited in this connexion by Huxley *et al.* do not appear to exist or are irrelevant to this point.

Two further matters raised in the article by Huxley *et al.* seem to deserve some comment. First, the somewhat uncritical acceptance of some evidence suggesting that future schizophrenics may be differentiated from their sibs at a relatively early age, differences which could not be associated with environmental influences or early trauma. It is perhaps worth noting that the article cited to support this contention has a clinical/subjective bias, is retrospective and not in any way based on scientifically acceptable evidence. The only acceptable evidence would be of the kind that could emerge from fairly continuous longitudinal studies with closely controlled techniques of a sufficiently large sample of children which would eventually contain a large enough sample of schizophrenics about whose developmental antecedents meaningful conclusions could be drawn.

A final point may be made concerning the thinking characteristics of the parents of schizophrenic patients which is indirectly referred to by Huxley *et al.* Experiments by McConaghy[16] and by Lidz[17] have tended to show that on a so-called object sorting test, the scores of the parents of schizophrenics were closer to the scores frequently obtained from schizophrenics than the scores of parents who had no schizophrenic offsprings. It is implicit in the article by Huxley *et al.* that they accept this as evidence of the genetic transmission of schizophrenia (as does McConaghy himself) because it supports their hypothesis of "schizoproneness" or undeveloped schizophrenic predispositions which have become openly expressed only as the result of the low penetrance of a dominant gene in their offsprings. While this kind of evidence is necessary for a genetic theory of schizophrenia, it is by no means sufficient. None of the experiments has succeeded in controlling the environmental component which through intellectual, social or occupational learning might yield forms of conceptual thinking which are sufficiently infrequent to be comparable with the performances of schizophrenics on this kind of test. Moreover, anxiety is known to affect the efficiency of conceptual thinking, so that when comparing samples of parents with or without schizophrenic offsprings, the anxious involvement of the former is likely to affect their performance perhaps in the direction obtained. Quite apart from these possibilities, however, the presence of rare, unusual or intellectually less efficient forms of thinking in the parents of schizophrenics may be of very great importance for the development of later-appearing forms of thinking in their children which society classifies as being schizophrenic. As the result of imitation or other forms of social learning, inappropriate and irrational forms of thinking may be established in successive generations with a similar degree of predictability as would apply to the transmission of, say, racial or class prejudice. These forms of thinking would in turn affect the degree of veridicality with which such an individual will perceive his environment, with the result that perception that is class-, group- or family-specific will develop. Under these conditions, the development of progressively more logical modes of thinking may also be inhibited, and thus intellectual parentogenic influences might conceivably result in the kinds of deficits in primitive cognitive skills which have been described here. This, however, is most likely to happen only under conditions in which a child feels parent-bound by excessive demands for parent-dependence and obedience, and where, through non-compliance, the child may feel over-exposed to real or implied threats of punishment. The anticipatory sensitivity of schizophrenics to punishment has been experimentally demonstrated by Rodnick and Garmezy[4], who also describe the results of experiments on the possible effects on the development of schizophrenia of an over-protective mother whose punitive control of her child is only partially hidden by her overt expressions of love and affection. In other words, systems of communication between parents and children could develop from which the child would have the greatest difficulty in extracting a veridical and unequivocal message to which a response is required. This situation is likely to be fraught with considerable anxiety for the child because the presence of meta-messages, or "meta-meta-messages", as they have been called[18], is likely to hinder the development of certainty with respect to stimulus or response or both. In this "double-bind" situation, as it has been termed by its authors, patterns of cognitive as well as emotional responses considered as normal and appropriate by society are thus less likely to develop, either because a set of stimuli to this child does not mean what it means to the vast majority of his peers, or because interaction with other individuals becomes so stressful because of the absence of certainty and predictability that he will attempt to remove himself from the influence of such an environment. This isolation is likely to increase the degree of subjectivity in the individual's thinking and perception; it will reduce opportunities for feed-back and self-correction so that primitive processes develop less readily into more complex and rational ones, and a basis for adult processes which by their irrationality are considered abnormal will have been laid. A child's statement that he is afraid that the Moon might enter his bedroom at night and hurt him reflects the present developmental state of his reasoning ability. An adult's statement that lunar forces are injurious to him and are determining his behaviour towards others, and who habitually proceeds to act on this statement, may be indicative of schizophrenia and an impairment of average logic. It has been the purpose of the investigation reported here to show that a variety of behavioural deficits classified as schizophrenia by virtue of their irrationality and illogicality may be found in conjunction with impaired pre-logical cognitive skills which are normally established adequately in pre-adolescent children.

I thank Miss B. Bambridge for carrying out parts of the experimental work.

LETTERS TO THE EDITOR

ASTRONOMY

Solar Eclipse of May 20, 1966, observed by the *Solrad* 8 Satellite in X-ray and Ultra-violet Bands

THE solar eclipse of May 20, 1966, was observed by the U.S. Naval Research Laboratory's 1965 93 *A* satellite and telemetered at Arcetri. This observation, so far as we know, is the first one performed by an orbiting device.

The photocells mounted aboard the satellite operated in the bands 0·5–3, 1–8, 8–16, 1080–1350 and 1225–1350 Å (further information on the satellite and its measuring system is given elsewhere[1]).

Fig. 1 shows: (*a*) the projection of the orbit of the satellite from 10h 06m 30s U.T. to 10h 15m 00s U.T. on May 20; (*b*) the projection of the umbral and penumbral cone of the Moon at 10h 10m 00s U.T. It can be seen that during these few minutes the orbit of the satellite crossed only the penumbral zone and therefore the photocells carried by the satellite observed a partial eclipse. This fact is confirmed by the telemetered signals which are graphically shown in Fig. 2 (the abscissae are the times of observation and the ordinates the solar flux in arbitrary units of three photocells). The behaviour of the signal

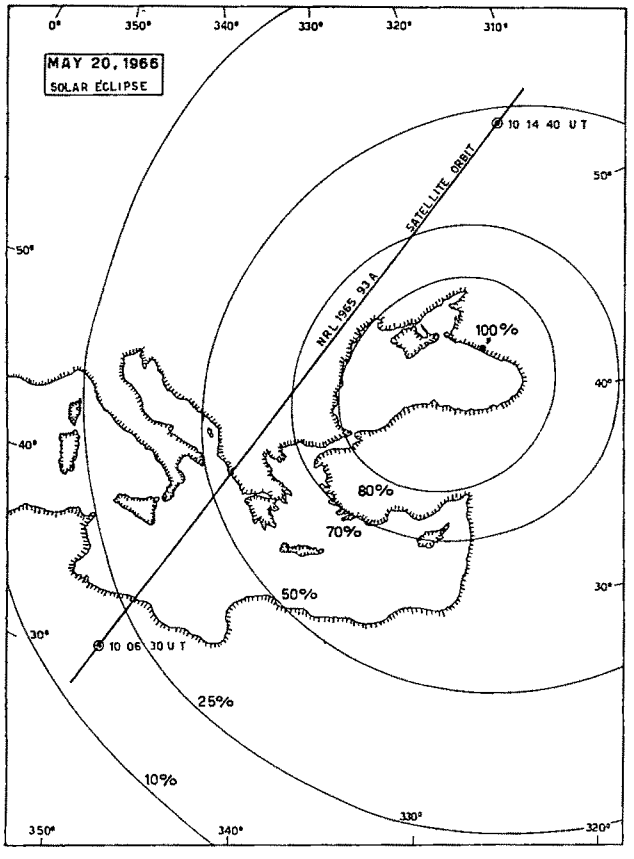

Fig. 1. Map of Eastern Europe showing the satellite orbit during the maximum phase of the solar eclipse of May 20, 1966. The circles labelled with percentages give an approximate picture of the various fractions of the occulted solar disk at the altitude of the satellite at 10 10 U.T.

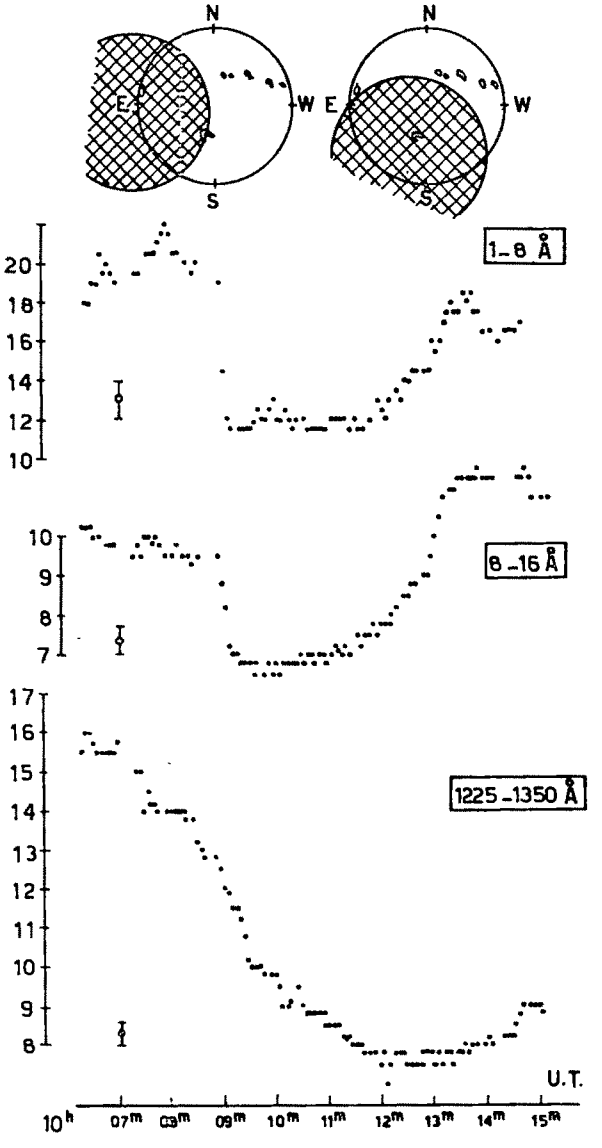

Fig. 2 Solar eclipse of May 20, 1966, observed in some X-ray and ultra-violet bands. The variations of signal (arbitrary units) for the bands 1–8, 8–16 and 1225–1350 Å are plotted against the time between 10 07 and 10.15 U.T. The symbol Φ indicates the reading error for each plot. At the top of the figure the Moon–Sun reciprocal positions, as viewed from the satellite, are shown for the time 10.09 U.T. (occultation of the central source) and 10.13 U T. (appearance of the eastern limb source), respectively

occultation for the ultra-violet band is very different from that for the X-ray band.

The difference is mainly concerned with the time of the minimum, the value of the minimum and the shape of the decreasing phase of the signal. Such behaviour can be interpreted by assuming the presence of active regions on the solar disk: these would contribute in a different way to the emission of the X-radiation and ultra-violet radiation. On May 20 there were three main sources on the disk. One remained uncovered during the whole eclipse. At the beginning of the observation the east limb source

was already occulted. It can be seen from the maps at the top of Fig. 2 that the occultation of the central active region occurred at about 10h 09m U.T.; at the same time the X-ray flux dropped abruptly. The occultation of the central source was complete within about 13 sec for the 8–16 Å band and within 9 sec for the 1–8 Å band: these values correspond to angular dimensions of 50″ and 35″, respectively. The spatial resolution along the direction of the lunar motion was 15″ of arc, which is lower than the best resolution so far obtained for pictures of the Sun in the X-ray and ultra-violet regions[2].

At about 10h 13m U.T. the source on the east limb was uncovered and the X-ray flux increased again. The ultra-violet radiation does not show any sharp variation, which indicates that the emission of ultra-violet light by the Sun is far less dependent on the localized sources.

A more detailed investigation is being carried out and will be reported later.

Umbra Intensity of a Large Sunspot

OBSERVATIONS of the relative umbra intensity as function of the position of sunspots on the solar disk can provide information concerning the temperature distribution within the sunspots. Unfortunately, earlier workers in this field usually combined observations of different spots at several positions on the solar disk. As the umbra intensity can change considerably from one spot to another it is possible that serious errors may have been introduced. Therefore observations of the same spot on several days during its passage across the solar disk are likely to give data which are more reliable.

The large sunspot (umbra area about 150×10^{-6} solar hemisphere) which was visible during March 15–27, 1966, was observed in several positions on the solar disk at the Solar Observatory, Harestua. Intensity profiles of the spot were obtained by a pinhole photometer in three wave-length regions. The instrument used consists of a metal screen with three pinhole apertures. Just behind each hole is placed the following combination of filters (Schott u. Genossen) and detectors (Siemens):

Filter	*BG*18/2	*RG*8/2	Silicon-window
Detector	Silicon	Silicon	Germanium
Half-width	200 Å	300 Å	1400 Å
Effective wave-length	5300 Å	8800 Å	13,000 Å

The detected signals are amplified in three transistor amplifiers connected to Sanborn high-speed recorders. The image of the Sun (27·25 cm in diameter) is focused on to the screen and the scan performed by stopping the coelo-stat driving mechanism, thus causing the image to drift across the screen at a speed of 15 sec of arc per sec. Each time the spot passes the pinholes a picture is taken by a camera placed in front of the screen (slightly off-axis) and simultaneously a marker pen on the recorder indicates the time. This makes it easy to compare individual scans and to make isophote maps of the spot. After each registration, the instrument is calibrated by a step filter in front of the pinhole apertures. Possible drifts in the amplifiers are checked by blocking the holes at regular intervals. The theoretical angular resolution is set by the dimensions of the pinholes and is 1, 1.75 and 2.4 sec of arc at wave-lengths λ_{eff} 5300 Å, λ_{eff} 8800 Å and λ_{eff} 13,000 Å, respectively.

Intensity profiles of the spot were obtained on 10 days during the passage of the spot across the solar disk. On two days the observations were seriously hampered by haze and these registrations are not included. The centre-to-limb variation of the ratio $\varphi_\lambda = I_u(\lambda)/I_{ph}(\lambda)$, where I_u is the umbra intensity and I_{ph} the intensity of the photosphere, is shown in Fig. 1. The variation with position angle is pronounced on all wave-lengths, but is greatest in the blue region where $\varphi_{5300\text{Å}} = 0{\cdot}10$ at $\theta = 29°$ and $= 0{\cdot}30$ at $\theta = 80°$ (θ denotes the heliocentric angle). A comparison of the observations in the eastern and the western hemispheres reveals that the umbra intensity is constant with time; however, the spot showed certain changes in topology during the period. The scatter of individual scans through the central parts of the umbra is small. The lowest values are plotted in Fig. 1.

The scatter in previous observations of the ratio $\varphi_\lambda(\theta)$ is so great that it is difficult to be certain of the true mean centre-to-limb variation. It is often assumed that the entire variation is due to the increasing influence of scattered light toward the solar limb, and this may be the case for smaller spots.

Because the present spot is so large, the scattered light has minor influence. As seen from the tracings in Fig. 2, the umbra intensity profiles are remarkably flat even for spot positions close to the solar limb, thus indicating that possible corrections for scattered light must be insignificant. This is evident (especially in the near- and infra-red regions) from the intensity profiles at $\theta = 75°$, where the scan direction is perpendicular to the solar limb so the gradients in the spot profiles can easily be compared with the limb gradients. Corrections for scattered light can also be neglected for the observations at $\theta = 29°$.

One of the controversial questions about present sunspot models is concerned with the transparency of the umbra. Michard[1] used the observed centre-to-limb variation of $\varphi_\lambda(\theta)$ in order to determine a temperature distribution. From the equivalent widths of certain iron and titanium lines he found the electron pressure and obtained a transparent umbra model ($\tau = 1{\cdot}0$ at 2,000 km depth). Mattig[2], using the same temperature distribution, but assuming hydrostatic equilibrium in deriving the electron pressure, obtained a less transparent model with nearly the same transparency as the photosphere. Makita and Morimoto[3] also determined a temperature

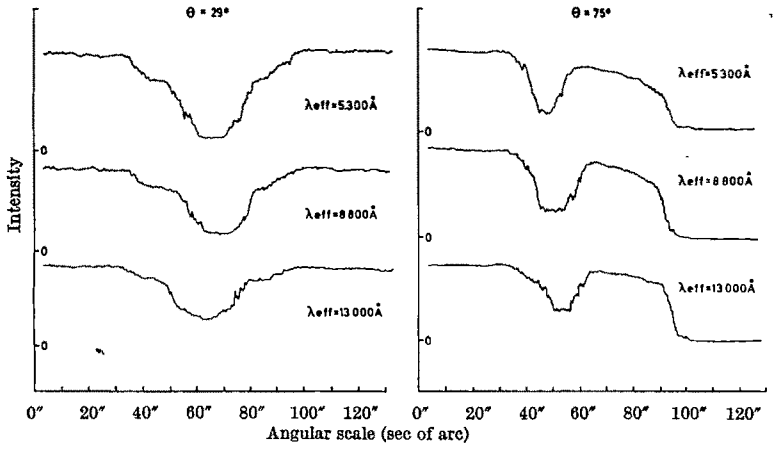

Fig. 2. Recorder-tracings showing the intensity profiles at two positions on the solar disk. The intensity scale is linear and the zeros indicate the dark level

distribution from the observed $\varphi_\lambda(\theta)$-curves at three wave-lengths. Several precautions were taken (in their observations) to avoid scattered light. They obtained a temperature distribution considerably below Michard's for spots of nearly identical size (mean umbra area in Michard's and Makita and Morimoto's measurements is 80×10^{-6} and 70×10^{-6} solar hemisphere, respectively). The difference increases with increasing optical depth and amounts to over 700° K at $\tau = 2{\cdot}0$. As was pointed out by Makita and Morimoto, the reduced temperature would solve the discrepancy in Michard's and Mattig's models if the lower temperature was used in the derivation of the electron pressure assuming hydrostatic equilibrium.

Previous observational data concerning the θ-dependence of I_u/I_{ph} consist of measurements of a number of spots at various heliocentric angles, while the present observations are for the same—rather stable—spot during its passage across the solar disk. Thus the latter should yield a more reliable temperature distribution than the earlier ones, mainly because the uncertainty due to the intrinsic scatter of umbra intensities is eliminated.

I have compared my observations at $\lambda_{eff} = 5300$ Å with Michard's and Makita and Morimoto's at λ 5452 Å and λ 5451 Å, respectively. The present observations fit well the measurements of Makita and Morimoto (toward the disk centre these give about half the values of Michard's intensity). Because the present spot is much larger than the mean spot in Michard's observations, the deviation could arise from a size-dependence of umbra temperatures. However, as the agreement with Makita and Morimoto's observations is very good, it is more likely that the deviations are caused by the different influence of scattered light, and of the intrinsic scatter of individual umbra intensities in the earlier measurements.

Infra-red Stars

MUCH interest has been aroused by the discovery of stars which radiate most of their energy at wave-lengths of several microns[1].

It has been suggested that these are newly formed stars in the process of gravitational contraction to the main sequence, but the time scale of the contraction is so short that the objects should be much less numerous than they are, unless contraction is slowed down as a result of the proto-star experiencing difficulty in getting rid of its angular momentum[2].

Multi-colour photometry has shown that all the infra-red stars appear to be heavily reddened by interstellar dust clouds, and that the spectral types of the stars themselves fall into two widely separated groups, intrinsically hot early-type stars, such as Cygnus II No. 12, and cool late *M* stars[3–6].

Measurements of the obscuration by interstellar dust of young hot stars in stellar associations have shown that in some associations the obscuration is highest for the most luminous stars[7,8]. Recent observations of the Cygnus II association[9] have provided a striking example of a strong correlation between luminosity and obscuration for some 400 *OB* stars, leading to the conclusion that the individual stars are still surrounded by parts of the clouds of dust and gas out of which they formed, and that these clouds have diameters of not more than a few tenths of a parsec each, with masses about equal to the masses of the stars embedded in them. One of the brightest and most heavily dust-reddened of these stars is Cygnus II No. 12.

No substantial HII radiation is observed from the Cygnus II association; it is not known whether this is because of high obscuration, very high cloud densities, a lack of hydrogen with the dust in the clouds, or extreme youth. It is significant that the association is at a minimum in the thermal radio emission from the region[10], indicating that the absence of visible Hα radiation is not the result of high obscuration by interstellar dust.

The hot *OB* stars will heat up the clouds in which they are embedded, from ~100° K to several thousand °K. Two questions arise: Will the dust be evaporated, and how far will the clouds expand?

The chemical composition of the dust is still uncertain; present observations are best accounted for by the theory of graphite grains[11], which have an evaporation temperature ~2,400° K. The kinetic temperatures in HII regions vary widely[12] and may well be as low as this in parts under extreme conditions. On the other hand, the presence of large quantities of interstellar dust embedded in large, bright, well-developed HII regions, such as in the clusters *NGC* 6611 and *IC* 5146, indicates that it is not easily evaporated and the evaporation temperature may be considerably higher than 2,400° K. In addition, there is the possibility that dust is formed in the denser regions behind shock fronts as the HII regions expand.

The extent of the expansion may be limited by the elasticity of the surrounding interstellar medium. Evidence of non-gravitational forces acting on the interstellar gas[13,14] suggests the existence of substantial pressures, possibly produced by strong magnetic fields, in regions of very low gas density outside the clouds. Thus the heated clouds surrounding *OB* stars may be contained by the surrounding medium.

The lifetimes of these *OB* stars are very short, probably much shorter than current predictions now that the theory of evolution by mass loss has received support from the discovery of strong emission lines in ultra-violet spectra of early-type stars obtained from rocket flights[15]. After not more than a million, and perhaps only a few hundred thousand, years the *O* stars will evolve into *M* supergiants. This evolution occurs relatively quickly. The sharp reduction in the temperatures of the stars in the expanded clouds will result in de-ionization and cooling of the gas. The gas pressure will fall and the clouds will be re-compressed around the stars by the surrounding medium in a time probably comparable with that in which the original expansion occurred. Thus the *M* star will become surrounded by an obscuring cloud and will suffer considerable interstellar reddening.

It is therefore proposed that the infra-red M stars have evolved from O stars surrounded by the remnants of the interstellar clouds out of which they formed. If this is so, two predictions can be made: the spatial and velocity distributions of the infra-red M stars should be similar to that of the O stars, and they should be highly luminous supergiants.

If these objects occur in expanding associations, their distances from the centres of the associations should be rather larger than those of the O stars on account of their slightly greater ages; on the other hand, if they are contracting stars they will be younger than the O stars and should be nearer the centres; this may be used as a criterion for deciding between the alternative theories of contracting stars and evolved stars.

PLANETARY SCIENCE

Implications of the Revised Mars Radius

Kliore, Cain and Levy[1], in an analysis of the trajectory of the *Mariner* IV vehicle across Mars in July 1965, have presented revised values for the radius of Mars. For the radii measured from the centre of mass, they give 3,384 ± 3 km at the entrance occultation (50·5° S. lat.) and 3,379 ± 4 km at the exit (60° N. lat.). These figures formally yield 3,392 km for the mean radius R, but give a rather greater value for the ellipticity of figure ε than the usual value (near 1/192) inferred from dynamical observations. If the usual value of ε is used the yielded value of R is nearer 3,388 km. If one accepts the authors' estimates of the observational uncertainties, it would therefore appear safe to assume that the observations yield 3,390 ± 6 km.

This result is a substantial increase from earlier estimates over the past 10–15 years, and has interesting implications on the internal structure of Mars. In 1949, I formally arrived[2], on certain assumptions, at an estimate of 3,391 km for R. Later, the observational evidence appeared to favour a value of order 3,330 km (see, for example, ref. 3), and this was used as a principal argument by many authors for rejecting one or more of the assumptions made in 1949. The return to 3,390 km, in removing this objection, means that the assumptions can now be rejected only on other grounds.

The assumptions are, essentially, that (*a*) Mars has the same overall composition as the Earth model B (ref. 4); (*b*) the changes at the Earth's mantle-core boundary are associated with change of phase rather than with change of chemical composition, in line with the postulate of Ramsey[6] and myself[8].

As regards (*a*), the crucial property of model B in this context is the comparatively high density reached fairly high up in the mantle, as compared with most Earth models. Some difficulties have arisen in sustaining this high density, but the question is by no means closed. Recent work by Lyttleton[7] takes, in effect, a slight variant of (*a*) (see ref. 8).

I am under no misapprehension as to the difficulties associated with (*b*), which involves a phase change at a pressure of 1·3 million atmospheres, accompanied by a density jump in a ratio of the order of 1·7. But again the matter is not closed, and several writers, including Lyttleton[9], continue to follow the phase-change postulate. Al'tshuler and Kormer[10] point out that an argument from shock waves (see ref. 11) that has been used to refute the postulate is not conclusive.

An essential point in the revised Mars radius is that it does shift the probabilities somewhat on the matters mentioned, and carries with it the need for a measure of re-assessment of previous theories and models.

The revision, if sustained, is also valuable in enabling theories on the internal constitution of Mars to be somewhat narrowed. For example, it removes the necessity for considering Mars models of the type constructed by me in 1957[3], and it rules out the type of structure examined by Kovach and Anderson[12]. These authors had shown the feasibility of an overall common composition for Mars and the Earth without the need for resorting to the phase-change postulate, but subject to the proviso that R does not much exceed 3,310 km. The new Mars radius would also entail some revision of calculations by Urey[13].

It may be added that the *Mariner* IV observations also yield a slightly reduced value for the mass M of Mars. The revisions of R and M thus both act in the direction of reducing the estimated mean density of Mars and are of interest in relation to curves for planetary models connecting masses and mean densities (see, for example, ref. 14).

I thank Dr. E. A. Gaugler of the National Aeronautics and Space Administration, Washington, and Mr. D. L. Cain of the Jet Propulsion Laboratory, Pasadena, for kindly amplifying the *Mariner* IV results to me in personal communications.

Atmospheric Pressure Wave from an Explosion

PRESSURE waves were obtained from one of two explosions set off at White Sands Missile Range (33° 27′ N., 106° 34′ W.; elevation 4,900 ft. above mean sea-level), New Mexico. The first explosion occurred at 1100 p.m. M.S.T., October 28, 1965, and the second at 1100 a.m. M.S.T., November 2, 1965. These explosions were identical shots of 10 tons of TNT. Pressure waves from the first explosion

were recorded at the Socorro Campus of the New Mexico Institute of Mining and Technology (34° 4′ N., 106° 54′ W.; elevation 4,617 ft. above mean sea-level) and at the Institute's Irving Langmuir Mountain Laboratory (33° 59′ N., 107° 11′ W.; elevation 10,630 ft. above mean sea-level). No pressure waves were recorded from the second event.

At Socorro, the pressure disturbance was recorded with two hot-wire pressure transducers and also with three seismographs. The seismographs were not compensated for pressure changes and thus were not of much interest to this report. At the Mountain Laboratory, the pressure wave was recorded with a third hot-wire pressure transducer. The hot-wire pressure transducer consisted of two grids in a metal tube connected to a reference volume. The two grids were connected to a bridge circuit which detected differential variations in their resistances. The grids were cooled differentially by the air passing through the transducer into or out of the reference volume. The resistance of the two grids varied as their temperature, and the differential output of the bridge was recorded.

Meteorological soundings obtained from White Sands for the approximate times of the two explosions showed significant differences. The sounding for October 28 showed a ground-level temperature inversion with a height of 300 ft. At this time the ground temperature was 10° C and the temperature at the top of the inversion was 21° C. The sounding for November 2 gave no indication of such an inversion. No surface wind was reported on October 28. A north-east surface wind of 4·1 knots was reported on November 2.

Fig. 1 shows the pressure wave as recorded at Socorro and at the Langmuir Laboratory. The wind speed at both locations was very small. Both records continue for about 40 sec with small fluctuations. The Mountain Laboratory record shows a marked change in character after the third overpressure peak when compared with the Socorro record. The maximum overpressure at Socorro is 82 μbars and at the Langmuir Laboratory 11 μbars. The distance from the explosion site to Socorro and Mountain Laboratory is 47·5 and 50·5 miles, respectively. The difference in observed amplitudes at the two stations can be explained by considering the propagation inside and outside the temperature inversion layer. Within the layer the energy decays as the inverse of the distance. Outside the layer the energy falls off as the inverse square of the distance. Coupled with these considerations, if Snell's law is taken into consideration the calculated ratio of amplitudes turns out to be about twice the observed value. This is understandable, as the effects of wind and the leakage of energy at the boundary layer are neglected. It is anticipated that, if these two factors are properly considered, the calculated value should equal the observed one. The unfavourable wind at the explosion site and the absence of a temperature inversion were probably responsible for the failure to record the wave on November 2.

Fig. 2 shows the observed dispersion for the two records of Fig. 1, by the method of Ewing and Press[1]. The slopes of the linear portions are 14·4 ft./sec² and 13·0 ft./sec² for Socorro and Mountain respectively. The variation in group velocity for these pressure waves is from 1,134 ft./sec to 1,106 ft./sec. The signal velocity or group velocity of the first overpressure peak can be interpreted because of an average temperature over the travel path. For Socorro the signal velocity is 1,142 ft./sec which corresponds to a temperature of 27° C. For Mountain the signal velocity is 1,130 ft./sec which corresponds to 20° C.

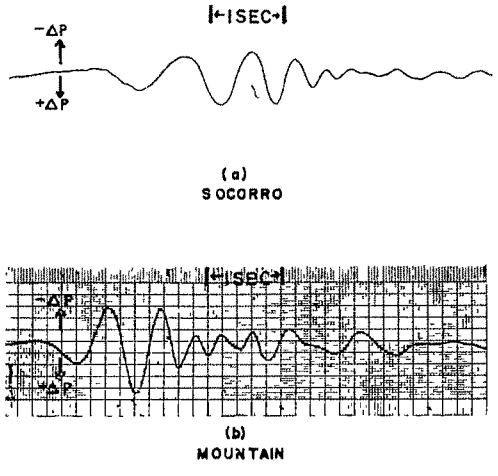

Fig. 1. Atmospheric pressure waves from a 10-ton TNT explosion

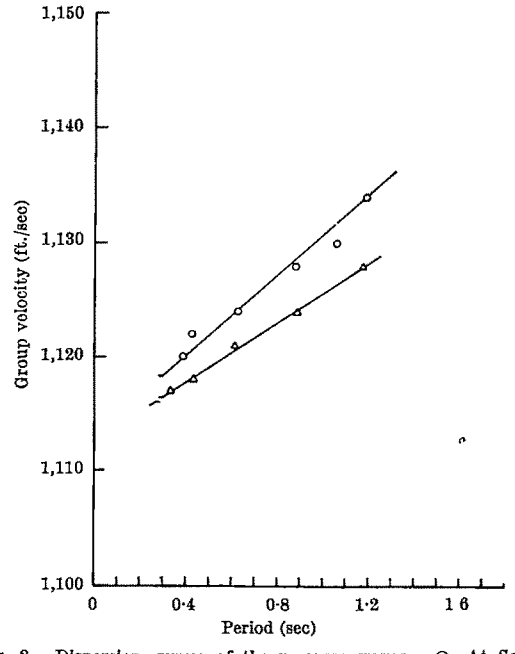

Fig 2. Dispersion curves of the pressure waves. ○, At Socorro, △, at Mountain

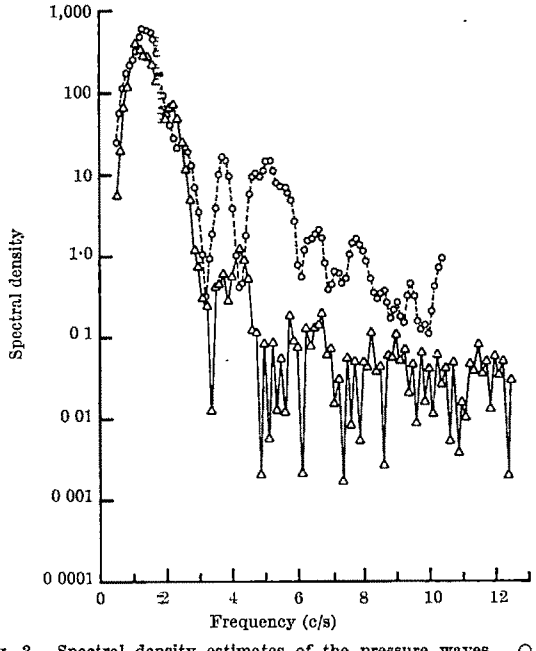

Fig. 3. Spectral density estimates of the pressure waves. ○, At Socorro, △, at Mountain

Fig. 3 shows the results of a power spectral analysis of the records shown in Fig. 1. Forty seconds of each record were digitized and the spectral density was computed on an IBM-1620 computer. The computational procedure has been described by Blackman and Tukey[2]. The Nyguist frequency is taken to be 10·4 c/s for the Socorro record and 12·5 c/s for the Mountain record. For Socorro, the maximum energy is found at 1·35 c/s with smaller maxima at 3·74 and 5·20 c/s. For the Mountain Laboratory, the maximum energy is at 1·13 c/s with a smaller maximum at 4·25 c/s.

Noctilucent Clouds observed in Antarctica

FOGLE[1] recently directed attention to the paucity of observations of noctilucent clouds in the southern hemisphere; in fact he was able to cite only three observations of doubtful reliability and concluded that "the question of whether noctilucent clouds do occur in the southern hemisphere is still an open one". However, he himself has since answered this question with observations and photographs of a display over Punta Arenas[2].

We kept a watch at the Australian National Antarctic Research Expedition's station, Mawson (67·6° S., 62·9° E.), on every evening and morning in the periods October 19–November 6, 1964, and February 4–February 23, 1965, while the solar depression angle was greater than 6°. Noctilucent clouds were observed on three occasions.

On October 30, 1964, from 1900 U.T. to 1930 U.T. the display consisted of two moderately bright bands to the south-west. On February 8, 1965, the display lasted from the commencement of observations at 1830 U.T. until 2030 U.T. It consisted initially of bands of moderate brightness developing into bright bands and waves, then waning over a period of an hour as bands and veil. The display extended from azimuth 152° to 193° east of north between elevations 7·4° and 25·2°; colour photographs were obtained. On February 12, 1965, between 2030 U.T. and 2115 U.T., veil and moderately bright bands were observed and photographed to the south-east.

Towards the end of the display of February 8, extremely thin, bright filaments, not visible to the naked eye, were observed through a theodolite telescope of × 6 magnification. This structure is probably similar to that reported by Paton[3].

Ancient Continental Configurations

DR. K. M. CREER's attempt[1] to superimpose the palaeomagnetically derived polar wandering paths of the various continents is a promising new method which may eventually help to solve the problem of the former continental configurations. At present, however, many of the palaeomagnetic results are still too doubtful, as Van Hilten[2] pointed out, to eliminate the guess-work in the construction of the paths of polar wanderings. Van Hilten's acceptance of Creer's paths of polar wanderings for Africa and South America makes it desirable to point out some of the uncertainties and discrepancies contained in Creer's data:

(1) *The Silurian pole.* Neither the Silurian age of the Urucum beds nor that of the Table Mountain Series has been proved by fossils. The Silurian pole, as derived from the Urucum beds, seems to lie too far from the thick glacial deposits of the Silurian Zapla beds[3] to fit the geological evidence.

(2) *The Devonian pole.* The reconstruction shows the Devonian pole situated on northern Africa. Such a position is contradicted by the extensive development of Devonian coral reefs in West Africa[4]. The only well-documented Palaeozoic glacial deposit in northern Africa is of Ordovician age[5]. This discrepancy between the geological facts and the palaeomagnetic measurements casts doubt on the age of the magnetization of the South American Devonian red-beds as used by Creer. The fact that Devonian glacial deposits have been reported from Argentina[6] and from Brazil[7,8], though the evidence is perhaps not completely conclusive, strengthens this suspicion. No evidence for a Devonian pole has as yet been derived from African rocks.

(3) *The Pennsylvanian pole.* The pole position used for the reconstruction of the polar wandering path would harmonize with the geological observations, but the palaeomagnetic data cannot be regarded as reliable according to Irving's list of palaeomagnetic pole positions[9].

The conclusion seems unavoidable that the polar wandering paths of Africa and South America have not yet been satisfactorily established. In Africa the almost complete Palaeozoic succession, which exists in northern Africa, should offer opportunities for the much-needed additional palaeomagnetic studies.

Nomenclature of the Keuper–Lias Facies of the Bristol Channel Region

WHILE working on the Keuper, Rhaetic and Lower Lias strata of the Cowbridge district in the Vale of Glamorgan, which are typical of those of the Bristol Channel region, it was felt that the terms in present use for the two main facies developed in these strata were inadequate. Some of the terms previously used are misleading and may suggest palaeoecological or palaeogeographical relationships which may not exist.

Buckland and Conybeare[1] considered the Dolomitic Conglomerate of the Keuper to represent screes accumulated on the sides of steep hills. This may be so for part of the Dolomitic Conglomerate, but it does not account for the majority of occurrences which are horizontally bedded. This interpretation does not agree with the evidence from the Rhaetic and the Lias.

De la Beche[2] attributed a beach origin to the same conglomerate. Although ahead of his time, his conception is not supported by evidence from these rocks which indicates accumulation under continental, and possibly sub-aerial, conditions.

The term 'abnormal deposits' was introduced by Moore[3] when referring to the coarse-grained facies. He used 'normal deposits' for the fine-grained facies. Both

terms have much to recommend them since neither qualifies genesis or palaeogeography. However, they do suggest a relative state of 'normality' which is impossible to assess.

Strahan and Cantrill[4,5] used the terms 'littoral' and 'normal' deposits. The former conveys a palaeoecological concept which is difficult to prove for the Rhaetic and Lias and which is definitely out of place for the continental Keuper. The latter fails on the same count as does Moore's 'normal'.

'Near-shore' and 'off-shore' facies have been introduced more recently[6]. These terms suggest a palaeogeographical relationship which cannot be proved at all times. So-called 'near-shore' facies may develop around an inlying mass of older strata projecting above the depositional interface but not necessarily projecting above the surface of the body of water in which deposition occurred.

Because the inferences of the terms mentioned here cannot be verified, are ambiguous or are misleading, new terms must be introduced. Terms conveying purely geometrical relationships must be considered. These terms should best be defined in relation to the distribution of the facies on one depositional interface. Two possible terms are: peripheral and periphractic for the coarse- and fine-grained facies, respectively. These terms are cumbersome and almost homophones and therefore do not seem practical. 'Proximal' and 'distal' are more familiar and like peripheral and periphractic do not have any palaeoecological or palaeogeographical connotations.

'Proximal' facies have accumulated along the periphery of one depositional interface and are closely associated with masses of older rock projecting above the interface immaterial as to whether these masses occur as submerged reefs or land. The sediments in this facies are on the whole coarse-grained, often containing much rudaceous material. 'Distal' facies are those general to the parts of the same depositional interface at some distance from the margins of the interface. This facies is generally fine-grained.

Regarding the two main facies of the Keuper to Lias strata of the Bristol Channel region, I should like to propose that the term 'proximal' be used for the generally coarse-grained facies which has developed close to the masses of older rock projecting above the depositional interface, and 'distal' for the generally fine-grained facies which has developed at a distance from these masses.

Part of this work was done while I was in the Department of Geology, University College, Cardiff, and while I was holding a D.S.I.R. research scholarship.

Origin of Pillow Structure in Lavas

SINCE pillow structures were first observed, their origin has been controversial and diverse suggestions have been put forward (for excellent summaries see refs. 1 and 2). Despite a number of fairly recent papers favouring a sub-aerial origin, the consensus of opinion falls heavily on an aqueous environment for pillow formation. This conclusion is based mainly on field association, and also on the idea that the pillows are akin to emulsions, with the magma dispersed in the aqueous phase[1,3,4]. Fuller[3], and Snyder and Fraser[4], briefly mention the role of surface tension. Fuller suggests that "As in all emulsions, the dispersal of the fluid with the higher surface tension may have been attained either by the agitation of the two phases or by its entry as detached units". Snyder and Fraser, however, suggested that "some force akin to surface tension is instrumental in the formation of the Unalaskan pillows".

I suggest that the two major factors in the formation of pillows are: (i) the surface tension of the molten magma; (ii) the density of the medium in which the pillows develop.

When lava erupts into any medium, it will tend to reduce its surface area to a minimum, that is, form spheres. If the density of the magma equalled that of the medium, a sphere would form and grow indefinitely, provided magma continued to be supplied. As it grew, the force required to enlarge the sphere (P) would decrease, because $P = 2\gamma/r$, where γ = surface tension and r = radius of the sphere. However, where the density contrast between medium and magma is great, gravitational forces would prevent growth of a sphere and cause the magma to spread out as a sheet. The surface tension of basaltic magma in air is probably in the region of 300 dynes/cm (ref. 5) and this force is insufficient to maintain a sphere in air. However, in water the situation is much more favourable because the density contrast between magma and medium is reduced from, say, 1,500/1 in air to 1·5/1 in water. The contrast is still further reduced if the magma enters unconsolidated mud or tuff. The fact that many of the best developed pillows have formed in muds and unconsolidated water-laden tuffs supports this conclusion[4,6]. It is likely that most of these pillows are essentially intrusive in that they never reach the main sediment-water interface.

Gravitational forces tend to put an upper limit on the size of stable spheres, depending on the density contrast, and near this limit pillows tend to neck or bud. In some cases, the chilled skin developing on the pillow may retard or prevent further pillow growth, as was pointed out by Rittmann[6]. However, chilled skins may thicken quite slowly if convection in the surrounding poorly-conducting water is inhibited, as it might be in mud or tuff, and it is clear that many pillows and their skins remain at sufficiently low viscosity to undergo considerable plastic deformation due to accumulating overburden. Thus the effect of the chilled skin on growth may often be small.

In conditions of fairly rapid cooling, a high rate of lava emission would presumably favour formation of large pillows.

Several other factors are likely to affect the tendency of a magma to form pillows. For example, a relatively high viscosity would make the surface tension effect negligible, and this, combined with the effect of the high viscosity on the explosiveness of the magmas, is probably why there are only a few examples known of rhyolitic or andesitic pillows.

The size of the orifice through which the magma emerges must also be an important factor, and it seems reasonable that relatively small orifices (for example, cracks on the edges and surface of a flow) will favour pillow development.

A Proposed Correlation between Elastic Strain Rebound Increments and Isostatic Gravity Anomalies

ELASTIC strain rebound increments have been extensively considered by Benioff and others[1–6]. The results of their investigations indicate that strain rebound increments vary from region to region. Their characteristics are

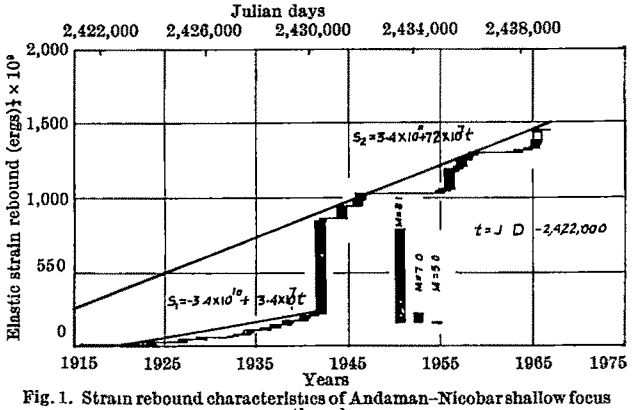

Fig. 1. Strain rebound characteristics of Andaman–Nicobar shallow focus earthquakes

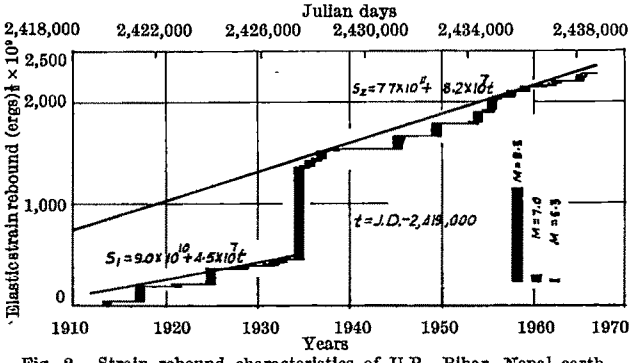

Fig. 2. Strain rebound characteristics of U.P., Bihar, Nepal earthquakes (shallow)

found to be linear and non-linear, tending to asymptotic and irregular. Such elastic strain rebound increments are simply a plot of the cumulative strain factor, $J^{\frac{1}{2}}$, versus time, where J is the seismic wave energy and can be calculated from Gutenberg–Richter's relation[7] as used by Benioff:

$$\text{Log } J = 9{\cdot}0 + 1{\cdot}8M$$

where M is the magnitude of the earthquake.

The elastic strain rebound increments of the Andaman Nicobar[5] and Bihar Nepal[5] regions shown in Figs. 1 and 2 are very similar. Both consist of two linear segments of the $S = A + bt$, where S is the strain rebound increment and where A and B are constants and where t is the time in Julian days. The activities and phases of strain recovery are also similar. The isostatic gravity anomalies given by the Survey of India and by Woollard[8] show that negative gravity anomalies of the order of -40 to -60 mgal prevail in both regions. This correlation is at first surprising, but an investigation of the elastic strain rebound increments has led me to enquire whether other similarities exist in these regions. The earthquakes used in plotting the elastic strain rebound increments are shallow focus shocks and thus the foci of all the earthquakes are located more or less in the crust. For this reason, I feel that some other similarities may exist in these regions.

In this type of correlation the magnitude of the range should be about the same. Other regions which show similar elastic strain rebound increments are Dhubri[5], Kashmir[5] and North Japan[4], where they consist of a single segment of the form $S' = a + b \log t$, where S' is the elastic strain rebound increment, a and b are constants, and t is the time in Julian days. These three regions show identical earthquake activity, and the fact that the rate of strain release decreases with time indicates that creep occurs. Here the isostatic gravity anomalies are of the order of -60 to -80 mgal and thus fit the correlation. It would seem that a definite relation exists between the elastic strain rebound increments and the isostatic gravity anomalies.

Applying this correlation to the Sadiya[5] and Tonga Kermadec[4] regions, where only shallow shocks are used in the construction of elastic strain rebound increments, it is observed that the elastic strain rebounds are of a similar nature and that they are very irregular. If this correlation is valid, it can be said that the isostatic gravity anomalies prevailing in these two areas must be similar in size and sign.

This investigation has for the main been confined to India, but such a correlation can also be established for other regions of the world. I thank Dr. V. K. Gaur for his help and Dr. Jai Krishna, director, School of Research and Training, for providing facilities for this work.

PHYSICS

Modulation of Diffracted Neutrons with a Piezoelectric Crystal

THE production of pulses of neutrons from a reactor beam by means of a rotating scatter is a well-known technique[1]. We have investigated the possibility of using a

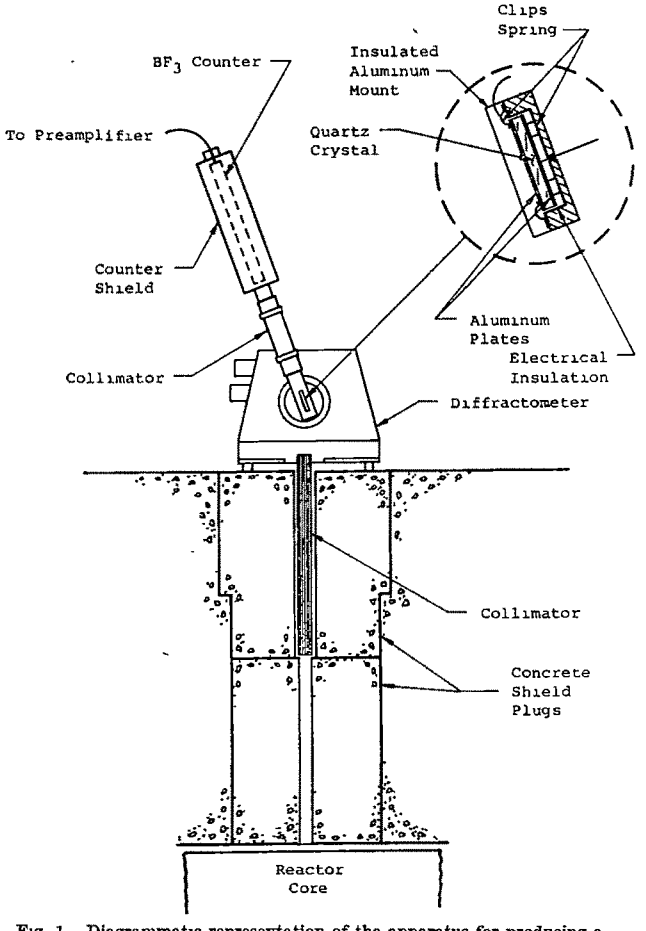

Fig. 1. Diagrammatic representation of the apparatus for producing a modulated neutron beam

quartz piezoelectric crystal as a means of modulating a beam of neutrons. It was believed that in this way it might be possible to obtain a variable frequency pulsed or sine-modulated source of mono-energetic neutrons.

A diagrammatic representation of the apparatus is shown in Fig. 1. An X-cut 500 kc/s quartz crystal 2 in. × 2 in. × 0·25 in. was used. The crystal was mounted in an aluminium holder designed to be used with a diffractometer (Picker Model No. 3527). Care was taken to eliminate all hydrogenous material from the crystal holder. Aluminium plates covered each face of the crystal and the crystal and plates were clamped in the holder with springs.

The oscillator circuit was driven by a signal generator and amplifier. The voltage across the crystal was measured with an oscilloscope which indicated when the crystal was in parallel resonance.

To restrict the divergence of the neutron beam, a Sollar collimator was used in the centre vertical port of the University of Florida Training Reactor. The angular divergence of the collimator was about 13·0 min. A second collimator was used between the crystal and the borontrifluoride detector (Reuter-Stokes model No. *RSN*-1805).

The first results we obtained were rocking curves with the crystal set for a neutron energy of about 0·03 eV; the data are plotted in Fig. 2. Here the rocking curve with the vibrating crystal is much more intense than that for the stationary crystal. The full width at half maximum for both cases is about 0·30 and the maximum counting rates differ by a factor of about two. This ratio was observed to vary directly as the power dissipated in the crystal.

To investigate whether the effect is energy dependent, we next scanned the spectrum of neutrons from the reactor with the crystal and detector fixed to maintain the Bragg condition. The factor of two in intensity between the vibrating and static crystal was essentially constant for all neutron energies.

Finally, we measured the time dependence of the detector output with a fast time analyser. Typical results are shown in Fig. 3; it appears that the neutron beam is modulated at 500 kc/s.

Possible explanations for this effect include: (1) Focusing effect of the quartz crystal when it is vibrating. (2) Change in the effective crystal plane spacing, *d*, which permits a larger 'bandwidth' of neutrons to impinge on the detector. (3) Polarization of the scattering nuclei,

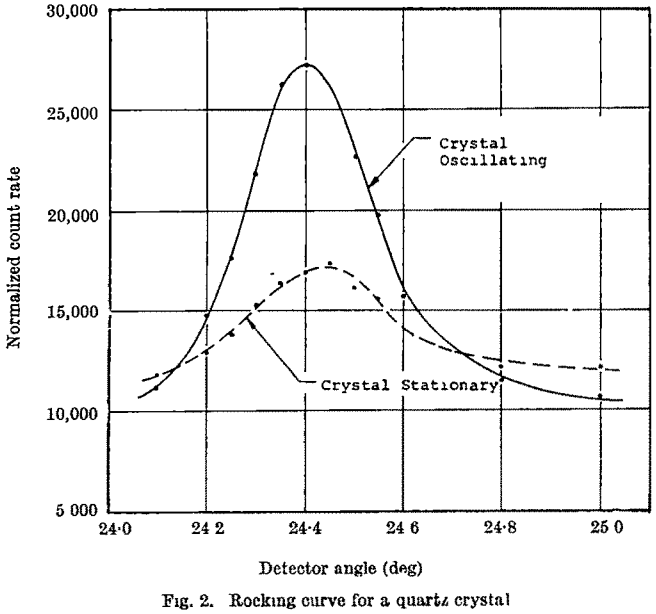

Fig. 2. Rocking curve for a quartz crystal

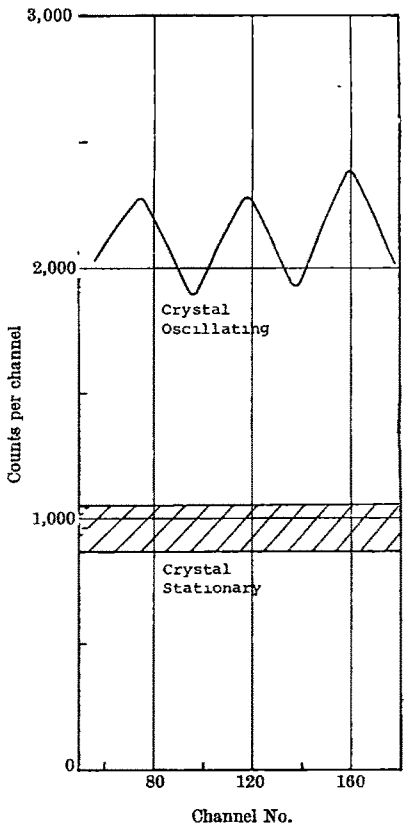

Fig. 3. Time dependence of modulated beam

which decreases the randomness of vibration and enhances the diffracted neutron intensity.

Whatever the explanation for the effect, it seems to offer a unique method for producing modulation of mono-energetic low-energy neutrons.

Photoelastic Behaviour of Sodium Nitrate

Experimental investigations of the photoelastic behaviour of sodium nitrate are of particular interest because the single crystal of sodium nitrate is highly birefringent but very soft and brittle. It has a cleavage plane parallel to face *r* (ref. 1) which can be cleaved very easily. This sets a limit to the maximum stress that can be borne by the crystal. Unfortunately, this maximum stress is too small to produce additional birefringence measurable with the usual optical devices. All soft crystals such as alums and alkali halides require a stress ranging from 0·5 to 0·8 kg/mm² for photoelastic studies. A part of the load (about 0·2–0·3 kg/mm²) is used to make the crystal prism sink a little into the thin lead washers and its orientation is then maintained steady at all subsequent loads. This is particularly necessary in the case of naturally birefringent crystals like barite and quartz, for the slightest tilt of the prism is sufficient to vitiate the result. The birefringence of sodium nitrate is about twelve times that of quartz or barite and still greater attention has to be paid to the correct orientation of the crystal prisms. Several trials on prisms of sodium nitrate for different directions of stress showed that the maximum stress that

could be carried was about 0·35 kg/mm². The major portion of this stress was necessary for maintaining steady the orientation of the prism. Hence the small additional birefringence that might be produced as a result of the safest additional load was too small to be detected by the usual optical devices. It has been found that if any information could be sought at all on the photoelastic behaviour of this crystal, it was only by the ultrasonic method which I have developed[2].

Because of the existence of a very easily cleavable plane and considerable brittleness of the crystal, the cutting, grinding and optical polishing of the raw sodium nitrate crystal to give the necessary rectangular prisms for the ultrasonic experiments proved very difficult. Cutting with a jeweller's saw had to be abandoned. Grinding carborundum powder and cast iron base proved ineffective. The final method adopted was as follows: the raw crystal (grown in these laboratories by the evaporation of an aqueous solution) was rubbed on the moist surface of a soft and uniformly worn piece of cotton cloth stretched on a plane glass block. The water content on the cloth slowly dissolved the unwanted material of the crystal and the crystal was thus reduced approximately to the desired shape and size. The prism was then ground on the polished surface of a glass block using high-grade emery powder, with kerosene oil as lubricant. Immense patience and care were necessary during this stage, otherwise the crystal cleaved. The faces of the prism were then polished on a freshly prepared polishing tool of putty powder. The crystals keep remarkably well in dry weather.

The results obtained in the ultrasonic experiments are as follows: $p_{12}/p_{11} = 3{\cdot}19$; $p_{31}/p_{11} = 0{\cdot}41$; and $p_{13}/p_{33} = 1{\cdot}02$. It is interesting to note the high photoelastic anisotropy of sodium nitrate for ultrasonic excitation along the X-axis and the observations along Y and Z axes respectively[3].

I thank Dr. S. Bhagavantam under whose guidance the work was carried out in the Physical Laboratories, Osmania University.

Stress Relaxation of Bitumen and Bituminous Mixtures

THE rheological properties of bitumens and bituminous mixtures are well known and standard procedures for testing them have long been established. Relations between fundamental rheological parameters and quantities measured in routine tests have been reported by several authors. A study of creep and response to dynamic loading has been published by Van der Poel[1]. In a recent investigation on stress relaxation, Kubát[2] found that the normalized inflexion slope of the relaxation curve $\frac{1}{\Delta\sigma}\left(\frac{d\sigma}{d \ln t}\right)_{\text{Inflexion}}$ (where t is the time, σ is the stress, and $\Delta\sigma$ is the stress reduction due to relaxation) was the same for a wide variety of materials, including plastics, rubbers and metals—the last-mentioned also in the form of single crystals. The numerical value was $0{\cdot}1 \pm 0{\cdot}01$. This relationship applied provided the samples were free from internal stress.

I have found that the same expression applies for petroleum bitumen and bituminous mixtures, and gives a value close to 0·1. In these experiments the samples were compressed in an 'Alwetron' universal testing machine at 25° C. The temperature of the testing atmosphere was kept constant at $\pm 0{\cdot}1$° C and the stress relaxation, after compression had been discontinued, was recorded until a constant stress value was obtained. For bituminous mixtures, this required several days. The samples of bituminous mixtures, with a bitumen content of 6·7 per cent, were compacted in moulds for a Marshall stability test. Samples of pure bitumen were cast in the same moulds and during the test they were either kept in these or removed and submerged in a water thermostat. The upper pressure plate in the tester had a diameter of 60 mm and the lower one 76 mm. In neither case, therefore, was the test one of pure compression. All samples contained a 250 pen. straight-run petroleum bitumen, and the aggregate was crushed moraine (largest size 4 mm). The following parameters were varied: void fraction, rate of compression and compressive force at the start of relaxation (Table 1). The normalized inflexion slope varied between 0·1 and 0·16, and apparently was independent of the experimental parameters. It can be concluded that for bitumen and bituminous mixtures, after compressive stress, the inflexion slope of the relaxation curve is similar to that for the substances examined by Kubát even though they are fundamentally of a different nature. The comparatively large values for the pure bitumens may be due to the fact that they were compressed considerably more than the bituminous mixtures before relaxation.

Table 1. NORMALIZED INFLEXION SLOPE OF RELAXATION CURVES OF BITUMEN AND BITUMINOUS MIXTURES UNDER COMPRESSION

Void fraction (per cent)	Rate of compression (mm/min)	Maximum pressure (kg)	Inflexion slope

MINERALOGY

Pyrrhotite: a Common Inclusion in South African Diamonds

LARGE batches of industrial diamonds from several South African localities were carefully examined and any that showed large dark regions were weighed and then crushed by a sharp blow in a stainless steel mortar. The crushed fragments were then examined under a binocular microscope (× 15). Any particle which did not appear to be diamond was transferred to a drop of ethyl acetate on a glass microscope slide. After the drop had evaporated, a rubber ball mount of the grain was prepared[1], and the mount cemented to the end of a small plastic brush fibre ready for mounting in a 57·54 mm diameter Debye–Scherrer powder camera. Each specimen was X-rayed for 3 h using cobalt radiation ($\lambda = 1{\cdot}7902$ Å) with an iron filter. If the resulting pattern was weak, the exposure was repeated for 9 h.

The X-ray powder photographs showed, except for one specimen of pentlandite (DP-3, $a = 10{\cdot}108 \pm 0{\cdot}01$ Å),

Table 1. LATTICE PARAMETERS OF PYRRHOTITES RECOVERED FROM CRUSHED SOUTH AFRICAN DIAMONDS

* *DP*, De Beer's Pool (mixed Wesselton, Bultfontein, and Dutoitspan); *SH*, Stadium Heap (mixed Kimberley, De Beer's and De Beer's Pool); *CA*, Congo alluvial; *J*, Jagersfontein Mine; *P*, Premier Mine.

that all the brassy coloured particles picked out from among the diamond fragments were pyrrhotite. The d-spacings were then measured using diamond ($a = 3{\cdot}567$ Å) as an internal standard. The lattice constants were calculated by Cohen's method of least squares by assuming an NiAs type of cell. The final results are given in Table 1 together with the calculated d_{102}, which can be used to infer the composition[2]. Eleven of these specimens are iron deficient and can be classed as ordinary pyrrhotite; the remaining two (*J*-4, *J*-20) are nearly stoichimetric and can be considered to be troilite.

From a total of eighty-nine South African diamonds specially selected for detailed examination, twenty were definitely coloured, and of these, only five had inclusions that could be X-rayed, whereas of the uncoloured, forty-six had inclusions that could be X-rayed. Eleven of the twelve pyrrhotites and the single specimen of pentlandite were recovered from uncoloured diamonds. Pyrrhotite was thus found in 13 per cent of all diamonds examined and in 24 per cent of the diamonds containing inclusions that could be X-rayed. Furthermore, pyrrhotite was found in diamonds from all localities that were checked. This included specimens from the Congo, one of which is included in Table 1 for comparison.

The X-ray patterns of the pyrrhotite showed that the specimens were commonly intergrown with other phases. The most common was pentlandite ($a = 10{\cdot}05 \pm 0{\cdot}02$ Å), which occurred in ten of the thirteen pyrrhotite specimens listed. In specimens *SH*-2 and *P*-46, additional lines were found which are best attributed to pyrite ($a = 5{\cdot}403 \pm 0{\cdot}02$ Å and $a = 5{\cdot}381 \pm 0{\cdot}02$ Å, respectively). The assemblages of pyrrhotite + pentlandite, and pyrrhotite + pentlandite + pyrite are probably the result of exsolution from a former high-temperature phase included at the time of diamond formation. Specimen *J*-20 was very unusual because it consisted of an intergrowth of cohenite with troilite. The cell dimensions determined on the cohenite were: $a = 4{\cdot}516 \pm 0{\cdot}01$ Å, $b = 5{\cdot}072 \pm 0{\cdot}01$Å and $c = 6{\cdot}742 \pm 0{\cdot}01$ Å.

In the past, iron pyrite has been reported as an inclusion in diamond[3–6]. Although pyrite is reported here, no specimens were found in which pyrite occurred as an original inclusion. The question is greatly confused by the occasional occurrence of irregular broken diamonds with masses of pyrite attached. I have recently examined a 2-carat stone of this kind from the Premier Mine, and am of the opinion that the pyrite is a secondary growth on the diamond which was probably formed at the same time as the other well-formed pyrite crystals frequently occurring in the blue ground of the Premier Mine. I therefore believe that, at present, there are no verifiable reports of pyrite as an original inclusion in diamond.

The results suggested by this study are: (1) that pyrrhotite is a common inclusion in diamond; (2) that it is more than coincidence that pyrrhotite (troilite) should be found so closely associated first with diamonds in meteorites[7] and now with diamonds from kimberlite pipes.

I thank the Mineralogy Section of the Anglo-American Research Laboratory, and Mrs. Eckert in particular, for helping me to X-ray the samples and to develop the films.

METALLURGY

Stress-corrosion Cracking of Aluminium

ALUMINIUM forging alloys used in aerospace technology have, on occasion, suffered catastrophic failure as a result of stress-corrosion cracking. Study of this problem by thin-film transmission electron microscopy has disclosed

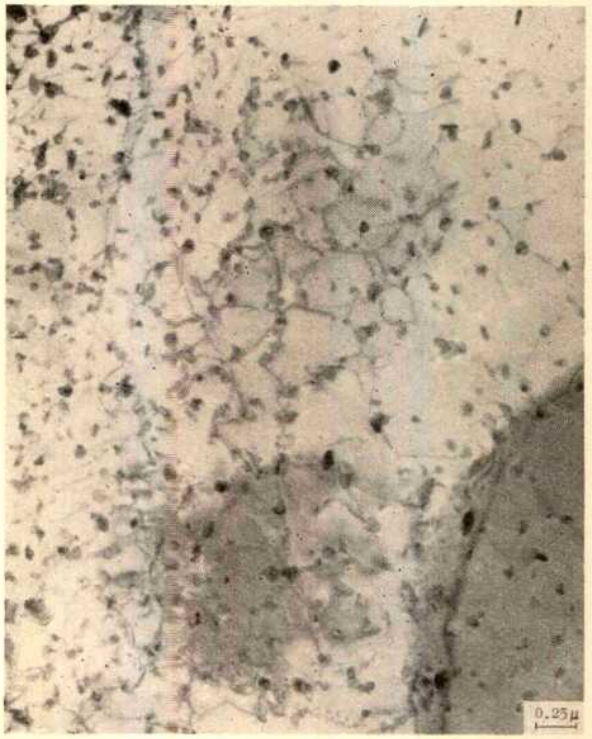

Fig. 1. Alloy 7075 *T*6 highly susceptible to stress-corrosion cracking. Note dislocation lines—many are associated with $MgZn_2$ precipitates

Fig. 2. Alloy 7075-*T*73 immune to stress-corrosion cracking. Note absence of dislocations. Coarse and fine precipitation is $MgZn_2$

a fundamental relationship between those aluminium structures within the same alloy (achieved by heat treating) that are highly sensitive to stress-corrosion cracking and those that are immune.

Specifically, the Al–Zn–Mg–Cu 7075 alloy (a typical composition is, in per cent, 5·5 zinc, 2·2 magnesium, 1·2 copper, 0·18 chromium, balance aluminium) is susceptible to stress-corrosion failure in the $-T6$ temper (highest strength condition), but is completely immune to cracking in the $-T73$ temper (low strength condition). The $-T6$ structure contains dislocation networks (Fig. 1) which are absent in the $-T73$ structure (Fig. 2).

Because pitting proceeds identically in the $-T6$ and $-T73$ tempers, namely, by the dissolution of large $MgZn_2$ precipitate particles in the grain boundaries, it is concluded that the critical role of dislocations is to assist in the nucleation of cracks of appropriate geometry for propagation.

These new findings possibly apply to any precipitation hardenable alloys that develop dislocations during the quenching operation. Similar situations have been found to exist in the 2014 and 2024 alloys.

These findings will be of practical use in the identification of structures susceptible to stress-corrosion, and may also be useful in the development of heat treatments that will give alloys of high strength and no tendency toward cracking by stress-corrosion.

CHEMISTRY

Infra-red Luminescence (Fluorescence) and Reflectance of Coals, Coal Derivatives and Graphite

WE have investigated the infra-red luminescence (fluorescence) of coal and coal derivatives. Little, if any, visible luminescence is shown by coal except (1) in the presence of fluorescing minerals, and (2) in solutions of coal derivatives. Substances containing presumably large amounts of polynuclear aromatic compounds as well as large amounts of free radicals should exhibit appreciable visible luminescence. The lack of luminescence in solid coals or solid derivatives, such as coal-hydrogenation asphaltenes and pyridine extracts, can be explained on the basis of quenching due to various factors. But in the dissolution of asphaltene or coal extract, an intense light blue luminescence develops. A corresponding increase in specific absorption with dilution of coal-hydrogenation-asphaltene solutions was previously found and was correlated with an increase in free radicals, presumably formed by dissociation[1]. The free radicals existing in solid coal may be of such a large size that luminescence missing from the visible could possibly exist beyond the visible range. With the development of a new method for determining infra-red luminescence[2], it has become possible to check coal and coal derivatives for luminescence in this region. Infra-red luminescence has now been observed.

Experimental procedures used are described in detail in ref. 2; excitation in the blue-green region was used, and luminescence in the near infra-red region was detected photographically. Two other infra-red luminescence investigations have been reported[3]. Fig. 1*a* shows the infra-red reflectances of the eight samples examined together with a reference piece of greenockite (native cadmium sulphide); Fig. 1*b* gives the infra-red luminescences. The results obtained are shown in Table 1.

Table 1

No.	Sample	Infra-red luminescence	Infra-red reflectance
(1)	Anthracite, Glen Burn, Pa.	None	Strong
(2)	Asphaltene from 400° C hydrogenation, Pittsburgh coal	Med. strong	Med. strong
(3)	Coal (*hvab*), Pittsburgh, Pa.	Weak	Med. strong
(4)	Vitrain (*hvab*), Pittsburgh, Pa.	Very weak	Strong
(5)	Lignite, Velva, North Dakota	None	Strong
(6)	Pyridine extract from Pittsburgh coal	Weak	Weak
(7)	Graphite, spectral grade	None	Med. strong
(8)	Solution of asphaltene in benzene	Med. strong	Very weak
	Greenockite (control)	Strong	Very strong

Luminescence is observed in the infra-red in decreasing order: Coal-hydrogenation asphaltene dissolved in benzene > solid asphaltene > Pittsburgh coal = extract from Pittsburgh coal > Pittsburgh vitrain.

Part of the top surface of the asphaltene sample was scraped in order to produce a fresh unoxidized surface. The luminescence of this fresh surface is appreciably greater than that of the rest of the sample. Pittsburgh coal shows stronger luminescence than the vitrain. This can probably be explained by the fact that the coal contains other petrographic constituents which may luminesce to a greater extent than vitrain. The stronger luminescence of the coal cannot be attributed to mineral matter, for anthracite, which contains much larger amounts of similar minerals, would show an even greater luminescence. But anthracite shows no luminescence at all. Also no luminescence is exhibited by lignite; infra-red luminescence was found only for the medium rank coal. Graphite also showed no luminescence. In both anthracite and graphite, luminescence may occur at even longer wave-lengths than can be attained at present.

It is doubtful whether the infra-red luminescence observed in coal and coal products can be attributed to polynuclear aromatics; aromatics even as large as ovalene, with ten condensed rings, exhibit luminescence in the visible region of the spectrum and it is probable that they do not exhibit luminescence in the infra-red region. It would seem that infra-red luminescence of coal can be attributed to free radicals, which generally exhibit luminescence at longer wave-lengths than non-radicals of similar structure and molecular weight. It is also possible that charge-transfer complexes may be involved.

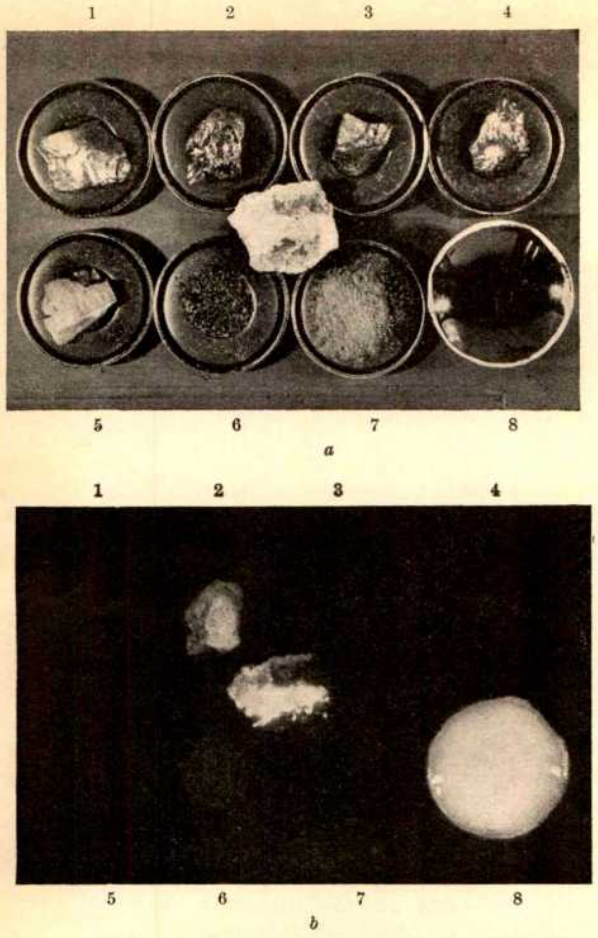

Fig. 1. *a*, Infra-red reflectance of various coals and coal derivatives. (Numbers as in Table 1. Reference piece of greenockite in the centre.) *b*, Infra-red luminescence of the same as *a*

Comparisons of infra-red reflectances and of reflectance versus luminescence are of interest. Infra-red reflectance is intense for Pittsburgh vitrain, anthracite, and lignite. Pittsburgh coal, solid asphaltene and powdered graphite have appreciable reflectances. Asphaltene in solution and pyridine extract have low reflectances. The infra-red reflectances of anthracite, lignite and graphite given in Fig. 1*a* are reflectances only; they do not involve emission of luminescence as the luminescence observations were negative (Fig. 1*b*). In general, the highest infra-red reflectances are observed for the weakest luminescing samples; and the strongest infra-red luminescence is found for the weakest reflectors.

Petrographic constituents of coals with fresh and oxidized surfaces will also be investigated. Other work will cover solutions of pyridine extract at various concentrations, residues from pyridine extractions, known free radicals, charge-transfer complexes, and polynuclear condensed aromatic compounds.

Diffusion of Triplet Excitons produced by Ionizing Radiation in Aromatic Materials

THIS report demonstrates that the analysis of experimental radioluminescence decay curves provides estimates of the diffusion coefficient of triplet excitons produced by ionizing particles in aromatic materials; the values obtained are in accordance with the hopping model calculation.

The diffusion of triplet excitons in molecular crystals has been the subject of several recent publications[1-6]. A treatment of triplet energy transfer has been developed by Jortner *et al.*[1] and is based on a hopping model; according to these authors, their calculated diffusion coefficient ($D_T \simeq 5 \times 10^{-6}$ cm^2 sec^{-1}) in anthracene is in good agreement with measured triplet–triplet annihilation rate constant[2,3] and exciton diffusion lengths[4]. More recently, Singh *et al.*[5] and Kepler and Switendick[6] reported that the diffusion coefficient of Jortner *et al.* in anthracene seemed to be between two and four orders of magnitude too small and that a band model would be more appropriate to describe triplet exciton transfer in this crystal.

In a study of the time dependence of scintillation intensity in aromatic materials[7], a theoretical model has been developed to describe the origin of the delayed scintillation component[8] and excellent agreement with experimental results has been obtained. The delayed component was attributed to emission from singlet states ('delayed' singlets) formed during the encounter of two triplets in the particle track.

During the retardation of a charged particle in the organic medium, slow secondary electrons are produced, which in turn induce molecular ionized and high excited singlet states, located in small, approximately spherical volumes, referred to as 'spurs' and 'blobs' in a recent work[9]. Within these highly activated areas, a great triplet density results from the major processes of ion recombination and direct excitation by slow electrons; the local concentration of singlet states is reduced by fast quenching effects which concern mainly the primary upper singlet levels ('ionization quenching')[7]; intersystem crossing from the lowest singlet states is not expected to influence to any great extent the triplet state population. In the case of heavy particles with high specific energy loss (for example, 5-MeV α-particles) the distance of successive spurs is so small that the activated species are distributed along the particle path within a cylindrical track; the initial triplet distribution function can then be considered in cylindrical symmetry as:

$$c_T(r,0) = \frac{n_T(0)}{\pi r_0^2} \exp\left(-r^2/r_0^2\right) \qquad (1)$$

Here $c_T(r,0)$ denotes the triplet density at time $t = 0$ and at a distance r from the particle path and $n_T(0)$ the total number of triplet excited states produced per unit path-length; the length r_0 characterizes the lateral distribution of triplet states and should be comparable with the dimensions of the elementary blobs. With these conditions, the following kinetic-diffusion equations for excited triplet and delayed singlet states were resolved:

$$\frac{\partial}{\partial t} c_T(r,t) = D_T \nabla_r^2 c_T(r,t) - \frac{1}{\tau_T} c_T(r,t) - \gamma_{tt} c_T^2(r,t) \qquad (2)$$

$$\frac{\partial}{\partial t} c'_s(r,t) = D_s \nabla_r^2 c'_s(r,t) - \frac{1}{\tau_s} c'_s(r,t) + k_{tt} c_T^2(r,t) \qquad (3)$$

where $c'_s(r,t)$ is the density of delayed singlets, D_s the singlet state diffusion coefficient, τ_s and τ_T the fluorescence and phosphorescence decay times respectively, γ_{tt} the bimolecular annihilation rate constant, and k_{tt} the rate constant for singlet state production resulting from the bimolecular reaction between triplet states.

For times when $t \gtrsim 10\ \tau_s$, the light intensity as a function of time was found to be given by:

$$I(t) = M\,[1 + A \ln (1 + t/t_d)]^{-2}\,(1 + t/t_d)^{-1} \qquad (4)$$

where M and A are constants and $t_d = r_0 2/4D_T$.

Experimentally, using a single photo-electron technique[10,11], we have measured the luminescence decay pulse shapes for liquid scintillators excited by ionizing radiation. In Fig. 1, two typical decay curves are shown, obtained with deoxygenated toluene solutions irradiated by 5·3-MeV α-particles. Taking $A = 1{\cdot}0$ and $t_d = 5$ nsec, it is seen that the shape of the delayed component is well described by relation (4). This equation also accounts accurately for the slow-scintillation decay in crystals and, by comparison with experimental curves published by Bollinger and Thomas[10] and Wasson[12], we obtained $t_d = 40$ nsec for a crystal of anthracene and $t_d = 80$ nsec in the case of *t*-stilbene.

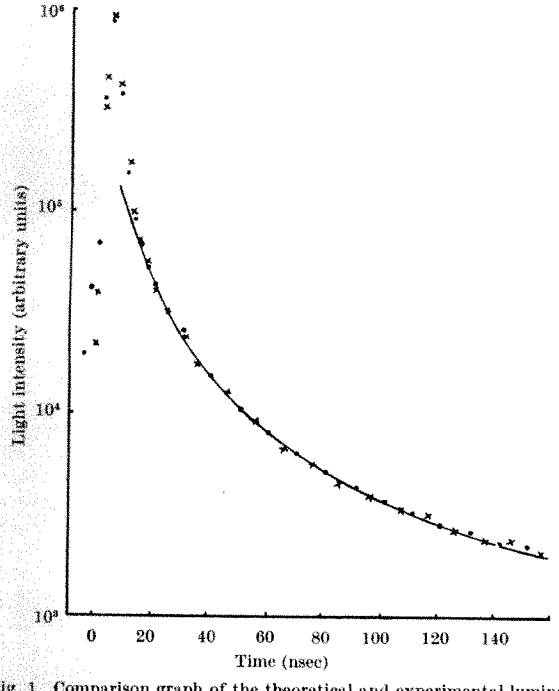

Fig. 1. Comparison graph of the theoretical and experimental luminescence decay curves for liquid scintillators (2-phenyl 5-bi-phenyloxadiazole (PBD) and terphenyl (TP) in toluene) excited by 5·3 MeV α-particles. Experimental points: ●, PBD (10 g/l.) in toluene; ×, TP (7 g/l.) in toluene. ———, Theoretical curve ($A = 1{\cdot}0$, $t_d = 5$ nsec.)

Analysis of the values of t_d measured with liquid toluene, in conjunction with those obtained for crystalline anthracene and stilbene, provides estimates of the length r_0 and of the triplet state diffusion coefficients in the crystals. In liquids, D_T is close to the material diffusion coefficient; so that, for the two scintillator solutions shown in Fig. 1 having toluene as a solvent, $D_T = 2{\cdot}2 \times 10^{-5}$ cm² sec⁻¹; with $t_d = 5$ nsec, we then obtain $r_0 = (4D_T t_d)^{1/2} = 7 \times 10^{-7}$ cm. This value is in agreement with $r_0 = 5 \times 10^{-7}$ cm previously used for an aromatic crystal[13]. Also it is comparable with the predicted dimensions of the blobs generated by slow secondary electrons[9], the ranges of which are not expected to differ notably in the aromatic liquids and crystals. Assuming, therefore, a similar value for r_0 to be valid for the crystalline scintillators and using the measured values of t_d, we obtain $D_T = 3{\cdot}0 \times 10^{-6}$ cm² sec⁻¹ for anthracene and $D_T = 1{\cdot}5 \times 10^{-6}$ cm² sec⁻¹ for *t*-stilbene.

These triplet state diffusion coefficients are in good agreement with those calculated using the hopping model. It should be noted, however, that analysis of the delayed scintillation component decay—which is essentially controlled by triplet diffusion out of the particle track, where the crystal lattice is possibly perturbed by radiation effects—may give values of D_T which are slightly different from the actual value corresponding to diffusion in the perfect lattice. The possible extent of this difference, the validity of the assumptions regarding r_0 in crystals together with the exactitude with which the theoretical equations fit the available experimental data, all require consideration for an assessment of the accuracy of the derived values in this work. These values are expected to be valid to within an order of magnitude, but further experimental work should allow a more precise comparison.

Retardation of the Crystallization of Calcium Sulphate Dihydrate

CONCENTRATED aqueous suspensions of calcium sulphate hemihydrate generally convert into a solid mass within 20–40 min owing to the crystallization of dihydrate ($CaSO_4{\cdot}0{\cdot}5H_2O + 1{\cdot}5H_2O \rightarrow CaSO_4{\cdot}2H_2O$). It is common practice to increase this time to about 4–6 h by addition of water-soluble substances in amounts of 0·1–1 per cent. These 'retarders' are usually hydrolysates of protein, although a variety of widely different materials such as phosphates, borates, citrates and tartrates are also effective[1].

Investigations of materials that retard the crystallization of dihydrate reported so far have been carried out without consideration of the structure and the functional groups of the retarder molecules[2,3]. Thus, an investigation was undertaken of the mechanism of retardation and special emphasis placed on the types of functional groups of aliphatic α-amino-acids present in protein hydrolysates. Using equal molar concentrations, it was found that the retarding potency is considerably higher in hydrolysates containing a large percentage of aspartic acid, glutamic acid or cysteine, which have carboxyl or thio groups at the end of the aliphatic side chain in addition to carboxyl groups in the α-position. The presence of hydroxyl, amino or amide groups in place of terminal carboxyl or thio groups decreases the retarding potency. Poor retarders are obtained when the amino-acids have largely straight or branched aliphatic side chains, without functional groups. The effect of molecular size of the hydrolysates is negligible provided they can be made to dissolve in water.

To study the role of the carboxyl groups, a number of aliphatic amino-acids have been condensed with formalde-

hyde. This technique produces molecules which differ from protein hydrolysates in that the amino-acids are linked together with repeating $-CH_2NR-$ groups instead of $-CH-CO-NH-$ groups (R = amino-acid rest). Therefore, carboxyl groups instead of amide groups are present in condensates, and these can be located near the main chain, at the end of the aliphatic side chains or in both positions depending on the type of amino-acid used. The results show that the retarding potency of condensates is always greater than that of protein hydrolysates; this is particularly so for aspartic acid, glutamic acid and all amino-acids where the carboxyl groups are located at the end of the side chains. Carboxyl groups are present near the main chain when α-amino-acids are used, which results in potent retarders only if the aliphatic side chain is very short or absent as in the case of glycine.

A series of polyamino carboxylic acids has been synthesized to examine the relationship between amino-groups and carboxyl-groups with respect to the chelation of calcium ions. It was found that one of the most potent of the chelating agents, ethylenediamine tetraacetic acid $(HOCOCH_2)_2N(CH_2)_n\ N(CH_2COOH)_2$, $n = 2$, is a poor retarder. Its homologues with $n = 3$–6, which form incomplete chelates with calcium ions are considerably more potent. Carboxymethylated and carboxyethylated polymers of ethylenediamine or propylenediamine are excellent retarders provided the ratio of amino-groups to carboxyl-groups is 1 : 1 or smaller. The difference in performance between these polyamino polycarboxylic acids is insufficient to contribute to the advancement of a theory for a mechanism of retardation. It seems that the complete chelation of calcium ions in solution does not explain the delay of the crystallization of dihydrate. However, it is evident that complex formation plays an important part.

The relative importance of carboxyl-groups, amino-groups and thio-groups was studied with a number of aliphatic polycarboxylic acids. In the course of this investigation, it was observed that retardation is possible only when at least two carboxyl groups are present in a molecule. The distance between them should be equivalent to 2 or 5 carbon atoms in the aliphatic chain of the molecule. Thus succinic and pimelic acid are more powerful retarders than the neighbouring members of the same dicarboxylic acid series with a smaller or greater number of carbon atoms separating the carboxyl groups. The preferred distance would seem to be five carbon atoms.

Although polyamines do not retard the crystallization of dihydrate, the presence of an amino-group in a dicarboxylic acid always increases its retarding potency. For example, α-amino pimelic acid is a more potent retarder than pimelic acid. The presence of a thio-group instead of an amino-group in a dicarboxylic acid results in an equal or greater increase of the retarding potency. Other functional groups are not effective with the exception of phosphoric acid-groups.

Based on these observations, retardation of the crystallization of dihydrate is considered to be due to chemisorption of the retarder molecule by complex formation with more than one calcium ion across the a- and c-axis of the growing dihydrate crystal. The distances of the calcium ions at the a- or c-axis of the dihydrate crystal correspond to an equivalent distance of five or two carbon atoms respectively[4]. The proposed mechanism is akin to the threshold effect of phosphates preventing the precipitation of calcite.

Surface Tensions of Molten Mixtures and Thermodynamic Ideality

ONLY a few of the techniques available for studying the thermodynamic properties of ionic melt mixtures[1] can be used to study mixtures of technological interest above 1,000° C. Volumes of mixing of the sodium *meta*phosphate: potassium *meta*phosphate system have been measured by one of us[2], and this technique could be used to study phosphate–silicate melts of interest to steelmakers. The thermodynamic ideality of a molten system can also be tested by measuring the surface tension of the molten mixtures and comparing these with the predictions of Guggenheim's ideal equation[3,4]. We have used this method for studying molten phosphate mixtures and shall here describe the results for the sodium *meta*phosphate: potassium *meta*phosphate system.

The *meta*phosphates were prepared by heating the respective dihydrogen phosphates at 1,100° C for 2 h, and were analysed by the method of Boltz[5]. Surface tensions were measured with an apparatus similar in design to that described by Bradbury[6], and depending on the "Maximum pull on a cylinder". A platinum-10 per cent rhodium cylinder was suspended from the arm of a balance into the melt held in a platinum crucible heated in a molybdenum wire-wound furnace controlled to ± 1° C at 1,000° C. The apparatus was calibrated using carbon tetrachloride, water, benzene and nitrobenzene by the method of Harkins and Jordan described by Bradbury[6]. The measured surface tensions were estimated to be accurate to within 0·5 dynes/cm.

Measurements were obtained in the range 850° C–1,200° C and some results are shown in Fig. 1. The variation of surface tension with temperature was of the order of 0·045–0·050 dynes/cm/° C. The experimental results were fitted to Guggenheim's formula:

$$\exp(-\gamma a/kT) = x_1 \exp(-\gamma_1 a/kT) + x_2 \exp(-\gamma_2 a/kT)$$

where T = temperature (° K), x_1 and x_2 are the mole fractions of components 1 and 2, γ is the surface tension of the mixture while γ_1 and γ_2 are the surface tensions of pure components 1 and 2, k is Boltzmann's constant and a is an adjustable parameter.

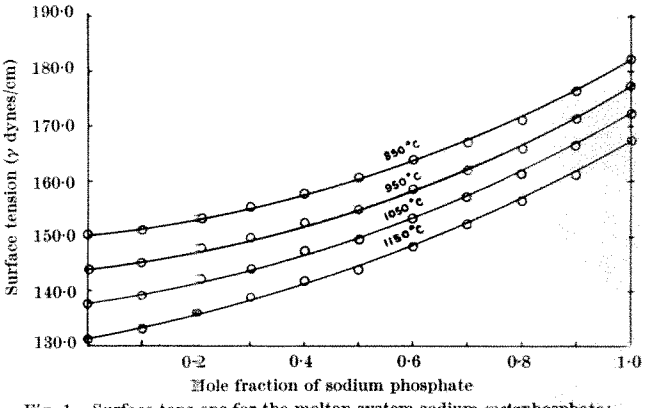

Fig. 1. Surface tensions for the molten system sodium *meta*phosphate: potassium *meta*phosphate

A value of $a = 50·0$ Å²/molecule gives very close agreement for the calculated surface tension of the mixture (γ) for the temperatures 850°, 950°, 1,050°, 1,150° C. For the three highest temperatures, indeed, the deviation of the calculated γ is within the range ± 0·6 dynes/cm for all but two of the twenty-seven compositions studied. For the results at 850° C, and with the same value of the constant a, the maximum deviation is 0·8–0·9 dynes/cm. Simple calculation shows that at the composition $x_1 = 0·4995$, $x_2 = 0·5005$, a variation of 10 Å²/molecule causes a variation of 1·0 dynes/cm in the calculated value of γ.

These results would thus seem to be consistent with the view that the molten system sodium *meta*phosphate:

potassium *meta*phosphate is thermodynamically ideal. Similar results have been obtained for the systems lithium *meta*phosphate : potassium *meta*phosphate and lithium *meta*phosphate : sodium *meta*phosphate, and will be reported in greater detail elsewhere.

Reactivity of Excited Water Molecules in Photochemical Carboxylation

WE have shown that carbon dioxide in aqueous solution can be reduced and converted into simple organic substances under the influence of ultra-violet light[1–3]. The reduction process is the result of the action of hydrogen atoms produced by the photolysis of water and also of excited molecules of water (H_2O^*) (refs. 2 and 3):

$$H_2O \rightsquigarrow H_2O^* \rightarrow H + OH \qquad (1)$$

for $\lambda = 184{\cdot}9$ nm the quantum yield for H and OH is $\Phi = 0{\cdot}6$ (ref. 4).

Subsequent reactions are:

$$CO_2 + H \rightarrow COOH \qquad (2)$$

$$k_2 < 8 \times 10^6 \text{ moles}^{-1}.\text{sec}^{-1} \text{ (ref. 5)}$$

$$(CO_2.H_2O) \rightsquigarrow (CO_2.H_2O)^* \rightarrow COOH + OH \qquad (3)$$

and:

$$(CO_2.H_2O)^* \rightarrow CO_2^- + H_2O^+ \qquad (4)$$

For simplicity, instead of reactions (3) and (4), the following reaction can be written:

$$CO_2 + H_2O^* \rightarrow COOH + OH \qquad (5)$$

In the presence of aqueous bicarbonate the excited water molecules can also lead to the formation of CO_2^- radical ions, according to the reaction (6) (ref. 6):

$$HCO_3^- + H_2O^* \rightarrow CO_2^- + OH + H_2O \qquad (6)$$

In addition we have been able to carboxylate a number of organic substances in aqueous solutions by ultra-violet irradiation[3,6,7]. In an investigation of the carboxylation process of methanol we found a possible method for calculating the rate constants of reactions (5) and (6). Besides reactions (2), (5) and (6), reactions (7) and (8) are also responsible for the formation of glycolic acid, which is the carboxylation product of methanol:

$$CH_3OH + OH \rightarrow CH_2OH + H_2O \qquad (7)$$

$$k_7 = 3 \times 10^8 \text{ moles}^{-1}.\text{sec}^{-1} \text{ (ref. 5)}$$

$$CH_3OH + H \rightarrow CH_2OH + H_2 \qquad (8)$$

$$k_8 = 2 \times 10^6 \text{ mole}^{-1}.\text{sec}^{-1} \text{ (ref. 8)}$$

Hence:

$$CH_2OH + COOH \rightarrow CH_2(OH).COOH \qquad (9)$$

$$CH_2OH + CO_2^- \rightarrow CH_2(OH).COO^- \qquad (9a)$$

$$k_{9a} = 5 \times 10^8 \text{ mole}^{-1}.\text{sec}^{-1} \text{ (ref. 5)}$$

The yield of glycolic acid as a function of the concentration of methanol at two different *p*H values is shown in Fig. 1. Both curves pass through a maximum at 4×10^{-1} moles methanol/l. The yield of the glycolic acid formed achieves a maximum only when the concentration of both radicals—CH_2OH and COOH (or CO_2^-)—is equal. Below the concentration of 4×10^{-1} moles methanol/l. solution the COOH (or CO_2^-) radicals are in excess. In this case they lead as a result of dimerization to the formation of oxalic acid[6]:

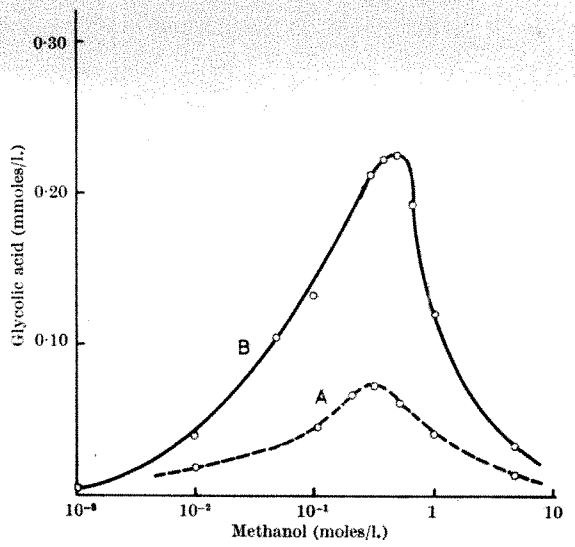

Fig. 1. Yield of glycolic acid as a function of methanol concentration. Irradiation time, 3 h; ultra-violet source: Hanau lamp, type *NK*6/20. *A*, 0·1 M sodium bicarbonate solution, saturated with carbon dioxide gas, *p*H 6·7; *B*, 0·1 M sodium bicarbonate solution, *p*H 8·5

$$COOH + COOH \rightarrow H_2C_2O_4 \qquad (10)$$

or:

$$CO_2^- + CO_2^- \rightarrow C_2O_4^{--} \qquad (10a)$$

At a concentration above 4×10^{-1} moles of methanol/l., glycol is produced according to:

$$CH_2OH + CH_2OH \rightarrow C_2H_4(OH)_2 \qquad (11)$$

For the formation of glycolic acid at *p*H = 6·7 reactions (2), (5), (7) and (8) prevail and one can calculate the rate constant k_5 for the maximum of the curve *A* as follows:

$$k_5 = \frac{C_{CH_3OH}.(2k_7 + k_8) - k_2.C_{CO_2}}{2.C_{CO_2}} \qquad (12)$$

In this case we assume: $C_{H_2O^*} \simeq C_{OH}$, since $\Phi = 0{\cdot}6$ (ref. 4). By substitution of $C_{CH_3OH} = 4 \times 10^{-1}$ moles/l., $C_{CO_2} = 1{\cdot}5 \times 10^{-2}$ moles/l. and the *k*-values for reactions (2), (7) and (8) given here in equation (12) are obtained as:

$$k_5 = k_{CO_2+H_2O^*} = 8 \times 10^9 \text{ moles}^{-1}.\text{sec}^{-1} \qquad (13)$$

In basic media (*p*H 8·5) glycolic acid is produced at three times the yield (see Fig. 1). This can be explained, as already mentioned, as being due to the action of excited water molecules on bicarbonate with the formation of CO_2^- radical ions by way of reaction (6). In this case, reaction (14) need not be taken into consideration:

$$H + OH^-_{aq} \rightarrow e^-_{aq} \qquad (14)$$

$$k_{14} = 2{\cdot}4 \times 10^7 \text{ moles}^{-1}.\text{sec}^{-1} \text{ (ref. 9)}$$

This becomes important only at higher *p*H values. As a consequence of this, reaction (15) also plays a negligible part:

$$CO_2 + e^-_{aq} \rightarrow CO_2^- + nH_2O \qquad (15)$$

$$k_{15} = 0{\cdot}77 \times 10^{10} \text{ moles}^{-1}.\text{sec}^{-1} \text{ (ref. 10)}$$

By a process similar to the one just applied to curve *A* we can now determine the k_6-value from the maximum of curve *B*. Under these conditions (for $C_{HCO_3^-} = 10^{-1}$ moles/l.) one can estimate:

$$k_6 = k_{HCO_3^- + H_2O^*} = 1{\cdot}2 \times 10^9 \text{ moles}^{-1}.\text{sec}^{-1} \qquad (16)$$

Although the k_6-value is lower than the k_5-value, the higher yields of glycolic acid at *p*H 8·5 (curve *B*) can be explained as a *p*H effect and because k_{9a} is relatively high. Similar results have been obtained also by the carboxylation of methanol induced by cobalt-60 gamma-rays[5,11].

I thank Prof. B. Karlik for her interest in this work and Prof. H. Nowotny for valuable discussions. This work was supported by the Bundeskanzleramt, Verstaatlichte Unternehmungen (Section IV) of the Federal Republic of Austria.

Analysis of the Major Constituents of Fuel Gases by Gas Chromatography

RECENTLY, Hollis[1] has reported retention data for the separation of methane, carbon dioxide, and polar materials on porous polymer beads. In these laboratories a polymeric bead column packing commercially available in the United Kingdom[2] has been investigated, and has been found to have considerable advantages over conventional adsorption columns for the analysis of fuel gases which contain hydrogen, carbon monoxide, methane, carbon dioxide, and the C_2-hydrocarbons as major constituents.

Hitherto the gas chromatographic analysis of fuel gas has necessitated the use of two adsorption columns. Usually a type 5*A* or 13*X* molecular sieve column is preferred for the separation of methane and carbon monoxide, but because this material strongly absorbs carbon dioxide, which eventually poisons it, a second column of silica gel must be used to separate this gas and the C_2-hydrocarbons[3]. It has now been found possible using a single column to analyse a fuel gas for these components including carbon dioxide.

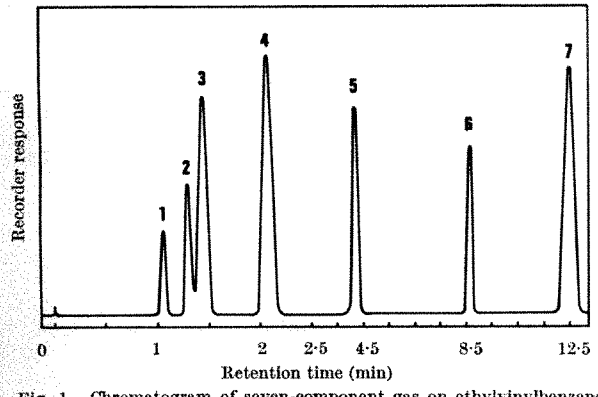

Fig. 1. Chromatogram of seven-component gas on ethylvinylbenzene polymer at 30° C. (1) Hydrogen; (2) air; (3) carbon monoxide; (4) methane; (5) carbon dioxide; (6) ethylene and acetylene; (7) ethane

The chromatogram in Fig. 1 was produced using a Perkin–Elmer model 451 gas chromatograph. A methane-rich gas containing 3 per cent carbon monoxide was analysed at 30° C using a column 10 ft. long and 3/16 in. internal diameter, packed with 80–100 mesh beads of an ethylvinylbenzene polymer. This was conditioned before use by heating to 230° C for 1 h as recommended by the manufacturer. Helium was used as carrier gas at an inlet pressure of 15 lb./in.^{2} gauge and a flow rate of 40 ml./min, and the components were detected using a thermistor katharometer. On this column carbon monoxide and methane were well separated, and carbon dioxide eluted within 5 min of injection. The column separated unsaturated C_2-hydrocarbons from ethane under the same conditions.

When ethylvinylbenzene polymer was used as column packing, rapid analyses were obtained with good separation and without the 'tailing' peaks associated with other adsorption columns. In this laboratory it has enabled a gas to be analysed for seven components in 30 min with a single injection on one column, the sample size being adjusted according to the recommendations of Pauschmann[4] so as to obtain a nearly linear response for hydrogen using helium as carrier gas.

Sensitivity to Oxygen of an Ionization Detector with Helium and Neon as the Carrier Gases

WE are interested in the analysis by chromatography of trace (v.p.m.) mixtures of oxygen in gases, and the Lovelock radioactive ionization detector[1] was selected as the most appropriate for the purpose. This detector, originally developed for sensitive detection of organic compounds in a carrier stream of argon, is not very sensitive to permanent gases in argon because the metastable energy of argon (11·6 eV) is slightly less than the ionization potentials, 12–16 eV, of most of the permanent gases. Berry[2] suggested that helium which has a metastable energy of 19·8 eV would be a suitable carrier gas. We have carried out tests first with helium[3] and later with neon, the metastable energy of which is 16·5 eV.

In these tests we determined the sensitivity of a Lovelock strontium-90 detector (made by W. G. Pye, Ltd., Cambridge) to helium and neon containing constant (v.p.m.) amounts of added oxygen, for different voltages applied to the detector. In each case, the flow was maintained at 85 cm^3 (N.T.P.)/min and the original carrier gas was purified to less than 0·1 v.p.m. oxygen. The sensitivity was found to increase with detector voltage up to 1,300 V for helium and 850 V for neon, above which voltages spark discharge occurred.

Table 1

Carrier gas	Detector voltage (V)	Standing current (amp)	Sensitivity amp/v.p.m. oxygen	Noise-level (amp)
Helium	1,300	5×10^{-9}	3×10^{-9}	5×10^{-11}
Neon	850	5×10^{-9}	5×10^{-9}	5×10^{-11}

Using these voltages, we determined the standing current and the noise-level for this current with carrier gas containing no added oxygen, and the change in current with added oxygen. The variation in current with added oxygen is linear up to at least 1·0 v.p.m.

The results are given in Table 1, from which it can be seen that the minimum detectable addition of oxygen, defined as that producing a change in detector current of twice the noise level, is 0·03 v.p.m. oxygen for helium and 0·02 v.p.m. oxygen for neon.

In practice, neon with its much higher cost would scarcely be chosen in preference to helium unless there were some special reason, for example if the gases to be detected were already mixed with neon, or if a recirculation system were used, the gases being recirculated through the purifier which is needed in any event when

the detection of trace amounts of permanent gases is attempted.

Observation of the Nitrene in the Flash-photolysis of 1-Azidoanthracene

NITRENES have been postulated as intermediates in the decomposition of organic azides, iminoxides, nitro- and nitroso-compounds[1–3]. Most of the evidence in support of this is convincing but circumstantial[4–9]. Direct proof of the existence of nitrenes is based on the electron spin resonance spectra of triplet species in the photolysis products of several aromatic azides in a solid matrix at 77° K (ref. 10). Several alkyl-nitrenes have also been discovered in the even more extreme conditions of an organic matrix at 4° K (ref. 11). Recently we recorded the absorption spectra of several aromatic nitrenes[12] produced by photolysis in organic glasses at 77° K and were able to detect the nitrene intermediate in the photocyclization of 2-azidobiphenyl[13].

All these observations relate to solid-state systems at very low temperatures, and their bearing on what happens in the more usual liquid conditions at normal temperature is uncertain. Lwowski *et al.*[14] looked for nitrenes in the flash-photolysis of methyl and ethyl azidoformate but could only detect the spectrum of the fragment NCO.

This communication reports a preliminary experiment which demonstrates the appearance of 1-anthrylnitrene as a short-lived intermediate at normal temperature. A solution of 1-azidoanthracene in ethanol (5×10^{-4} M) was exposed to a photolytic flash of 170 J in a flash-photolysis unit. The spectrum of the system was recorded photographically with an analytical flash 4 μsec after excitation (the half-life of the photolytic flash being 3 μsec). Curve (*a*) in Fig. 1 is a densitometer trace of a photograph of the spectrum before photolysis, curve (*b*) is the trace for the system 4 μsec after excitation, and curve (*c*) was obtained without excitation after the sample had received two photolytic exposures. The absorption bands on the curves are identified by comparison with the low-temperature spectra of 1-azidoanthracene and its nitrene (EPA matrix at 77° K), Fig. 1 (*d*) and (*e*) respectively. The appearance of the characteristic peak of the nitrene at 342 mμ is clearly visible in curve (*b*). The half-life of the nitrene in these conditions is estimated provisionally to be between 3 and 10 μsec.

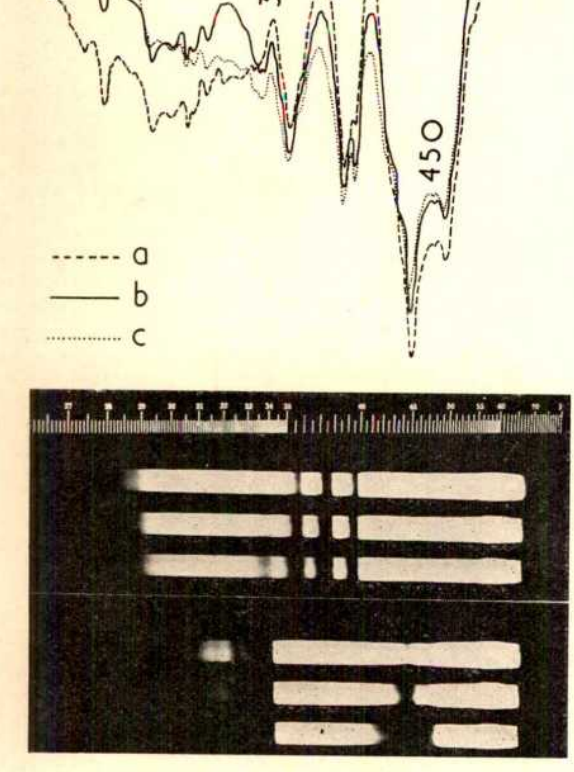

Fig. 1. Spectra of 1-azidoanthracene

A more detailed investigation of nitrenes by flash-photolysis is at present under way.

Effect of Deuterium Substitution on Radiation-less Decay of Anthracene Triplet

ALTHOUGH radiation-less transitions in aromatic molecules have been investigated experimentally for more than 10 years, it is only recently that any real understanding has been achieved. The main reason for this is that interpretation of the experimental results has been limited by the difficulty of distinguishing between temperature and viscosity effects in systems where temperature and viscosity are dependent variables[1]. Concomitant theoretical developments have contributed towards the resolution of some of the experimental problems, approaching the subject from the point of view of both intramolecular and intermolecular perturbations.

In the Robinson–Frosch theory[2,3], the radiation-less conversion probability is considered to depend largely on intramolecular vibrational perturbations characteristic of the molecule which is being investigated. The transition probability for radiation-less conversion between the lowest triplet T and the ground singlet G is given by:

$$P \propto [< \varphi_G | H_{s\cdot o\cdot} | \varphi_T > \pi_r < \theta_{G,n} | \theta_{T,O} >]^2 \qquad (1)$$

Here the first factor is the matrix element for the spin-orbit perturbation coupling the lowest triplet and the ground singlet, and the second factor is the vibrational overlap integral (Franck–Condon factor) of the 'zero' vibrational wave-function of the triplet with nearby (excited) vibrational wave-functions n of the ground state, taken over all normal modes r. The theory explains, *inter alia*, the reason why the observed lifetime of anthracene triplet, for example, is small compared with

benzene triplet (the vibrational overlap integral for the low-lying anthracene triplet being large compared with that for benzene), and the deuterium isotope effect[4,5] whereby deuterium substitution in benzene and naphthalene results in a marked increase in the phosphorescence lifetime of these compounds. The product over r in equation (1) includes C—H as well as C—C modes and substitution of hydrogen by deuterium is responsible for a decrease in the transition probability owing to reduction of the overlap integral by the lower energy C—D modes. In addition, the theory predicts that there will be no marked temperature effect on the transition probability and that as the triplet-ground singlet energy gap becomes small, deuterium substitution will not affect the transition probability.

Anthracene is of particular interest because its triplet state lies less than five vibrational quanta above the ground state and may already be so low-lying that there will be a vanishing deuterium effect in this molecule. The decay kinetics of both perprotonated and perdeuterated triplet anthracene in room temperature and 77° K glasses were monitored by triplet → triplet* absorption at 4250 Å using an E.M.I. 9592*B* multiplier phototube d.c. coupled to a wideband pre-amplifier and displayed on a calibrated 'Tektronix 535' oscilloscope. Samples had a path-length of 10 cm and were solid-solutions of the hydrocarbon in polymethylmethacrylate prepared from the thoroughly degassed monomer using 0·001 per cent *N*,*N*′-azodiisobutyronitrile to initiate polymerization. The exciting radiation was a 10-μsec 300-J xenon flash passing into a horizontal quartz Dewar system through Schott–Jena *WG*3 windows (2 mm thick) of transmission:

$$T(\lambda) < 10^{-5} \text{ for } \lambda < 3200 \text{ Å}$$
$$T(\lambda') > 0{\cdot}5 \text{ for } \lambda' > 3400 \text{ Å}$$

Decays of the transients were strictly exponential and no difference in transient lifetime was observed over many successive flashes. The mean lifetimes for the triplets of perprotonated and perdeuterated anthracene at room temperature and 77° K are shown in Table 1.

Table 1. MEAN LIFETIMES (k^{-1} VALUES) OF PERPROTONATED (τ_P) AND PERDEUTERATED (τ_D) ANTHRACENE TRIPLETS IN LUCITE

Temperature	τ_P(sec)	τ_D(sec)
298° K	0·025	0·073
77° K	0·048	0·153

It can be seen from Table 1 that there is a definite deuterium effect in anthracene, and that deuterium substitution causes a threefold reduction in the transition probability for radiation-less decay of the triplet. The effect is, however, far smaller than the effect in other polynuclear hydrocarbons which have higher triplet energies, deuterium substitution in naphthalene increasing the phosphorescence lifetime by an order of magnitude[4], and in pyrene[6] by a similar factor. Such comparisons are, of course, only valid if vibrational perturbations in the polynuclear hydrocarbons do not affect the radiative transition probability. Consideration of the nuclear co-ordinate dependence of the transition moment for the phosphorescence process:

$$\vec{M}_{TG} \propto < T_{\pi,\pi^*}|H_{s\text{-}o}|S_{\sigma,\pi^*} > < S_{\sigma,\pi^*}|\vec{r}|G >$$

shows that vibronic coupling between triplet and ground state can in fact occur, and in benzene may be relatively important[7]. In polynuclear hydrocarbons, however, vibronic coupling between triplet and ground state is of secondary importance: the phosphorescence emission polarization is pure out-of-plane throughout the spectrum[8], which indicates that spin–orbit coupling with upper σ,π^* singlets is the primary mechanism for the radiative transition.

The results also show that in the rigid matrix used, the radiation-less transition probability is virtually independent of temperature and that the effect of deuterium substitution is completely independent of temperature. The difference between the value of 48 msec for the lifetime of the protonated anthracene triplet in lucite at 77° K and the value of 95 msec quoted by Hilpern, Porter and Stief[1] for the same triplet in isopentane at 77° K is most likely a medium effect, as the viscosity of lucite is about 10^{15} poise at room temperature—thus bimolecular quenching processes at 77° K will therefore be negligible. It would in fact be surprising if the radiation-less mechanism were completely intramolecular and not subject also to solvent perturbation.

This work was supported by the U.S. Atomic Energy Commission. I thank Dr. M. A. El-Sayed for helpful discussion.

Chromogenicity of Sakaguchi-reactive Compounds, Monosubstituted Guanidines and Histidine

THE chemistry of the Sakaguchi reaction—between arginine, *l*-naphthol and alkaline hypochlorite—is not known. As originally described 40 years ago[1], this sensitive reaction fortuitously revealed itself as a red coloration which slowly developed and faded. By substituting hypobromite[2] for hypochlorite, almost instantaneous colour development was effected, and more recently Szilagyi and Szabo[3] achieved an improvement in the reproducibility of the reaction with the aid of *N*-bromosuccinimide (BSI)—a more stable source of available bromine.

Sakaguchi[4] also observed that the *l*-naphthol could be replaced by 8-hydroxy-quinoline (OHQ), in which case an orange-yellow colour is produced, and Satake and Luck[5], using OHQ, were able to develop reasonably stable colours from arginine. However, I have found that at normal laboratory temperatures a reagent blank reaction slowly develops, which compensates for the slow disappearance of the Sakaguchi chromogen.

In the absence of Sakaguchi-reactive compounds, bromination of *l*-naphthol or OHQ in N sodium hydroxide results in a yellow coloration. This reaction is inhibited by an increase in the concentration of bromide, a decrease in *l*-naphthol concentration or a low temperature. If a strongly alkaline solution of OHQ (2·8 μmoles) and aqueous BSI (5·6 μmoles) are mixed together and allowed to stand for a few seconds, no colour is obtained on adding the mixture to an arginine solution, although the addition of more BSI will result in a pink colour. Apparently OHQ (or *l*-naphthol) competes with the guanidine derivative for bromide, and the higher the temperature the more successfully does it do so (see Table 1). For this reason, a fairly stable and low temperature (0–5° C) is essential for accurate and reproducible arginine analysis. This was stipulated by Sakaguchi[1,4], although the condition has been ignored in more recent attempts[5,6] to adapt the reaction for quantitative analysis.

Amino-acids have been shown to inhibit the Sakaguchi reaction[7]. It can be demonstrated, however, that small amounts (0·05–0·2 μmoles) of many amino-acids intensify the colour reaction developed from 1 ml. 0·01 mM arginine with *l*-naphthol (2 ml., 0·25 mM) and BSI (1 ml., 2·5 mM)

Table 1. EXTINCTION COEFFICIENTS OF SAKAGUCHI REACTION MIXTURES

	Arginine (μmoles)				
	0	0·025	0·05	0·10	0·15
Method *A*

30	81	190	288	475	615

A, Arginine solution (1 ml.): 1·0 mM OHQ (2 ml.); 5·0 mM BSI (1 ml.).
B, Arginine solution (1 ml.): 0·25 mM *l*-naphthol (2 ml.); 2·5 mM BSI (1 ml.).

or with OHQ (2 ml., 1·4 mM[5]) and BSI (1 ml., 5 mM). The increase in colour occurs with glycine and with taurine, and is most marked with lysine and ornithine. It is also found with ethylene diamine. No such effect on the arginine reaction is seen with similar small amounts of cystine, glutamine, citrulline, glucosamine, creatinine, urea or EDTA. The group responsible for the colour-enhancing effect appears to be $-CH_2.NH_2$. A larger amount (1–5 μmoles) of any amino-acid and also of glutamine, cytosine, guanidine and bilirubin may remove bromine and thereby decrease colour production from 1 ml. 0·01 mM arginine; adenine, EDTA and haematin are without influence.

Histidine also reacts under similar conditions with alkaline *l*-naphthol and BSI to give a rose-red colour (λ_{max} : 495 nm). This reaction appears not to have been previously reported. It is about twenty times less sensitive than the arginine reaction. It occurs when hypochlorite is used as the oxidizing agent, as in the original technique of Sakaguchi[1]. It does not occur in the absence of *l*-naphthol (or alternatively OHQ), and thus it differs from the Knoop reaction[8] in which bromination of histidine at *p*H 1 produces a similar coloured product. The histidine colour, but not the arginine colour, is intensified by the addition of a few μmoles of a cupric salt. Neither urocanic acid nor histamine, which gives a positive Knoop reaction[9], yields colour in the Sakaguchi reaction.

With high concentrations of OHQ (for example, 2·8 moles per 5 ml. reaction mixture) lower blank colours develop than with similar concentrations of *l*-naphthol[5]. However, with smaller amounts of *l*-naphthol (0·25–0·5 moles), that is, about one-fifth that used by previous workers, I find there is no blank colour. Furthermore, at the lower *l*-naphthol reagent levels the pink arginine colour is always more intense than the yellow colour given by OHQ for the same concentration of arginine, and a two- to three-fold increase in the sensitivity of the original reaction may readily be achieved.

The monosubstituted guanidine compounds, methyl guanidine, *l*-guanidino acetate, *l*-guanidino butyrate and octopine (*N*-(*l*-carboxyethyl)arginine), are known to show a similar colour reaction to arginine[1,2]. The molar chromogenicity of these and some other compounds is indicated in Table 2. Not all monosubstituted guanidine derivatives are 'Sakaguchi-reactive'. Canavanine, for example, yields no coloured product. Under optimum reaction conditions, methyl guanidine yields the most

Table 2. CHROMOGENICITY OF SAKAGUCHI-REACTIVE COMPOUNDS

Compound	No. of guanidine groups	No. of nano-moles compound required to give colour*
Albumin, human	24	1·5
Salmine (mol. wt., 4,000)	20	2·8
Methyl guanidine	1	11
Arginine	1	18
l-Guanidino acetate	1	36
l-Guanidino butyrate	1	36
Octopine	1	36
Streptomycin	2	40
Dicyandiamidine	1	140
Histidine	0	440

* Optical density of 0·100 at 510 nm, 1·5 cm given by arginine solution (2 ml.), alkaline *l*-naphthol solution (2 ml.), bromosuccinamide solution (1 ml.) at 5° C.

colour, while the Sakaguchi product of human albumin has a molecular extinction per guanidine group equal to that of *l*-guanidino acetate and is not increased by trace amounts of copper.

These observations were made at the Regional Urological Centre, Liverpool, during the course of a study of blood serum amidine transferases, full details of which will be published elsewhere. The work was supported by a grant from the Department of Surgery, University of Liverpool.

BIOCHEMISTRY

Infra-red Spectroscopy of Tissues in the 700–400 cm^{-1} Region

As part of the study of the far-infra-red spectroscopy of biological materials, the spectra of various tissues were examined to determine if any unique absorption bands were present. Previous investigations of the infra-red spectroscopy of tissues[1] did not include this region. These results represent the extension of infra-red studies on tissue into the region of 700–400 cm^{-1}. The tissue examined included samples of bone, various rat tissues, and human cerebrospinal fluid.

The samples of bones were obtained from human femoral diaphysis and were treated in various ways: sample 1 was heated to 650° C for 8 h; sample 2 was treated in an autoclave[2]; sample 3 was treated with glycol[3]; sample 4 was treated with ethylene diamine[4]. A sample of ossein was prepared by decalcification of this bone sample with 2 per cent nitric acid for 24 h. The rat tissues were prepared by lyophilization of homogenates of the tissue immediately after removal from the animal. They were then stored until they were used in a desiccator as dry powders. The cerebrospinal fluid was removed from seven human patients with various neurological diseases. Immediately on receipt, the fluids were lyophilized without removing the salts normally present.

All samples were examined as caesium bromide disks. The caesium bromide was prepared as suggested by Bentley *et al.*[5]. The disks were prepared by mixing the sample and the caesium bromide in 'Wig-*L*-Bug' for 15 sec. In general, the disks contained about 10 mg per 380 mg of the bromide. The mixture was then pressed for 2–4 min under vacuum. The infra-red spectra of the disks were run on a Perkin Elmer model 21 infra-red spectrophotometer equipped with a caesium bromide prism. It was flushed with nitrogen to remove carbon dioxide and water and calibrated using carbon dioxide and the water bands in this region.

The bone samples show absorption in this spectral region that would be expected for inorganic materials (Fig. 1). Comparison with the data of Miller *et al.*[6] indicates that the bands at 700, 600 and 560 cm^{-1} can be ascribed to the inorganic components of bone, phosphate and calcium carbonate (Table 1). The various samples of bone all showed the same spectrum, which indicates that

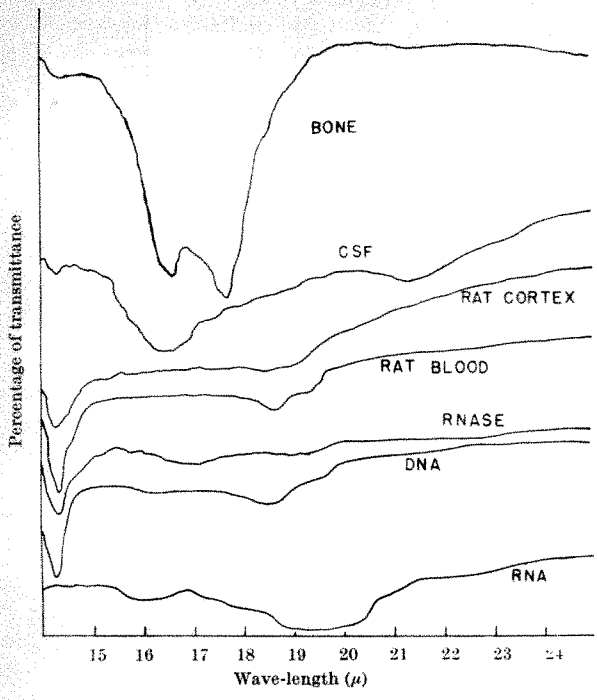

Fig. 1. Infra-red spectra of representative tissues and constituents in the 700–400 cm^{-1} region. All in caesium bromide disks

any change in bone due to treatment is not reflected in this spectral region. Ossein shows one large absorption band at 700 cm^{-1}, which is normally found in protein material.

Table 1. INFRA-RED ABSORPTION OF VARIOUS TISSUES AND ASSIGNMENTS*

Tissue	Absorption bands (cm^{-1})		
Bone	700*w* ($CO_3^=$)	600*s* ($PO_4^{\equiv}$)	560*s*
Spinal fluid	700*w* (protein)	600*s* ($PO_4^{\equiv}$)	465*m* ($PO_4^{\equiv}$)
Cerebral tissues†	700*m*		535*w*
Non-cerebral tissue‡	700*m*	676*sh*	535*w*
Ossein	700*m* (protein, DNA)		DNA

* *s*, Strong; *m*, medium; *w*, weak; *sh*, shoulder.
† Cortex, medulla and white matter.
‡ Blood, spinal cord and spleen.

An examination of the spectra of the rat tissues indicates that they fall into two groups (Fig. 1). The only difference between the two groups is a shoulder that occurs at 676 cm^{-1} (Table 1). For comparison, the spectra of a protein (ribonuclease), ribonucleic acid, and deoxyribonucleic acid are included. The tissue band at 700 cm^{-1} is found in protein, and the bands at 535 and 700 cm^{-1} are also found in deoxyribonucleic acid. Thus, the tissue band at 700 cm^{-1} results from the absorption by proteins and deoxyribonucleic acid, and the band at 535 cm^{-1} from deoxyribonucleic acid only. The nature of the 676 cm^{-1} band is still obscure.

The spectra of the lyophilized cerebrospinal fluid generally show bands at 600 and 465 cm^{-1}, and a band occurs at 700 cm^{-1} in some of the samples (Fig. 1). The bands at 600 and 465 cm^{-1} are associated with the inorganic components of the fluid (phosphate). The band at 700 cm^{-1} is related to the protein concentration in the fluid. To test this, several samples were redissolved in water, and the ultra-violet absorption measured. The specimens in which a peak appears at 700 cm^{-1} also show absorption in the ultra-violet at 280 mμ. This clearly confirms that the 700 cm^{-1} band is related to the protein concentration.

I thank Dr. S. Bakerman, University of Kansas Medical Center, for the gift of the bone and ossein samples, and J. Charbonneau for assisting me in obtaining the infra-red spectra. This investigation was supported by research grants from the U.S. Public Health Service.

Isolation of β-Naphthol from Urine after its Application to Skin

LOCAL applications of β-naphthol to the skin have been used in dermatology since its introduction by Ludwig and Kaposi in 1881. Although it has been known for many years that toxic effects have followed the application of β-naphthol to the skin of children[1], there has previously been no definite evidence for the absorption of this compound through the skin.

A β-naphthol peeling paste formed part of the treatment in a series of fourteen cases with acne vulgaris in whom urinary steroid excretion was being investigated. Considerable interference was observed in these steroid assays. Further investigation showed that this was associated with the presence of β-naphthol in the urine. A relatively large quantity of this phenol was isolated and identified in the urine of a young man after the application of β-naphthol to his skin. It was estimated that about 3–4 g of the compound was applied to about 20 per cent of the surface area of the patient[2] for 12 h. After this treatment a complete 48-h specimen of urine was collected.

The urine was extracted once with an equal volume of benzene and then hydrolysed with a β-glucuronidase preparation. After incubation at 37° C overnight, the urine was then extracted with ether and the acidic fraction removed by the method of Brown[3]. These extracts contained one main component when small portions were chromatographed on paper and thin layers of silica gel. This compound behaved chromatographically like β-naphthol and produced a blue colour with Folin and Ciocalteau's reagent. The residues obtained from the extracts were chromatographed on 10 × 1-cm columns of alumina with a Brockman activity of 1, to which 0·1 ml. of water per gram of alumina had been added. The columns were eluted with benzene; the 10-ml. fractions of the eluate containing phenolic material according to Folin and Ciocalteau's reagent were then pooled and evaporated to dryness. The residues were then crystallized from benzene : light petroleum (90 : 10 by volume) and recrystallized from benzene : light petroleum (10 : 90 by volume). A total of 0·3759 g of white crystals was obtained. The melting point corresponded to that of β-naphthol 122°–123° C (uncorrected) and was not depressed by admixture with authentic β-naphthol. The infra-red absorption spectrum in the region 625–4,000 cm^{-1} (16·0–2·5μ) was determined in carbon disulphide on a Perkin–Elmer 237 infra-red spectrophotometer; the absorption spectrum was identical with that of authentic β-naphthol. From all this evidence it was concluded that the material was indeed β-naphthol.

Some interference with steroid assays was observed in all fourteen patients who had been treated with β-naphthol. This interference was removed by thorough alkaline extraction of the phenol in the initial urinary extract. In order to remove this compound from diethyl ether, benzene and toluene, two extractions with one volume of N sodium hydroxide were required. When one wash of the solvent with 0·1 volume of 0·25 N sulphuric acid was used after

the alkaline extraction, only two washes with 0·1 volume distilled water were necessary to obtain neutral washings. Addition of this procedure to urinary neutral steroid methods with less efficient removal of acids and phenols[4,5] abolished the interference associated with the presence of β-naphthol in the urine.

We thank Miss Brenda Shanks for her technical assistance during this work.

Nuclear Magnetic Resonance Spectrum Changes accompanying Rigor Mortis

INFORMATION on the behaviour of water in biological cells is essential to developing an understanding of the roles of that ubiquitous molecule in biological systems. This communication reports observations of nuclear magnetic resonance spectra of cod muscle over a period of time from shortly after death to the cessation of rigor mortis, which suggests that cellular water suffers a loss in structure and an increase in mobility during this time.

Two codfish (*Gadus morhua*), each weighing approximately 4 lb., were filleted within 10 min of death. Three core samples of the dorsal muscle fillet were obtained using a modified core cutting nuclear magnetic resonance sample tube. Nuclear magnetic resonance spectra were run in a 'Varian *A*-60' high resolution nuclear magnetic resonance spectrometer (14·092 kG field) adjusted for optimum field homogeneity, and 'ringing' with distilled water. The probe temperature was +15° C. Spectra of the three samples were taken at approximately 45, 280 and 380 min after death.

At 150 min after death the fillets from which samples were removed were stiffened and had a rough, hardened texture. Rigor mortis subsided 5·5 h after death, at which time the fillet tissue had softened and was exuding clear liquid.

The muscle spectra all consist of a single symmetrical water peak which is four to eight times broader than that produced by pure water. The peak width, taken at 0·6 of the peak maximum, decreases by 14–22 per cent in approximately 6 h, as shown in Fig. 1. Peak area does not change appreciably.

Broadening of the nuclear magnetic resonance absorption peak of water in the presence of proteins, cellular material, starches and other materials has been previously reported[1–5]. Broadening is evidence of a decrease in transverse relaxation time ($T_2 = f[1/\text{peak width}]$), and reduction in proton mobility such as might result from adsorption or bonding of water by cell protein[1,6]. Bratton *et al.*[4] have reported that a reversible narrowing of water peak width (and increase in T_2) accompanies the contraction of living frog muscle, and suggest an explanation in terms of change in extent of the 'bound water' phase. Reduction in the water-holding capacity of muscle in rigor mortis is well established[7].

The core-cutting sample tube is essential for producing geometrically uniform samples and reproducible spectra, and may be useful to other nuclear magnetic resonance investigations of semi-solid materials. The tubes are made from 'Varian' 5-mm nuclear magnetic resonance sample tubes, by cutting off the sealed end and grinding a scalloped cutting edge in its place. The tube cuts a uniform cylindrical core when screwed into fish muscle. The core remains in the tube, the lower end of which is then sealed with a 5-mm plug of putty. The water contents of sample cores have been estimated at 81 ± 2 per cent by comparing their absorption peak areas to samples of known water content.

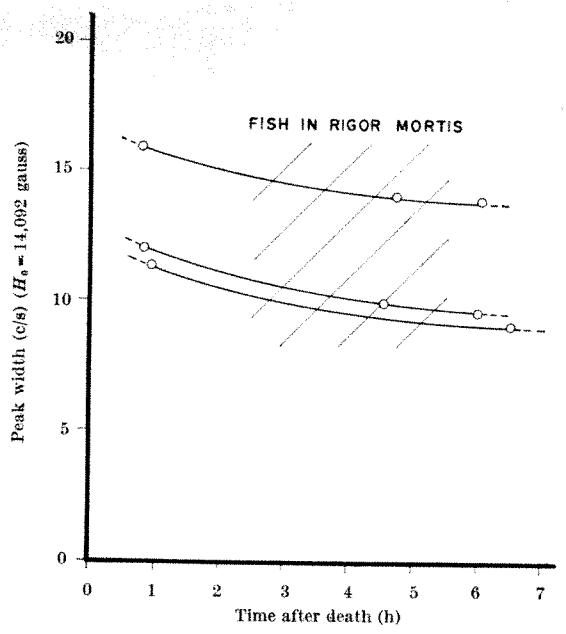

Fig. 1. Nuclear magnetic resonance peak width plotted against time after death

Two-dimensional Thin-layer Chromatography of the Major Mononucleotides of Ribonucleic Acid

THIN-LAYER chromatography, by virtue of its convenience, sensitivity, and short developing time, is useful for the separation and quantitation of many types of nucleic acid derivatives[1–3]. This communication describes the method used by this laboratory for the separation of the products of alkaline hydrolysis of ribonucleic acid.

Preparation of thin-layer plates: 15 g of '*MN*-cellulose powder 300*G*' (Macherey and Nagel, Düren, Germany) is mixed with 90 ml. of distilled water by shaking for 1 min. Clean 20 × 20 cm glass plates are coated with the use of a Desaga-Brinkmann 'Fixed-Thickness Applicator'. The plates are dried in air for 30 min and the cellulose is activated by heating for 10 min at 110° C. The plates are washed with water and air-dried before they are used.

Chromatography procedures: RNA is hydrolysed by incubation either for 18 h at 37° C in 0·3 N potassium hydroxide, or for 48 h at 60° C in 10 per cent piperidine. The potassium is removed by precipitation with perchloric

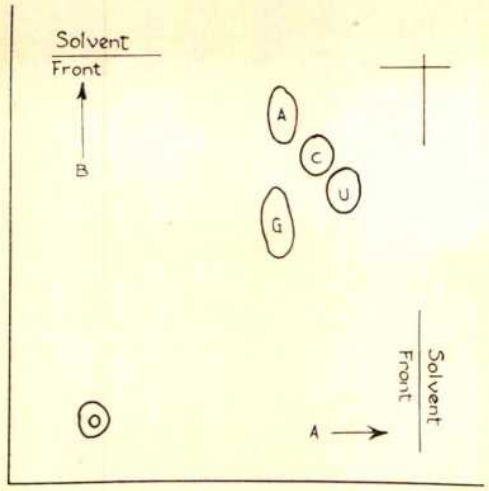

Fig. 1. Diagram of two-dimensional separation of nucleotides in solvents *A* and *B* as described in the text. *A*, AMP-2′,3′; *C*, CMP-2′,3′; *U*, UMP-2′,3′; *G*, *GMP*-2′,3′; O, origin

acid; the piperidine being volatile does not have to be removed. The nucleotide solution is applied with a micropipette to a spot 3 cm from two adjacent sides. The following solvents are used: *A*, Isopropanol/hydrochloric acid/water (85·0 : 20·5 : 19·5, v/v). *B*, Isobutyric acid/ammonium hydroxide/water (58·0 : 3·8 : 38·5, v/v). Development times at room temperature are 2·5 h for solvent *A* and 1·5 h for solvent *B*. The plates are thoroughly dried in air between developments.

The spots are located by their ultra-violet absorption (Fig. 1), and the nucleotides are eluted from the powder in 0·01 N hydrochloric acid. The R_F values under these conditions are given in Table 1.

Table 1. R_F VALUES OF NUCLEOTIDES

	Solvent *A* Isopropanol–hydrochloric acid	Solvent *B* Isobutyric–ammonia
AMP-2′,3′	0·59	0·84
CMP-2′,3′	0·68	0·75
UMP-2′,3′	0·77	0·63
GMP-2′,3′	0·55	0·54

Fractionation of Porcine Macroglobulins

PORCINE serum is particularly rich in macroglobulins: we have found it to contain 8 per cent of components with sedimentation coefficients up to approximately 17 *S* (Fig. 1). Gel filtration with 'Sephadex *G*200' offers a useful means for the preparation of macroglobulins[1–3] and preparative zone electrophoresis allows a good separation of the $\gamma_1 M$ and $\alpha_2 M$ globulins.

Serum samples were taken from slaughterhouses. 1 g of the 'globulin' fraction, obtained by precipitation with 2 M ammonium sulphate, was fractionated in a column (5 × 110 cm) containing approximately 70 g of 'Sephadex *G*200' (Pharmacia, Lot No. *To* 3016). Elution buffer consisted of 0·02 M sodium phosphate–0·08 M sodium chloride, *p*H 7·5. Protein appeared in the eluent in two main peaks (Fig. 2*a*); the localization of $\gamma_1 M$ and $\alpha_2 M$

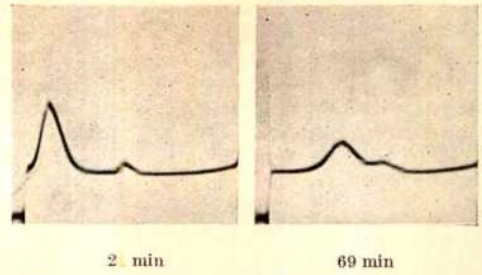

Fig. 1. Ultracentrifuge patterns of porcine serum. Pictures were taken after 21 and 69 min at 59,780 r.p.m. Peaks move from left to right on sedimentation with coefficients of 4·2 *S* (75 per cent), 6·6 *S* (17 per cent) and 17 *S* (8 per cent)

globulins in peak I was confirmed by immunoelectrophoresis, performed according to the micro-modification of the method of Scheidegger[4] with rabbit anti-porcine serum. The fractions making up this peak were pooled and precipitated with ammonium sulphate. The precipitate was dissolved in 0·05 M barbital buffer to make 20 ml.; 4 ml. were applied to a trough cut in a 'Pevikon' block (35 × 30 × 1·2 cm), 7 cm from the cathodal end, for electrophoresis fractionation. Electrophoresis was allowed to proceed at 500 V for 30 h at 0°–2° C in a 'Pherograph' apparatus.

After electrophoresis, the block was sliced transversely into 1-cm segments; each segment was eluted with 15 ml. of 0·9 per cent sodium chloride and the fractions were analysed for protein content by the method of Lowry[5].

The electrophoresis pattern was characterized by two peaks (Fig. 2*b*). It can be seen that a good separation of

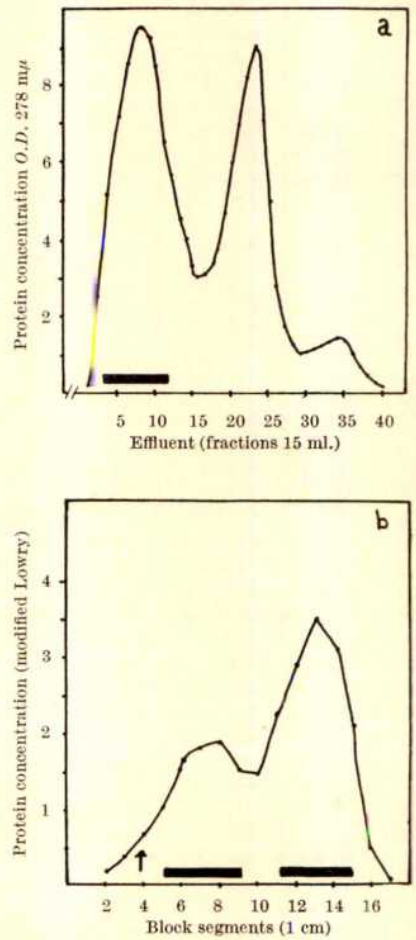

Fig. 2. (*a*) Gel filtration chromatogram of porcine serum globulins. (*b*) Zone electrophoresis in 'Pevikon' of proteins eluted as peak I from gel filtration

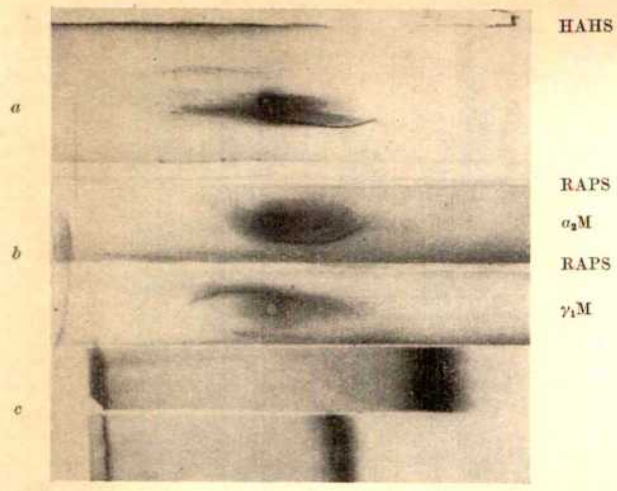

Fig. 3. Immunoelectrophoresis of peak I from (*a*) gel filtration and (*b*) fractions from the electrophoretic separation. RAPS, rabbit anti-porcine serum; HAHS, horse anti-human serum. (*c*) Cellulose acetate electrophoresis of fractions 8 and 13 from zone electrophoresis

the two macroglobulins had been accomplished: the γ_1M (segments 5–9) and the α_2M globulin (segments 11–15) appeared to be homogeneous (Fig. 3*b*). These fractions, examined in the analytical ultracentrifuge, were found to contain components with sedimentation coefficients of approximately 18 *S*. Immunoelectrophoresis of these porcine serum macroglobulins with horse anti-whole human serum (Central Laboratory of The Netherlands Red Cross Blood Transfusion Service, No. 2116) showed that porcine γ_1M globulin cross-reacted antigenically with human γ_1M globulin (Fig. 3*a*).

Changes in Muscular Glycogen Synthetase Activity following Denervation

Hines and Knowlton[1,2] have demonstrated a decrease of muscular glycogen levels after denervation. The biochemical mechanism underlying this phenomenon, however, is not clearly understood. It does not seem to be explained by an activation of phosphorolytic processes, as phosphorylase was shown by Huls and Leonard[3] to decrease in the skeletal muscle after nerve transection.

Bass[4] has reported a lower incorporation of glucose-^{14}C into the glycogen of denervated muscular tissue, which suggests that it might be possible to explain the loss in glycogen by an impairment of the biosynthetic processes.

In order to investigate further the turnover of glycogen in denervated muscle, we studied the activity of glycogen synthetase (uridindiphosphoglucose-glycogen transglucosylase) at various intervals after nerve section. Because Villar-Palasi and Larner[5] were able to show that glycogen synthetase is rate-limiting in glycogen synthesis, it might be possible to account for the loss of glycogen observed by a lowering of its activity.

Denervation was obtained by cutting the right sciatic nerve of white rats weighing about 250 g under light ether anaesthesia. The animals were killed by decapitation at various time intervals. Both recti femuri were excised and immediately chilled until determinations were performed. Spinal cord transection was performed under ether anaesthesia at the C6 level; fasted unoperated rats were used as controls.

Glycogen synthetase activity was determined according to the method developed by Leloir and Goldemberg[6], and non-collagen nitrogen according to that by Johnson[7]. The results obtained after denervation are presented in Table 1. Starting a few hours after cutting the nerve, the enzymatic activity steadily decreased until it reached about 30 per cent of the control level after 2 months.

After transection of the spinal cord (Table 2), a fall of glycogen synthetase activity was observed 24 h after surgery: eventually the enzymatic levels return to normal. Other experiments (not reported here) have shown that in this case the course of enzymatic variations is much more variable and may depend on the strain of the animals used.

Table 1

Time after denervation	No. animals	Glycogen synthetase*
—	20	2,031 ± 30·4
2 h	3	1,568 ± 79·7
24 h	4	1,250 ± 59·9
3 days	3	1,029 ± 4·6
5 days	5	991 ± 32·1
10 days	5	974 ± 33·1
15 days	5	910 ± 45·6
30 days	4	900 ± 20·6
60 days	3	696 ± 10·3

* Expressed as γ of UDP formed per 1 mg of nitrogen in 15 min at 37° C ± *S.E.* of the mean.

Table 2

Time after cordotomy (h)	No. of animals	Glycogen synthetase*	Per cent
—	20	2,031 ± 30·4	—
24 h	3	1,359 ± 17·7	−33
48 h	3	1,775 ± 44·6	−12·5
72 h	2	1,742 ± 96	−14

* Expressed as γ of UDP formed by 1 mg of nitrogen in 15 min ± *S.E.* of the mean.

It should be pointed out that, from a biochemical point of view, only form *D* (according to Rosell-Perez *et al.*[8–10]), which is fully active in the presence of glucose-6-phosphate, was determined in our experiments; no attention was paid to the relationships existing between this and the *I* form—that is, the one acting in the absence of glucose-6-phosphate. It would be advisable to undertake an investigation of the rate between the *I* and *D* forms, and of the process of interconversion $I \leftrightarrow D$ under our experimental conditions (denervation and spinal transection) because, as Danforth[11] has recently pointed out, this process in muscular tissue seems to be influenced by several experimental conditions such as nerve stimulation or administration of epinephrine.

From a biological point of view, our results would seem to suggest the existence of a nervous control of the muscular levels of glycogen synthetase. Although its exact mechanism is not understood, it is evident that a fully efficient peripheral innervation is required for the maintenance of normal levels of enzymatic activity in muscle. The results obtained with cordotomized animals indicate that spinal centres are probably independent of higher nervous control in regulating the muscular glycogen synthetizing activity. The short-lived fall of enzymatic activity observed immediately after spinal transection could be ascribed to the spinal shock following surgery.

This hypothesis is, at the present state of our research, only a tentative one aimed at interpreting our own experimental findings. Further investigations of the physiological and biochemical factors underlying the

phenomena observed should throw some light on the validity of this hypothesis.

Gigartinine: a New Amino-acid in Red Algae

A STUDY of free amino-acids and related compounds in a red alga, *Gymnogongrus flabelliformis*, revealed the presence of two different substances, both containing a guanylurea moiety. One was afterwards identified as 1 - amidino - 3 - (3 - carboxypropyl)urea or γ - guanylureido)butyric acid (I)[1], and we propose here to call it 'gongrine'. It is now reported that the other compound has been designated 'gigartinine' and shown to be N^5-(amidinocarbamoyl)-L-ornithine or L-α-amino-γ-(guanylureido)valeric acid (II).

After removing gongrine as precipitate from aqueous ethanolic extracts of the alga, the filtrate was passed through a column of 'Dowex 50 *X*-8'. The basic amino-acids were eluted from the cation exchange resin with ammonium hydroxide and the gigartinine was freed from the small quantity of arginine present by repeated recrystallization of its nitrate from 50 per cent aqueous ethanol. The nitrate was obtained as thin plates, melting at 197° C (uncorrected). Elementary analysis gave: carbon, 30·23 per cent; hydrogen, 5·70 per cent; nitrogen, 29·73 per cent. $C_7H_{16}O_6N_6$ requires: carbon, 30·00 per cent; hydrogen, 5·76 per cent; nitrogen, 29·99 per cent. $[\alpha]_D^{22}$ + 7·5° (c = 2·0 in water).

The ultra-violet spectrum (in 0·1 N sodium hydroxide) has a maximum at 225 mμ (ε = 23,000). The infra-red spectrum (in 'Nujol') shows bands at 1,530, 1,610, 1,680 and 1,725 cm^{-1}, in the region of 1,500 ~ 1,800 cm^{-1}.

Gigartinine gave an orange reaction with Sakaguchi's reagent, unlike the orange-red given by arginine, and with ninhydrin the typical violet colour, the intensity of which was 0·94 in leucine equivalent[2]. Carbon dioxide, guanidine and L-ornithine were obtained on degradation at 120° C either in distilled water or in 3 N hydrochloric acid; guanylurea and succinic acid on oxidation with potassium permanganate; citrulline and ornithine on hydrolysis with barium hydroxide. Each degradation product except carbon dioxide was isolated in appropriate forms and identified by melting point, elementary analysis, infra-red spectrum and other properties, respectively.

All these properties are in agreement with formula II.

(I)

(II)

A paper chromatographic survey on the distribution of these guanidino compounds in algae was carried out by using the basic fraction of aqueous ethanolic extracts, partially purified by ion exchange chromatography. The R_F values were 0·24, 0·32 and 0·70, respectively, for arginine, gigartinine and gongrine in a solvent system consisting of butanol/acetic acid/pyridine/water (4 : 1 : 1 : 2 by volume). Among fifteen species of red algae tested, gigartinine was found in the following seven species: *Gelidium amansii*, *Grateloupia livida*, *Polyopes polyideoides*, *Carpopeltis flabellata*, *Hypnea japonica*, *Gracilaria textorii* and *Gymnogongrus flabelliformis*. An appreciable quantity of gongrine was recognized only in the last species. These guanylureido compounds, however, were detected neither in brown algae (seven species) nor in green algae (three species) examined.

Hyperin and Nonacosane Constituents of Tutsan

I HAVE extended my investigations on tutsan (*Hypericum androsaemum*)[1] and have obtained from its leaves samples of hyperin (3-D(+) galactosidylquercetin)[2-4], and from its berries nonacosane[5].

Hyperin. The dried leaves were successively extracted with petroleum ether (80°–100° C), diethyl ether and methanol. The methanolic extract, when evaporated under reduced pressure, yielded a yellow solid which on repeated crystallization from ethanol furnished a yellow crystalline material, m.p. 235° C (*d*). An infra-red absorption spectrum[6] was obtained of the anhydrous vacuum-dried material and was found to be identical with that of an authentic specimen of hyperin (3-D(+) galactosidylquercetin), the latter also showing no depression of melt when admixed with the extracted solid.

Before these comparisons were made, the glycoside was hydrolysed in 2 per cent aqueous sulphuric acid to yield a mixture of quercetin and D(+) galactose. Quercetin was identified by acetylation to the penta-acetyl derivative, m.p. 197° C, which showed no depression of melt when admixed with an authentic specimen of penta-acetylquercetin. Both samples had identical infra-red absorption spectra. D(+) galactose was isolated from the aqueous solution by forming the yellow crystalline phenylosazone, m.p. 201° C, which crystallized from aqueous ethanol in an identical manner to that of an authentic specimen of D(+) galactose phenylosazone. The two had identical infra-red absorption spectra and there was no depression of melt when they were mixed.

Nonacosane. De-seeded unripe berries were distilled at oil bath temperature 220° C/12 mm for 5 h. A wax-like solid remained in the aqueous distillate. On crystallization from aqueous ethanol, this solid furnished a colourless solid, m.p. 62·5° C. An infra-red absorption spectrum of the sample (potassium bromide disk) showed absorption bands, which indicated methyl and methylene vibrations, together with two bands at 720 cm^{-1} and 730 cm^{-1}, which indicated the presence of —$(CH_2)_n$—. Thus it was concluded that the extracted material was a straight-chain hydrocarbon of high molecular weight. The hydrocarbon was subjected to mass spectroscopy, the resulting scan showing that the C_{29} molecular ion was intense although small abundances of C_{30}, C_{31} and C_{32} were present; however, the C_{29} peak was the major component at high mass and thus the chief constituent of the extract was nonacosane, $C_{29}H_{60}$. The small impurities of other hydrocarbons may account for the observed melting point being slightly lower than that cited (64° C) in reference sources.

I thank the Associated Electrical Industries, Ltd., for kindly effecting the mass spectroscopy, and Dr. E. Von Rudloff, Prairie Laboratory, Saskatoon, Canada, for supplying me with an authentic specimen of hyperin.

Detection and Estimation of Ochratoxin *A*

THE recent isolation[1] of ochratoxin *A* from *Aspergillus ochraceus* Wilh., which has a widespread natural distribution, made the development of a rapid method for the detection and estimation of the mycotoxin desirable. The following methods have been used during screening of fungal strains and media for toxin production.

A 20-g sample of mouldy material in a 100-ml. Soxhlet apparatus is extracted with 1 : 1 chloroform–methanol for 12 h. The extract is diluted with an equal volume of chloroform, extracted with 0·1 M aqueous sodium bicarbonate, and the toxin extracted with chloroform from the aqueous phase after acidification with 2 M hydrochloric acid. After removal of the solvent *in vacuo*, the residue is dissolved in 5 ml. chloroform and a 20-μl. portion spotted on a silica thin-layer chromatoplate together with a standard sample of pure ochratoxin *A*. The chromatoplate is developed in 3 : 1 benzene–acetic acid and inspected under ultra-violet light. Ochratoxin *A* appears as a green fluorescent spot at R_F 0·5. Blue-green and pale green fluorescent spots at R_F 0·35 and 0·65 indicate the presence of ochratoxins *B* and *C*, the dechloro and the ethyl ester derivatives of ochratoxin *A* (ref. 2). On spraying with 0·1 N aqueous sodium hydroxide, ochratoxins *A*, *B* and *C* exhibit a bright blue fluorescence. The ochratoxin *A* content of the original material can be estimated by comparing the size of the observed spot with that from a standard solution of ochratoxin *A*. In this manner 0·1 p.p.m. ochratoxin *A* added to maize meal could be detected.

In cases where unknown substances interfere with this method, or where additional proof is desirable, the results can be verified by thin-layer chromatography on silica using 12 : 2 : 1 benzene–methanol–acetic acid (giving a green fluorescent spot at R_F 0·6) or paper chromatography on Whatman No. 1 paper with the system 3 : 1 propanol–3 N aqueous ammonium carbonate (giving a blue fluorescent spot at R_F 0·65).

Elevation of Alkaline Phosphatase Activity in the Intestine of the Chick Embryo by Actinomycin *D*

DURING the development of the mouse, alkaline phosphatase activity in the duodenum rises sharply before birth, falls back slightly, and then increases twenty-fold or more between 15 and 20 days[1]. This second rise is accelerated rather than retarded by inhibitors of RNA and protein synthesis[2,3]. Injection of actinomycin *D*, an inhibitor of DNA-dependent RNA synthesis[4], into 9-day-old mice more than doubles their phosphatase activity within a 54 h period[3], and the enhanced activity shows the normal increased preference for phenylphosphate over beta-glycerophosphate. Because these effects were obtained at a period of development when a considerable amount of phosphatase activity is already present, we thought it would be interesting to investigate the effect of actinomycin at a time when phosphatase activity first appears.

In the duodenum of the chick embryo, alkaline phosphatase activity is first found in the brush border of the epithelial cells at about 17 days[5,6]. By 21 days the adult level of phosphatase activity is reached—the enzyme activity has undergone a 100-fold increase after its initial appearance[5]. The effect of actinomycin *D* on this increase has been investigated during the 16–19-day interval, during which the enzyme activity increases about ten-fold. It has been found that phosphatase activity in the chick embryo duodenum in these stages is elevated two to three times above the normal levels by actinomycin injection at 16 days.

Single 5 μg doses of actinomycin *D* (obtained from Merck, Sharp and Dohme) dissolved in 0·1 ml. of 0·9 per cent saline were injected into a vein in the chorio-allantoic membranes of 16-day-old chick embryos; controls received an equal volume of saline alone, or were not injected. Embryos were killed after 1 or 3 days (that is, at 17 and 19 days of incubation); the duodenal loop was removed, weighed, and homogenized in iced distilled water with a 'Ten Broeck' grinder. Homogenates were assayed for protein content[7] and for enzyme activity on phenylphosphate (PhP) and beta-glycerophosphate (BGP) as described by Kato[8], except that 0·2 M sodium carbonate–sodium bicarbonate buffer was used in the incubation mixture.

Table 1. EFFECT OF ACTINOMYCIN *D* INJECTED AT 16 DAYS ON ALKALINE PHOSPHATASE ACTIVITY OF THE DUODENUM OF THE CHICK EMBRYO

Injection	Day of killing	No.	Specific activity* (mean and range)	PhP† / BGP	Protein concentration (μg/mg fresh weight)
Saline	17	5	45·1 (13·5–84·6)	2·62	97·5
Actinomycin	17	7	159·7‡ (77·1–266)	6·59	97·5
None	19	7	402·6 (267–543)	7·98	90·7
Saline	19	14	372·0 (141–600)	7·39	89·4
Actinomycin	19	11	947‡ (301–2,203)	8·25	94·8

* μg phosphorus released from PhP per mg protein per 30 min.
† Ratio of the amount of phosphorus released from PhP to amount of phosphorus released from BGP.
‡ For actinomycin injected versus saline control, $P < 0·001$ as determined by Student's *t* test (ref. 10).

The results of these experiments are given in Table 1. In 17-day-old embryos which received actinomycin 24 h earlier, the duodenal phosphatase activity is more than three and a half times that of saline-injected controls. Even at 19 days the enzyme activity is more than twice the normal level for that stage. The increases in both 17- and 19-day-old embryos are highly significant. Histochemical investigations of duodena from embryos into which actinomycin had been injected show that the elevated phosphatase activity is localized in the brush border, where it is normally found[5]. Actinomycin treatment elevates phosphatase activity on both substrates tested, but a relatively greater enhancement of activity on PhP was observed, as indicated by the increased PhP/BGP ratio in 17-day-old embryos. This ratio normally rises at the time when phosphatase activity first appears in the apical border of the epithelial cells[8]. The protein content of the duodenum was not lowered by treatment with actinomycin; body-weight was not significantly affected, nor did development appear to be retarded.

The effects demonstrate that the paradoxical effect that actinomycin *D* exerts on the phosphatase activity of the duodenum of the nursling mouse may be elicited also in the chick embryo at a stage before the enzyme has normally begun to appear in the striated border. In the mouse, in which the low activity, low ratio form of the enzyme in the infant intestine is normally replaced during the third week by forms of higher activity and PhP/BGP ratio[9], the enhancing effect of actinomycin and other inhibitors of protein synthesis has been attributed to the inhibition of the synthesis of a repressor protein that is believed to restrain the shift from one form of phosphatase to another[3]. The present results suggest that a similar restraining mechanism may be operating even at a time when histochemical methods reveal no phosphatase in the striated border[5,6]. If this were so, it would seem that in the duodenum of the 16-day-old chick embryo, the enzyme is present in an inactive form, which may be activated later. To examine further this possibility, it is necessary to determine whether direct inhibitors of protein synthesis, such as *cyclo*heximide, would produce the same result as actinomycin *D*, and also to examine the effects of these antibiotics at earlier stages, both *in vivo* and *in vitro*. Such investigations are now in progress.

Production of Carbonyl Compounds by Tomato Fruit Tissue in the Presence of Aliphatic Alcohols

IT is well established that, in the absence of oxygen, many types of plant tissue produce ethanol. Under normal conditions, ethanol, other alcohols and various aldehydes are produced in small amounts by ripening fruits and other plant organs[1–3]. The question whether ethanol is metabolized by plant tissues has, on the other hand, been a source of controversy. In recent years Phillips[4], working with barley seedlings, Wager[5] with peas and Lowe and James[6] with mature carrot disks have found no evidence for appreciable utilization of ethanol. However, Cossins and Turner[7–9] showed that ethanol was consumed by the tissue in germinating peas and was converted initially to acetaldehyde and acetone, followed by the production of organic acids and amino-acids. Homogenates of a variety of germinating seeds were shown[10], by redox indicator, to have alcohol dehydrogenase activity when the normal C_2^-, C_3^- and C_4^- aliphatic alcohols were added as substrates. Less activity was evident in the presence of the normal C_1^- or C_5^-, secondary C_3^- or iso-C_4^-, and tertiary C_4^- or C_5^- alcohols. Recently, Cossins and Beevers[11] showed that carrot disks, corn and pea shoots, potato disks and castor bean endosperm rapidly metabolized carbon-14-labelled ethanol, while apple tissue consumed it very slowly. Their results suggested that acetyl coenzyme-*A* was derived from ethanol and converted to lipids, amino-acids, organic acids and sugars by known pathways.

During a study of ethylene production by tomato fruit tissue kept under sterile conditions (Meigh and Pratt, unpublished data) we observed that ethanol and acetaldehyde were present in the culture tubes. This phenomenon was investigated in greater detail to determine whether these substances arose because of the wound factor introduced in preparation of the tissue portions. However, the rings of tomato pericarp tissue had been prepared with the usual sterile techniques which included the use of alcohol in sterilizing the fruit, tools and the working surfaces in the sterile laboratory. As a result, alcohol vapour inevitably got into the culture medium. When the preparative sterile technique was modified to exclude alcohol from all stages of the procedure, subsequent analysis showed that both ethanol and acetaldehyde were absent from the culture tubes. In this respect, therefore, wounding of the tissue seemed to have no effect, and the production of ethanol and acetaldehyde were artefacts of technique.

In further experiments in which accidental alcohol addition was carefully excluded, but various alcohols were deliberately added, addition of ethanol to tomato tissue resulted in the production of acetaldehyde but no detectable acetone. Addition of *n*-propanol or iso-propanol yielded propionaldehyde or acetone respectively but no other carbonyl compounds. After methanol or *n*-butanol were added, carbonyl products could not be detected.

The identification of the carbonyl compounds was based (*a*) on analysis of the atmospheres in the culture tubes by gas chromatography, comparing the retention times with those of authentic compounds on three columns with stationary phases of varied polarity (silicone oil, tritolyl phosphate and polyethylene glycol 400), and (*b*) on separation by paper chromatography[2] of the 2,4-dinitrophenylhydrazones prepared by addition of an aqueous hydrochloric acid solution of the reagent to the culture solution, followed by extraction of the derivatives with carbonyl-free[12] carbon tetrachloride.

Table 1. PRODUCTION OF CARBONYL COMPOUNDS BY RINGS OF TOMATO FRUIT PERICARP TISSUE*

Substance added†	Sample	Compound identified in gas phase	Estimated concentration (mM) in the culture solution after the designated period of post-treatment gas accumulation‡ 0–16 h	40–56 h
(Ethanol used in sterile procedure)				
Water	Tomato tissue	Ethanol	4·6	3·8
		Acetaldehyde	0·3	0·3
(No ethanol in sterile procedure)				
Ethanol (0·08 M)	Control	Ethanol	22·2	20·4
		Acetaldehyde	0·0	0·0
	Tomato tissue	Ethanol	15·7	14·7
		Acetaldehyde	0·7	0·8
n-Propanol (0·08 M)	Control	*n*-Propanol	24·5	23·8
		Propionaldehyde	0·0	0·0
	Tomato tissue	*n*-Propanol	13·6	11·8
		Propionaldehyde	0·3	0·3
iso-Propanol (0·08 M)	Control	iso-Propanol	26·4	25·7
		Acetone	0·0	0·0
	Tomato tissue	iso-Propanol	16·3	15·4
		Acetone	0·1	0·6

* Each ring of tissue (average weight 1·3 g) was inserted under sterile conditions into a culture tube (19 × 150 mm) containing 1·5 ml. of culture solution (0·25 M glucose, 0·0002 M magnesium sulphate, 0·005 M potassium dihydrogen phosphate and a micromineral supplement based on White's (ref. 13) recommendations) initially adjusted to *p*H 4·5 with potassium hydroxide. The cultures were capped with filter paper and stored in a tube roller for 11 days at 20° C. For analysis of the gas phase, the culture tubes were placed inside larger tubes (29 × 200 mm) closed with soft rubber bungs (net gas phase volume *c.* 80 ml.).

† 0·5 ml. of test solution was added to each culture using sterile technique.

‡ The concentrations in the culture solutions were estimated from the concentrations in the gas phase after allowing about 16 h for accumulation and equilibration; the results from four tubes were averaged. A 1·0 ml. sample of the atmosphere was withdrawn with a hypodermic syringe inserted through the rubber bung and was analysed on a polyethylene glycol 400 column (15 per cent on 60–85 mesh 'Celite' : 4 mm × 184 cm long) at 70° C. For each compound a calibration curve was prepared, relating concentration in the culture solution to the peak height obtained under the standard analytical conditions.

Table 1 shows the results of a typical experiment in which a quantitative estimate of the course of the reaction was obtained. Concurrent determination of the carbon dioxide evolved by the tissue (using gas chromatography

with a silica-gel column) did not indicate any significant difference between the samples.

CYTOLOGY

Variability of Ribosomal Aggregation in Lymphocytes

WE have been studying the fine structure of the bovine lymphocyte as part of an investigation into the effects of prolonged lymphocyte depletion[1]. In the course of this work it was observed that large lymphocytes, which make up most of the cellular component of thoracic duct lymph in the lymphocyte-depleted calf, can be divided rather distinctly into two populations according to the distributions of their ribosomes.

One class of cells contains large numbers of membrane-free ribosomes which are dispersed more or less evenly throughout the cytoplasm, whereas the other class shows prominent aggregation of ribosomes into congeries of five to eight sub-units. This is illustrated in Fig. 1, which shows portions of cytoplasm of two adjacent lymphocytes, one of each type. These cells were obtained from thoracic duct fluid of a lymphocyte-depleted calf which was 7 months old and which had received no deliberate antigenic stimulation. For 16 days this animal was subjected to continuous removal of cells from the thoracic duct lymph by means of a refrigerated, continuous-flow centrifuge, cell-free lymph being returned to the venous system. Specimens of sedimented cells were fixed in glutaraldehyde followed by osmic acid, and sections were stained by lead citrate and uranyl acetate. The great majority of cells present were large lymphocytes, and about a quarter of them contained aggregated ribosomes and three-quarters dispersed ribosomes.

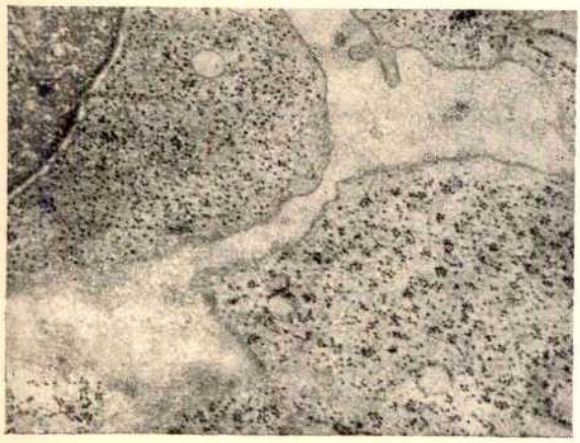

Fig. 1. A thin section showing cytoplasm of two adjacent large lymphocytes from the thoracic duct of a lymphocyte-depleted calf. The ribosomes of one cell are aggregated. (×24,000)

The two classes of cells seem to be morphologically identical in other respects. They have large, irregular nuclei characteristically divided into two lobes by a V-shaped notch. At the mouth of this notch a Golgi body is typically present. The cytoplasm of these cells is abundant and contains many spheroid mitochondria. The endoplasmic reticulum is inconspicuous, but a few scattered, non-parallel cisternae are present in most sections, and the membranes of these are lined by ribosomes which are apparently fixed.

Since it was first shown that haemoglobin synthesis occurs on polyribosomes of the rabbit reticulocyte[2], the association of ribosomal aggregates with protein synthesis has been established in many systems. The implication is that the two classes of large lymphocytes described here are either synthesizing protein at different rates or synthesizing protein molecules of different sizes. It is possible that this indicates a variation in the growth rates of morphologically similar lymphocytes.

A more interesting possibility is that these ribosomal aggregates represent the 'immune aggregates' found by Manner and Gould[3] in the ribosomal fraction of rat lymph nodes after stimulation by *Salmonella* antigen. These aggregates are associated with the synthesis of gamma-globulin, and differ from the usual polysomes in that they are disaggregated by mild treatment with trypsin rather than by mild treatment with ribonuclease. If the polysomes in bovine large lymphocytes are 'immune aggregates', then the all-or-none nature of this aggregation among various cells indicates that antigenic stimulation affects some cells and not others, thus providing a morphological marker for the 'immunologically committed' lymphocyte.

Form and Function of Lysosomes in Oral Epithelium

MUCH of the acid hydrolytic enzyme activity of many tissues is believed to reside in membrane-bound bodies termed lysosomes[1,2]. The cells of the oral epithelium, during their migration from the basal layer to the free surface, lose organelles such as mitochondria, melanin granules and probably keratohyalin granules[3]. This loss raises questions similar to those posed for the cells of skin by Riley[4].

Jarrett and Spearman[5] have suggested that this lysis of organelles in epidermal cells during keratinization is mediated by lysosomes deposited in the keratinocytes by cytocrine transfer[6] from high-level melanocytes (Langerhans cells). We have observed ultrastructural bodies having the commonly accepted morphology[2] of lysosomes

in Langerhans cells, but not in the keratinocytes, of human oral epithelium.

Our histochemical investigations confirm the presence of acid phosphatase in keratinizing and non-keratinizing oral epithelium, which has been reported by several workers[7,8]. The distribution of acid phosphatase and other acid hydrolases is similar in keratinizing oral epithelium to that in skin, where Diengdoh[9] has interpreted aggregates of acid phosphatase as lysosomes. We have preliminary electron histochemical evidence for the presence of acid phosphatase in Langerhans cells. Riley[4] found acid phosphatase in certain high-level dendritic cells by an azo-couple technique. In keratinocytes of oral epithelium we have detected some localization of acid phosphatase on, or near, the plasma membrane. This observation has been made using both the Gomori lead nitrate technique and an azo-couple method[10], and by electron histochemical techniques[11].

We suggest that these deposits represent small bodies containing acid phosphatase which are to be regarded as lysosomes and which may correspond to the small granular bodies commonly seen at, or adjacent to, the plasma membrane in oral epithelial keratinocytes[12,13].

We thank Mr. J. E. Linder for his advice in this work.

HAEMATOLOGY

Haemagglutinating Properties of Deoxyribonucleic Acid

Ishiyama has described[1] a phenomenon of 'direct haemagglutination' by the nucleic acids (DNA and RNA), and has shown that it is produced in a fixed range of *p*H (*p*H 2–6) and that it is inhibited by human, rabbit, sheep and guinea-pig sera. The present communication reports some results obtained in the investigation of this phenomenon.

In my experiments, sheep erythrocytes (2·5 per cent in physiological saline) were used. 0·1 per cent DNA solution was prepared with 'DNA Ex-herring Sperm' (Light and Co.) in physiological saline at *p*H 5·4. The possibility of there being any contamination with proteins was tested by ethanol and heparin precipitation. The tests were negative. Erythrocyte agglutination by DNA at *p*H 5·4 is reversible if the agglutinates are treated with a saline buffer at *p*H > 6.

Neither thermal denaturation of the DNA (when the solution is heated at 100° C for 10 min and then immersed in an ice-cold bath) nor ultra-violet denaturation (when 2 mm thick layers of the DNA solution were exposed for 45 min, 24 cm from a 450 W, type *Q*-99 ultra-violet lamp) destroys the haemagglutinating capacity of the DNA (ultra-violet denaturation was controlled spectrophotometrically—Hitachi recording spectrophotometer—at 260 mμ). The fact that both thermal and ultra-violet denaturation failed to destroy the haemagglutinating capacity of the DNA would seem to indicate that this property is not related to the structural integrity of the DNA macromolecule. Thermal denaturation results in a breakage of the hydrogen bonds and is responsible for the change-over from double-stranded to single-stranded structure[2,3]; ultra-violet denaturation modifies the helical configuration by breaking the hydrogen bonds into a minimum of ten bonds[4]. It is possible that during thermal denaturation a number of thermoresistant molecules persists in the solution, or that during its cooling a degree of renaturation of the DNA macromolecules occurs[3].

DNA haemagglutination is blocked by 0·01 M EDTA ('EDTA dinatriumsalz', Merck). The blockage is effected by treating the DNA solution with EDTA only. Previous treatment of the erythrocytes with EDTA does not destroy their susceptibility to the haemagglutinating effect of the DNA. It is probable that this effect is also related to the existence of some bivalent cations associated with the DNA macromolecule and that it plays a part in the agglutination phenomenon. Data have been reported on the association of Mg^{++} with DNA macromolecules and the part that it plays in the biological activity of this nucleic acid[5].

If the erythrocytes are treated for 30 min at 37° C with 0·002 M sodium metaperiodate the tendency for them to be agglutinated by DNA disappears. The trypsin (NBC 1 : 300), 1 per cent in buffered saline (*p*H 7·3), restores their susceptibility to agglutinate on treatment with DNA. The same can also be observed after erythrocytes which cannot be agglutinated by serum adsorption are treated with trypsin. It is known that the metaperiodate destroys the receptors for the influenza virus[6,7] and that trypsin restores the haemagglutinating capacity lost after treatment with metaperiodate[8]. These facts would seem to be consistent with the suggestion made by Ishiyama[1] that erythrocyte receptors for DNA intervene in the haemagglutination induced by some viruses.

The DNA haemagglutination is also inhibited by lecithin ('Lecithin ex ovo', Merck) at a final concentration of 1/20,000, but is not inhibited by cholesterol. In this respect, DNA haemagglutination differs from that produced by some bacteria (*Escherichia coli*), as in the latter case the haemagglutination is inhibited by both lecithin and cholesterol[9]. Lecithin acts at the DNA macromolecule level, and only treatment of the DNA solution by lecithin blocks the haemagglutination; even after previous treatment, the erythrocytes cannot be agglutinated.

Investigations are in progress in an endeavour to throw some light on the mechanism of interaction between DNA and cellular surfaces.

I thank Prof. V. Vasilescu for his help and encouragement, E. Truta for the spectrophotometric determinations, and Dr. G. Gancevici for the valuable discussion.

HISTOCHEMISTRY

Mast Cell Mucopolysaccharides

THERE has been a great deal of controversy in the past few years as to whether mucopolysaccharides other than heparin are present in mast cells. Although the biochemical analysis of normal rat peritoneal mast cells has only revealed heparin[1,2], some histochemical evidence strongly suggests that additional mucopolysaccharides may be present in rat mast cells[3,4]. Recently, the dual staining of mast cell granules in an alcian blue–safranin sequence was described by Worthington and Bailey[5]. They found, using alcian blue at a low *p*H with safranin as a counterstain, that even within a single mast cell some granules stain blue and others stain orange-red. It could be postulated that such dual staining arises from the partial removal of an alcian blue staining mucopolysaccharide, which is not heparin as the granules retain their metachromasia.

To test this hypothesis, mast cells in rat mesentery and loose areolar tissue from the dorsum of the foot were examined. Mesenteric biopsies were taken using spring clips with opposing loops at one end and the biopsies were fixed and stained intact. Sections of skin from the foot were examined from blocks which had been fixed and embedded in paraffin wax. In addition, frozen sections were cut from the loose areolar tissue beneath the subcutaneous fat and were stained immediately or post-fixed. Sections were stained with 3 per cent alcian blue in 2 N sulphuric acid for 30 min and counterstained with 1 per cent aqueous safranin for 1 min.

After fixation of the mesentery for 30 min in 10 per cent buffered formalin, the mast cells showed the characteristic dual staining described by Worthington and Bailey[5]. However, after fixation in methanol the mast cells stained uniformly blue. As the same staining reactions were obtained with extracellular granules following degranulation with compound 48/80, it would seem that alcian blue reactivity is a property of the granules alone and that both heparin and the alcian blue staining mucopolysaccharide are retained when the granules are discharged from the cell.

In paraffin-embedded sections of skin fixed in aqueous formalin and methanol, the mast cells stain orange-red with alcian blue–safranin. However, they stain blue in fresh frozen sections post-fixed for 24 h in 10 per cent and 20 per cent formalin, methanol, Bouin's fluid, Zenker's fixative and Carnoy's fixative. But they stain orange-red after post-fixation in 40 per cent formalin. The effect of concentrated formalin is not due to acidity, as alcian blue reactivity is retained after treatment with buffer solutions ranging from *p*H 1·0 to *p*H 7·0 for 24 h. This property of formalin was further studied and it was found that after fixation in 10 per cent formalin the mast cells in fresh frozen sections of skin from the foot also lost their alcian blue reactivity when the sections were later heated at 56° C for 2 h. Methanol-fixed sections retained their reactivity in this test.

Other procedures were investigated in order to determine whether the dual staining could be reproduced. After treatment with testicular hyaluronidase at *p*H 4·9 and *p*H 7·0 the mast cells all stained blue. However, the dual staining was produced when unfixed frozen sections were previously treated with 'tetracycline' (400 mg/100 ml. saline) or vitamin C (>1 mg/ml.) for 24 h, or with ultra-violet light for periods of more than 30 min. In all instances the metachromasia of the granules to safranin was retained and could be confirmed with toluidine blue.

From this study, therefore, it would appear that mast cells do contain a mucopolysaccharide in addition to heparin although the nature of this mucopolysaccharide is unknown. Because the mucopolysaccharide is completely removed by embedding in paraffin wax it is distinct from the mucopolysaccharides stained by other procedures[3,4]. The strong possibility that there are in fact a number of mucopolysaccharides in the mast cell granules should be reconsidered.

IMMUNOLOGY

Circulating Antigens in Cattle infected with *Babesia bigemina* or *B. argentina*

SOLUBLE antigens have been found in the serum of monkeys infected with *Plasmodium knowlesi*; these antigens fixed complement with homologous antiserum but had no immunogenic activity[1]. However, antigens found in the serum of rats and mice infected with *Trypanosoma brucei* have been shown to be effective immunizing agents[2,3].

This communication reports the occurrence of soluble antigens in the serum of cattle heavily infected with *Babesia argentina* or *B. bigemina*. In the preparation of antigens for use in complement fixation tests for the diagnosis of infection with these organisms, heavy parasitaemia was produced by serial passage of the protozoa through splenectomized calves[4]. Plasma from these infected calves was lyophilized and afterwards reconstituted to one-third of its original volume. These concentrated materials gave two precipitin lines in gel-diffusion tests with serum obtained from cattle 2–4 weeks after recovery from the clinical effects of infection with the homologous organism. As control tests with serum from uninfected calves and with extracts of normal bovine erythrocyte stroma were negative, these antigen–antibody reactions were assumed to be associated with babesial infection.

Antisera to serum from calves infected with *B. argentina* or *B. bigemina* were prepared in rabbits, and antibodies to the constituents of normal bovine serum were removed from the respective rabbit sera by absorption. In gel-diffusion tests with sera from infected calves and homologous absorbed rabbit antiserum, three precipitin lines were detected in the case of *B. argentina* and two lines in the case of *B. bigemina*. Only one line was common to both systems. The differences between the two sets of plates are taken as an indication that some reacting precipitinogens were not normal cattle or rabbit serum components but originated from specific protozoan antigens in the cattle sera inoculated into the rabbits.

Further investigations of the antigens of *Babesia* in the serum of infected cattle are being undertaken, particularly with regard to their isolation and to the assessment of their significance in the production of antibodies related to a state of acquired immunity.

Adenovirus Antibody and Antibody to 'T' Antigen (Neoantigen) Location in Gamma-globulin

THE properties and possible functions of the complement-fixing tumour and 'T' antigens (neoantigens) of adenoviruses and papovaviruses as related to virus infection and transformation have already been described[1-6]. The present communication reports the first of a series of investigations dealing with the location of antibodies to the 'T' antigen and to the virion of various adenoviruses.

Using sucrose density gradient separation[7], we separated the 19*S* and 7*S* fractions of human and hamster sera. The serum was diluted 1 : 2 with phosphate buffered saline and a portion was saved as control serum. 1 ml. of this material was layered over 4 ml. of a sucrose density gradient (12 per cent to 37 per cent) and centrifuged at 35,000 r.p.m. for 18 h. The 7*S* fraction was located just below the albumin fraction (stained with bromphenol blue for identification) and the 19*S* fraction was in the lowest millilitre of the gradient. The 7*S* fractions, removed by the 'side withdrawal' method[8] and the 19*S* fractions, removed by bottom puncture[7], were identified by electrophoresis. Paper electrophoretic investigations[9] revealed no differences between the patterns of sera from normal hamsters and those with tumours. The 7*S* component appeared mainly as γ-globulin and the 19*S* fraction migrated in the range of β-globulins. The adenovirus type 4 convalescent human sera gave a normal electrophoretic pattern. Although the same general appearance was noted for both human and hamster serum, the 7*S* fraction of human serum contained a small quantity of β- and γ_2-globulins. Each sample was investigated for antigenic titres in complement-fixation tests[10].

A pool of adenovirus type 12 hamster sera selected for its 'narrow' reactivity, that is to say, for its specific reaction with tumour antigens but not with virion antigens[4], was separated into 19*S* and 7*S* fractions. Antibody to adenovirus type 12 tumour antigen was located in the 7*S* fraction as shown in Table 1. The 7*S* fraction was also tested against two types of 'T' antigen preparations obtained from adenovirus 12-infected *HEK* cells. One of the 'T' antigens was produced in *HEK* test-tube cultures in the presence of cytosine arabinoside which blocked the formation of virion complement-fixing antigen and infectious virus while permitting the formation of 'T' antigens[6,11]. The other 'T' antigen was isolated from the supernatant of a 55 h collection of adenovirus 12-infected *HEK* cultures by a two-phase partition separation method[12]. Because the 'T' and tumour antigen complex has at least one heat labile and one heat stable component[1,4,11], the quantitative discrepancies observed between the reactivities of the 7*S* fraction with tumour and 'T' antigens from two different sources were not surprising.

Several sera from individual hamsters carrying adenovirus type 12 tumours were also separated into 19*S* and 7*S* components. The complement-fixing antibodies to adenovirus type 12 tumour antigen (Table 2) were located almost entirely in the 7*S* fraction of each serum.

A serum, from an adult volunteer two weeks after infection with adenovirus type 4, was obtained from Dr. R. M. Chanock and similarly fractionated into 19*S* and 7*S* fractions. This serum, which was devoid of any reaction with adenovirus 12 hamster tumour or 'T' antigens, revealed high-titred antibodies to virion mostly located in the 7*S* fraction; however, some antibody appeared in the 19*S* fraction (Table 3). This reactivity may be characteristic for adenoviruses in general, as almost identical results were obtained when the fractions were tested with the purified group antigen (A antigen) isolated from adenovirus type 12-infected cell culture fluids[13] (Table 3).

Three serial sera specimens were obtained from a child before and after infection with adenovirus 31 through the courtesy of Dr. A. Vargosko of the Children's Hospital in Washington, D.C. Density gradient separation investigations showed that the antibodies to virion were present in the 7*S* fraction (Table 4).

In conclusion, a preliminary investigation indicated that complement-fixing antibodies to the non-virion

tumour and 'T' antigens (neoantigens) found in sera of hamsters bearing adenovirus 12 tumours were located in the 7*S* γ-globulin fraction. Antivirion complement-fixing antibodies resulting from infection with adenovirus type 31 were also found entirely in the 7*S* fraction. Separation of a convalescent human serum taken from an adult patient with adenovirus type 4, 2 weeks after infection, revealed some antivirion antibody in the 19*S* fraction. However, at least four times as much antibody was demonstrated in the 7*S* fraction.

This work was supported by a field investigation contract with the National Cancer Institute.

Cells producing IgD Immunoglobulins in Human Spleen

A FOURTH class of immunoglobulins has recently been identified in human sera by Rowe and Fahey[1,2] and has been named IgD. This class is characterized by the unique antigenic and physico-chemical properties of the *H* chain; its concentration has been found to vary between wide limits in different sera, but it seldom exceeds 1 per cent of all immunoglobulins.

As it has been ascertained that, as a rule, the different classes of immunoglobulins are produced by different cells in human lymphoid tissues[3,4], it was of interest to investigate if this was also the case for IgD, as well as to determine the number and disposition of IgD-containing cells.

This has been done by conjugating the gamma globulin fraction of a specific anti-IgD antiserum, with fluorescein isothiocyanate, prepared as indicated by Rowe and Fahey[2], and by staining sections from three different human spleens obtained at necropsy from adult individuals with this conjugated antiserum. The specificity of the staining for IgD was checked by inhibition through previous treatment of the sections with unconjugated anti-IgD antiserum.

Adjacent sections were alternately stained with a fluorescein-conjugated anti-IgG antiserum. A typical result is shown in Figs. 1 and 2: it is clear that the anti-IgD antiserum stains a minority of the cells of the plasma cell line in the human spleen; this staining is as brilliant as that obtained, on a much larger number of cells, by means of the anti-IgG antiserum.

When the anti-IgD (fluorescein-conjugated) and the anti-IgG (rhodamine conjugated) antisera were applied in sequence to the same section, the cytoplasm of a few

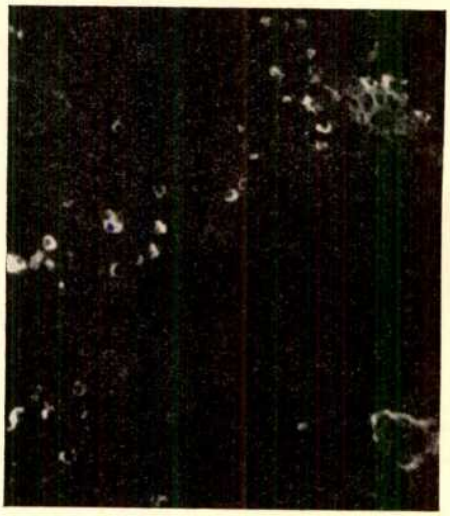

Fig. 1. Section of human spleen stained for IgG; many plasma cells and plasmablasts are visible in the peripheral zone of a periarteriolar sheath. The small artery is visible in the lower right corner, marked by its autofluorescence. (×250)

Fig. 2. Section adjacent to Fig. 1, stained for IgD; only one mature plasma cell containing IgD is present in this field. (×250)

cells showed a brilliant green fluorescence, while that of the majority of cells was stained by rhodamine. It can be concluded that the IgD globulins are produced by separate cells.

As already stated the number of these cells is very small, compared with that of cells producing IgG globulins. To estimate this ratio, all the IgD-positive cells present in a section of splenic tissue about 1 cm² were counted, and their number compared with that of all the IgG-positive cells visible in an adjacent section; the ratio obtained was found to be reproducible in different pairs of sections from different areas of the same spleen; on the other hand, significant differences were found among the three individual spleens examined, the values obtained being 0·13, 0·30 and 0·45 IgD cells per 100 IgG cells, respectively.

These values fall within the range of ratios of IgD to IgG molecules that exist in the majority of normal individuals, calculated on the basis of the concentrations of IgD observed by Rowe and Fahey and on the basis of a normal concentration of IgG of 12·63 mg/ml.[5]. It may be that the concentration of IgD in the serum depends on the number of IgD-producing cells in the lymphoid tissues.

With regard to the morphological characteristics of the IgD-producing cells, it can be said that they appeared similar to those elements positive for IgG; in fact many had the appearance of mature plasma cells, but IgD globulins were also found in the cytoplasm of 'immature' cells of the plasma cell line and in the cytoplasm of elements with a large nucleus and a high nuclear/cytoplasmic ratio (the so-called 'large lymphocytes').

The distribution of the IgD-positive cells in the human spleen appeared to be essentially random inasmuch as most of the cells appeared scattered throughout the tissue; clusters of a few IgD-positive elements were, however, seen in some instances. It seems likely that these clusters were derived from the recent cellular division of one element already differentiated towards the production of IgD; on the other hand, the fact that most of the cells were scattered might indicate that either the IgD-positive cells themselves or their precursors are endowed with considerable capacity for displacement, a property that is presumably possessed also by the cells involved in the production of other immunoglobulins.

PHYSIOLOGY

A Smooth Muscle Contracting Substance in Extracts of Human Umbilical Cord

At the birth of most mammals the umbilical cord is not ligatured and serious haemorrhage seldom occurs[1]. In man active constriction of the umbilical blood vessels follows delivery.

The umbilical blood vessels have been shown to constrict in response to a variety of stimuli. Haselhorst[2] has shown that the walls of cord vessels are sensitive to temperature and to irritation from handling. Schmitt[3] showed that umbilical vessels contracted when the oxygen content of perfusing fluid was increased. Umbilical vasoconstriction is also produced by the catecholamines, histamine, posterior pituitary extract and 5-hydroxytryptamine[4]. These facts suggested that a chemical substance may be released which will act on the umbilical blood vessels after birth.

Aqueous extracts of human umbilical cords were shown to contain a substance which stimulated smooth muscle. Preliminary investigations involved extraction of different parts of the umbilical cord and the placenta. The active substance seemed to be present only in the walls of the umbilical arteries and vein and was absent from the substance of Wharton's jelly, from extracts of placenta and from umbilical arterial and venous blood.

Purification of crude aqueous extracts was attempted and the active substance was shown to behave as a weak acid on partition between water and ether; it was retained in the aqueous phase at alkaline or neutral *p*H, but at acid *p*H it passed into the ether phase. It migrated towards the anode on paper electrophoresis.

From pharmacological investigations undertaken so far, it would seem that the smooth muscle-stimulating action of the umbilical cord extracts results from a hitherto unknown substance. The substance has been distinguished from active substances which are found in mammalian tissues namely esters of choline, histamine, 5-hydroxytryptamine, bradykinin, angiotonin, substance *P*, oxytocin, vasopressin and other polypeptides.

It was shown that the substance caused contraction of preparations of rat colon, guinea-pig small and large intestine, rat uterus and rabbit ileum. Guinea-pig proximal colon was used for the routine assay of the extracts of umbilical blood vessels as this preparation had been found to be the most sensitive. The purified extract also caused contraction of isolated umbilical artery preparation and isolated pregnant human myometrium.

The pharmacological, physical and chemical properties of the active substance, so far as they have been investigated, indicate that it is a lipid-soluble unsaturated hydroxy acid.

Its physiological significance is a matter for speculation, but it provides a possible explanation of the contraction of the cord vessels at birth.

Further experiments aimed at establishing the chemical structure of the active substance and its possible role in foetal placental circulation are in progress.

Effect of Muscle Loading on the Behaviour of Interneurones in the Lumbar Spinal Cord

In an earlier paper[1] we showed that when a muscle was loaded there was an increase in the synaptic activation noise recorded from within motoneurones and that this increase had two peaks, one as the load was being applied, the "on" peak, and one as it was released, the "off" peak. There would not seem to be any previous account of a muscle receptor the behaviour of which could explain the origin of this "off" peak. We speculated in our paper that the "off" peak may have its origin in the activity of spinal interneurones, and the results of an investigation of the behaviour of spinal interneurones during muscle pull are presented here.

The experiments were carried out on cats anaesthetized with pentobarbitone ('Nembutal', 35 mg/kg), and im-

mobilized with gallamine triethiodide ('Flaxedil', 20 mg/kg). Glass micropipettes filled with 2 M potassium citrate and having a resistance of 7–15 Mohms were inserted into the lumbar spinal cord which had been previously exposed by laminectomy. The extracellular spikes picked up by these electrodes were recorded on magnetic tape. The tendons of the tibialis anticus, gastrocnemius-soleus and semitendinosus muscles were dissected free and severed from their insertions and were loaded by weights hung on threads tied to their tendons[2].

The results are from thirteen spontaneously firing units located in and adjacent to the ventral horn of the spinal cord. All the units which showed a change during loading of gastrocnemius-soleus and semitendinosus except one showed no change during loading of tibialis anticus. In five of the six cases where units changed their firing rate during loading of gastrocnemius-soleus and semitendinosus but not with loading of tibialis anticus, the change with both loads was similar; in four of the five units there was increase in firing rate and in the other unit a decrease. One unit showed an increase with gastrocnemius-soleus loading and a decrease with semitendinosus loading. In one case a unit increased its rate with loading of semitendinosus and tibialis anticus but loading gastrocnemius-soleus had no effect. There were three units which responded to loading of only one muscle; those which responded to loading of gastrocnemius-soleus and tibialis anticus increased their rate of firing while loading of semitendinosus decreased the rate of firing of one unit. Six of the ten units which changed their firing rate during loading did so at "off" and in all cases there was an increase in rate.

Two examples of unit behaviour are shown: in Fig. 1 there is an increase in the firing rate both at "on" and "off"; in Fig. 2 there is a decrease in the firing rate at "on", and at "off" there is an increase above the spontaneous rate.

The behaviour of these cells contrasts markedly with that of seven units encountered more dorsally and medially in the cord which we have recorded from, with similar electrodes inserted so as to explore the dorsal horn. These cells, while showing an increase in firing rate during loading of the muscles, showed two types of behaviour when the load was released. One group reverted to the spontaneous firing rate without a period of increased firing whereas the other group showed a period of decreased firing and in some cases complete silence (Fig. 3). From these results it is suggested that the interneurones of the ventral horn, the behaviour of which we have described, could by their increased firing rate during the release of tension cause the "off" peak in the synaptic activation noise of the motoneurone.

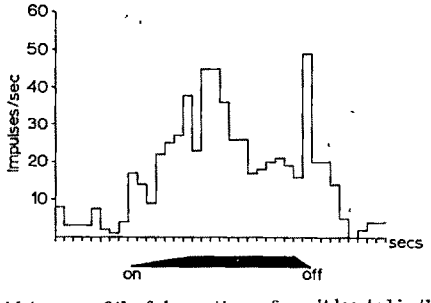

Fig. 1. A histogram of the firing pattern of a unit located in the ventral horn showing the effect of loading the semitendinosus muscle with 500 g

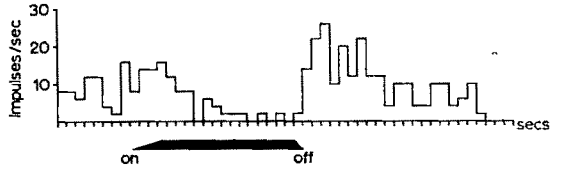

Fig. 2 A histogram of the firing pattern of another unit located in the ventral horn showing the effect of loading the semitendinosus muscle with 500 g

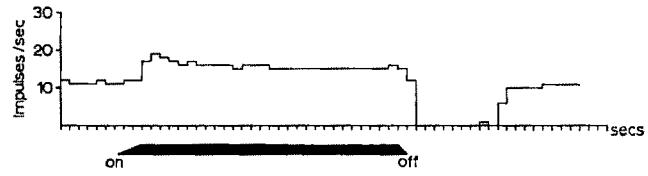

Fig. 3. A histogram of the firing pattern of a unit located in the dorsal horn showing the effect of loading the gastrocnemius-soleus muscle with 100 g

Work is now continuing to investigate whether the behaviour of these two groups of interneurones in response to muscle loading is related and also the part they play in regulating motoneurone function.

We are grateful to the Nuffield Foundation for supporting this work.

Stretchings and Yawnings induced by Adrenocorticotrophic Hormone

NATURAL crude or purified preparation of adrenocorticotrophic hormone (ACTH) and melanotrophin (MSH) can induce stretching and yawning motions in various species of animals when injected intracisternally. This property is also shared by synthetic polypeptides endowed with MSH and/or ACTH activity[1–4].

Experiments were performed to establish whether or not synthetic $\beta^{(1-24)}$ACTH can induce stretching and yawning motions. This polypeptide has an ACTH potency of 106 I.U./mg (ref. 5).

The experiments were performed on unanaesthetized adult mongrel dogs, cats and vervet monkeys (*Cercopithecus aethiops*). The animals, which had been fasting for 12 h, were injected intracisternally with various doses of the drug being tested. The drugs were dissolved in 0·5 ml. of saline and 0·5 ml. of liquor was withdrawn for each injection. The stretching potency of $\beta^{(1-24)}$ACTH was assessed in dogs by determining the minimal dose which produced the 'stretching crisis'. (It was considered that this had been reached when the dogs showed, at intervals not exceeding 30 min, long periods of stretching each of which began immediately after the preceding one.)

The results of experiments performed on dogs are shown in Table 1. They indicate that $\beta^{(1-24)}$ACTH is as potent as pure natural α_s ACTH in producing stretching motions. The symptoms induced by $\beta^{(1-24)}$ACTH are the same as those induced by the natural hormone: that is, after a delay of about 1–2 h, the dogs start to stretch and yawn in the way they usually do when wakening from physiological sleep. The intervals between successive stretching acts become shorter and shorter until eventually the stretching crisis is reached.

Table 1. STRETCHING ACTIVITY OF $\beta^{(1-24)}$ACTH IN DOGS

Peptide	γ/kg intracisternally	No. of animals with stretching crisis/No. of animals treated
α_s ACTH	3	18/20
	1·5	8/20
$\beta^{(1-24)}$ACTH	3	21/25
	1·5	12/20

$\beta^{(1-24)}$ACTH induces in cats repeated, isolated stretchings in a similar fashion to the natural hormone, but with only a few yawns. These symptoms are accompanied by marked drowsiness.

In monkeys, $\beta^{(1-24)}$ACTH mostly induces repeated yawning. (It should be remembered, however, that yawning in monkeys may be an emotional behaviour[6].) The periods of stretching are very limited in number. Furthermore, the yawnings and stretchings are accompanied by an obvious drowsiness.

The stretching activity persists for about 24–72 h in dogs, and 6–12 h in cats and monkeys; it ends with a complete return to normal behaviour.

We do not know whether the phenomenon described here has any physiological meaning. At present, we are investigating the effect of micro-injections of ACTH in different areas of the central nervous system.

We thank Dr. R. Schwytzer of Ciba, Basle, for providing supplies of $\beta^{(1-24)}$ corticotropin, and Dr. A. Lerner of the Section of Dermatology, Department of Medicine, Yale University, New Haven, for supplies of α_s ACTH.

PATHOLOGY

Comparison of Direct and Indirect Effects of Alkylating Agents and Radiation on Murine Leukaemia Cells *in vitro*

Reports have recently appeared concerning the quantitative assessment of cytocidal effects of alkylating agents and radiation on several mammalian cell lines *in vitro*. Alexander and Mikulski[1,2] have obtained dose-survival curves of murine leukaemic lymphoblasts (*L*5178*Y*) *in vitro* after treatment with alkylating agents and X-rays. Levis[3], using the technique of Puck *et al.*[4] in which macroscopic colonies are grown *in vitro* from single mammalian cells, compared the dose-survival curves of guinea-pig cells after treatment with nitrogen mustard and with X-rays. Berry[5] reported on the effects of several chemotherapeutic agents and X-rays on HeLa cells and mouse fibroblasts *in vitro*. We have recently compared the effects of nitrogen mustard and dimethyl myleran on *L*5178*Y* cell lines of different radiosensitivity *in vitro*[6].

A simple but fundamental question, common to all these studies, arises but has not yet been answered: what fraction, if any, of the cytocidal effects observed following alkylating agents or ionizing radiation represents an indirect effect exerted on the medium as distinct from a direct effect on the cell? From a previous investigation[6] it appeared that only a small fraction of the alkylating agent actually reacted with the cell, the vast majority being "wasted" by alkylation of constituents in the medium. Reactions of this sort conceivably could produce cytocidal effects by alteration of essential nutrients in the medium or by formation of toxic metabolites. Similarly, indirect effects of ionizing radiation could also be postulated.

In this study the direct effect of dimethyl myleran (DMM), nitrogen mustard (HN2) and ionizing radiation (cobalt-60) on murine leukaemic lymphoblasts (*L*5178*Y*) *in vitro* has been compared with their indirect effect on the tissue culture medium. Medium was treated with increasing doses of dimethyl myleran, nitrogen mustard and ionizing radiation. *L*5178*Y* cells were added to DMM-treated medium at 240 min, to HN2-treated medium at 300 min and to irradiated medium at both 2 min and 240 min after treatment. The purpose of these delays was to create a situation in which the direct cellular effect of alkylating agents could be separated from their indirect effect on medium. The half-life in tissue culture medium at 37° C is about 30 min for DMM[7] and 75 min for HN2[8]. Therefore, at the time cells are introduced into the treated medium (eight half-lives for DMM and four for HN2), a minimal residue of alkylating activity will remain to affect cells directly, and the dominant cytocidal effect will be indirect, achieved by reactions with constituents in the medium that may occur. The early (2 min) and late (240 min) delays after irradiation of the medium were arbitrarily selected. Control flasks with medium containing cells were treated at zero time with identical doses of DMM, HN2 and radiation. Radiation was administered from a radioactive cobalt-60 source at a dose rate of 79·5 rads/min. Cell number was determined by a haemocytometer count and growth curves of control and treated flasks plotted on a semilogarithmic scale with log of cell concentration on the ordinate against time on the abscissa. Dose-survival curves illustrating the effects of radiation were obtained by the method of Alexander and Mikulski[1,2].

The cytocidal effects observed when murine leukaemic lymphoblasts (*L*5178*Y*) were treated at zero time with DMM and HN2 are depicted by the growth curves shown in Figs. 1*A* and 2*A*. No cytocidal effects were observed

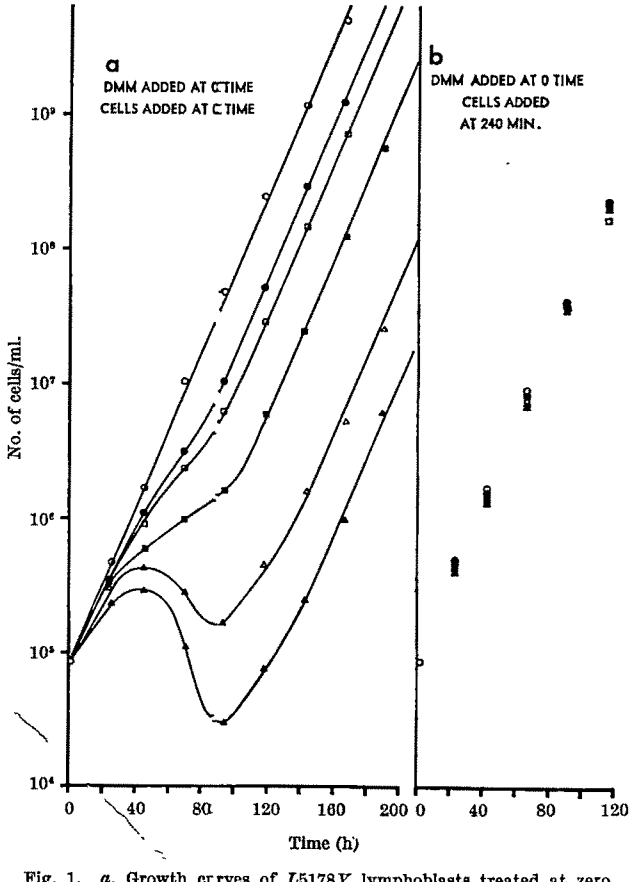

Fig. 1. *a*, Growth curves of *L*5178*Y* lymphoblasts treated at zero time with DMM at the following dose-levels: ○, none; ●, 5 μg/ml.; □, 10 μg/ml.; ■, 20 μg/ml.; △, 30 μg/ml.; ▲ 35 μg/ml. *b*, Growth curves of *L*5178*Y* lymphoblasts introduced into tissue culture medium, 240 min after the medium was treated with DMM, at 37° C, at the same dose-levels indicated in *a*

when the cells were introduced into the medium 240 min after DMM (Fig. 1*B*) and 300 min after HN2 (Fig. 2*B*). A complete absence of cytocidal action was also observed when cells were added to medium 2 and 240 min after irradiation as demonstrated by the dose-survival curves shown in Fig. 3. It would appear from this study that the cytocidal effect observed following treatment with DMM, HN2 and radiation represents a direct effect on the cell and does not involve any sustained indirect effect on the cell by alteration of constituents in the medium. The formation of cytocidal metabolites of very short half-life has not been excluded by this investigation.

I thank Mr. J. L. Everett of the Chester Beatty Research Institute for kindly supplying the dimethyl myleran and the Merck, Sharp and Dohme drug company for supplying the nitrogen mustard ('Mustargen'), and Miss S. Shniderman for technical assistance. This work was supported by a grant from the National Cancer Institute of Canada.

Toxic Effects of 7,12-Dimethylbenz(a)-anthracene in New-born and Adult Swiss Mice

DURING previous investigations of chemical carcinogenesis, we repeatedly found that new-born mice injected once with 7,12-dimethylbenz(*a*)anthracene (DMBA) died at a certain time after the treatment. On this basis we decided to investigate, in an exact manner, the toxicity of a carcinogenic dose of DMBA in new-born mice. Furthermore, we included in this investigation an adult group of mice in order to compare the toxicity rate of this carcinogen in two age groups of animals.

Randomly bred Swiss mice from a colony at our laboratory were used in the experiments. The DMBA used was obtained from Eastman Organic Chemicals and purified by chromatography on magnesia/'Celite'. For purposes of injection, it was dissolved in olive oil (Fisher Scientific Co.), and animals of both age groups received subcutaneous injections in the interscapular area. Siblings were weighed on a 'Gram-atic' balance (E. Mettler, Zurich), and only those which weighed 1·3, 1·4, 1·5 and 1·6 g and were less than 24 h old were selected for the treatment. Adult mice were weighed on a 'Shadowgraph' balance (The Exact Weight Scale Co., Columbus), and those weighing 19·5 g (5 weeks old) were used in the experiments. In the new-born group, only five siblings were allowed to remain with each mother. In the adult group the mice were separated according to sex and kept in groups of ten per cage. All animals were housed in clear plastic cages with sterilized granular cellulose bedding and were given Rockland diet in pellets and tap water *ad libitum*.

The experiment was divided into four groups as shown in Table 1. After treatment or, in the case of the control group, from birth, all groups were carefully checked each day for 1 month. Necropsies were performed on all dead animals and sections were routinely taken for microscopical examination. The treatment, toxicity rates, and percentage of mortality on the thirtieth day are presented in Table 1.

Epilation, hyperkeratosis and ulceration were observed at the sites of injection of most of the animals treated with DMBA. At autopsy, marked cellular depletion of the haematopoietic and myelopoietic systems, including bone marrow, thymus, liver and spleen, were readily discerned, as previously described[1,2]. A few of the mice which did not receive injections and those injected with

olive oil died of diarrhoea; however, the cause of death in other members of these groups was not established.

The present findings clearly show that when a carcinogenic dose of DMBA is administered on a strictly bodyweight basis to two age groups of animals, it is more toxic to new-born than to adult Swiss mice.

Considerable interest has recently been attached to the differences in susceptibility to carcinogenesis between new-born and adult animals. This has been particularly so for viral carcinogenesis[3], but additionally so in investigations of chemical[4–7] and radiation[8] carcinogenesis. In the present investigation it has once again been found that new-born animals are more responsive than adults—this time to the acute toxic administration of a chemical carcinogen. The reason for the difference has not been completely explained in any instance. Various suggestions have been put forward, including a difference in the immunological response, and more recently, differences in the rate of metabolic breakdown[9–11]. The present findings with DMBA are in keeping with suggestions that this carcinogen is metabolized far more slowly in new-born mice than in adult ones. It would seem likely, therefore, that the toxic action of this compound arises from the intact molecule rather than a metabolite.

Chronic Fluorosis in the Guinea-pig

DEATHS often reaching epidemic proportion occurred in at least eight major guinea-pig breeding units in Sydney and Canberra during 1964 and early 1965. Affected animals were characterized by loss of weight, depression, inappetence, a marked slobbering causing saturation and often excoriation of the chin, neck and venter, and ultimate death. All ages were affected, but newly-weaned animals and pregnant or post-parturient females appeared especially susceptible. Decrease in weight was evident for 1 to several weeks until increasing loss of fluid from the oral cavity presaged death within 5–20 days.

Autopsy revealed loss of body fat, lack of food in the anterior gastrointestinal tract and, occasionally, lung consolidation and increase in peritoneal fluid. Striking changes were found in the oral cavity. The lower molars were usually overgrown in a lingual direction so as to form an arch over the fixed part of the tongue, while the upper molars were correspondingly worn down to the level of the hard palate. Frequently there was a buccal elongation of the anterior upper molars and a wearing down of the anterior lower molars. Most molar teeth were coated with a tartar encrustation, and histopathological examination of them revealed imperfect calcification and hypoplasia of the enamel. The dentine and odontoblast layer showed changes characteristic of sub-acute hypovitaminosis C. Calcification of bone appeared to be impaired and resorption to be increased. The only other significant changes were in the kidney, in which corticomedullary calcareous deposits occurred in every case and distension of the tubules in some.

Aspects of the pathology suggested fluorine toxicosis, and diets used in the breeding units were investigated. Proprietary pelleted feed was used in all but one laboratory, which relied entirely on green feed and hay. No case of "slobbers" was recorded from the last unit. When bone flour had been difficult to obtain, Christmas Island rock phosphate had been substituted as a mineral source in the pellets. The rate of incorporation of the crude phosphate into the pellets varied from 0·8 to 2·0 per cent. The fluoride content of the Christmas Island phosphate dust has risen as quarrying has progressed from less than 1·5 to about 2·2 per cent. This would mean a fluorine content in the pellet in the range 60–440 p.p.m.

Samples of pellets from a colony in which only sporadic cases occurred had the lowest fluorine content (130 p.p.m.). The fluorine content of other samples from affected colonies varied from 190 to 400 p.p.m. High mortality, up to 100 per cent on occasion, was strongly associated with increasing levels of fluorine in the pellets used. The teeth and jaw-bones of a limited number of affected guinea-pigs showed fluorine contents of 3,940–6,700 p.p.m., the range in normal animals being 100–160 p.p.m.

The disease was reproduced with identical histopathology by administering calcium fluoride to healthy guinea-pigs, resulting in a 100 per cent mortality within 25 weeks. All cases showed characteristic molar changes and 90 per cent developed the symptom of slobbering.

The present communication is designed to bring immediate attention to the potential danger of incorporating certain crude phosphates in proprietary pellets. This investigation demonstrates one possible cause of a disease syndrome which has been known in the guinea-

pig, but little understood, for many years. Aspects of this syndrome have been reported by a number of authors[1-4].

RADIOBIOLOGY

Sensitivity of the Phage and Complementary Strands of the Replicative Form of Phage φ X 174 Deoxyribonucleic Acid to Ultra-violet Light

PHOTOPRODUCTS of pyrimidines are known to play an important part in the inactivation of nucleic acids by ultra-violet light. The replicative form (RF) of phage φ *X* 174 DNA is a convenient material to use for an investigation of the dependence of DNA ultra-violet sensitivity on base composition. The properties of both strands of RF DNA are similar, yet their nucleotide composition differs: the complementary strand contains 8·2 per cent less thymine and 5·6 per cent more cytosine than the phage strand[1,2]. The present investigation was undertaken to compare the ultra-violet inactivation of the infectivity of both chains of RF φ *X* 174 DNA.

The complementary chain was isolated from RF RNA. The replicative form was heated at 100° C for 10 min and the fraction of denatured DNA was separated on a MAK column[3]. The complementary chains present in this fraction were fixed in 'renaturation' with a 50–100-fold excess of ultra-violet inactivated φ *X* DNA. Renatured double-stranded DNA was eluted from a MAK column by 0·7 M sodium chloride and denatured. The infectivity of this preparation was due to the complementary strands. DNA from phage φ *X* 174 served as the phage-type strands. Infectivity of DNA was measured by the number of infected protoplasts of *E. coli C* (ref. 4). The concentration of DNA during irradiation was 0·005–0·05 μg/ml. Ultra-violet irradiation was carried out using a low-pressure *BUW*-15 lamp which predominantly emitted at 254 mμ.

Fig. 1 shows the kinetics of ultra-violet inactivation of both the RF DNA strands. The complementary chain is more resistant than the phage strand. If DNA inactivation arises mainly from thymine dimerization and if both strands of RF DNA have similar thymine–thymine nearest neighbour frequencies, then the sensitivity of the phage and the complementary strands to ultra-violet light should differ and depend on their thymine contents:

$$\frac{D_{37}^{\text{phage}}}{D_{37}^{\text{compl.}}} = \frac{N^{\text{compl.}}}{N^{\text{phage}}}$$

where D_{37} is the dose of ultra-violet light required to inactivate to a survival of 37 per cent (one hit), and N the number of thymines in the DNA strand. According to our measurements, the value of D_{37} for φ *X* DNA is 78 ergs/mm². As N is 1790 and 1342 for the phage and the complementary chains, respectively, then D_{37} for the complementary chain will be 104 ergs/mm². As can be seen in Fig. 1, the theoretical survival curve for the complementary chain constructed in accordance with the computed dose is close to the curve for the experimentally obtained results. This demonstrates that thymine plays an active part in the formation of lethal ultra-violet lesions. The sensitivity of the two polynucleotide chains in the RF DNA molecule to ultra-violet irradiation correlates well with their thymine contents. Correlation between the composition of a nucleotide and its sensitivity to ultra-violet light is not revealed when different phages are compared[6]. Here additional factors, including some of a genetical nature rather than base composition, determine the actual sensitivity to ultra-violet light.

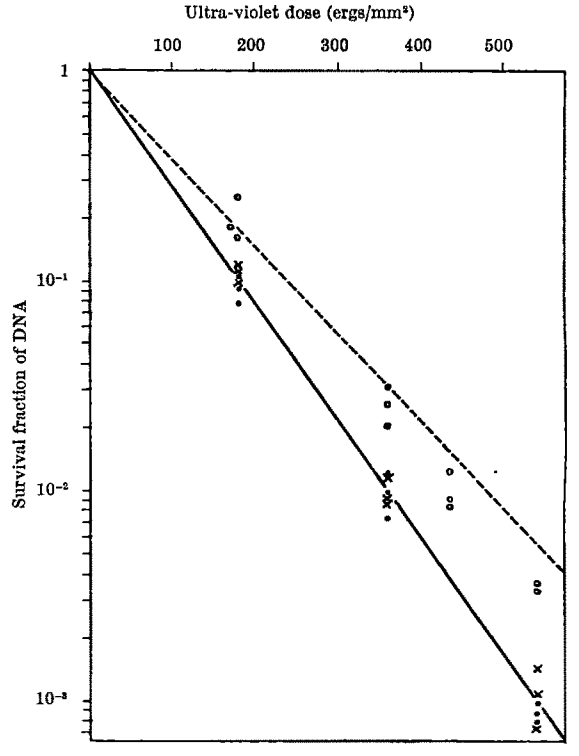

Fig. 1. Ultra-violet survival curves for φ *X* 174 DNA and complementary strand of RF DNA. ●, φ *X* 174 DNA; ×, φ *X* 174 DNA after reactivation; O, complementary strand of RF DNA; - - - -, theoretical curve for inactivation of complementary strand

Despite the approximate correlation between the sensitivity to ultra-violet light and thymine content, only about 40 per cent of lethal lesions result from thymine dimerization in φ *X* 174 DNA[5,6]. Apparently, the reaction of cytosine photohydration does not produce a lethal effect. Such cytosine photoproducts as 5-hydro-6-hydroxycytosine are unstable and at increased temperature in the dark revert to cytosine. As is shown in Fig. 1, the incubation of ultra-violet deactivated φ *X* 174 DNA at 37° and 42° C in the dark for 2–20 h is not accompanied by recovery of infectivity. Nevertheless, in addition to thymine dimers other lethal photoproducts exist in φ *X* 174 DNA.

Cysteine Incorporation and Radio-protection in *Saccharomyces*

THIS communication reports some data on the time dependence of cysteine incorporation and the increase of radio-protection in cells of a diploid *Saccharomyces* strain in two different physiological conditions.

There are many reports dealing with the radio-protective effects of cysteine and other SH-compounds in various organisms, but there is still no general theory about the mechanisms of radio-protection by sulphydryl compounds. It has been shown[1] that under *in vitro* conditions, that is in cell-free solutions of organic macromolecules, cysteine may act as radio-protector owing to its great reaction velocity with primary radiation products ("competition effect"). However, under conditions *in vivo*, that is in cells in aqueous milieu containing cysteine, the reactions leading to radio-protection may be more complicated[2].

In many experiments it has been shown that cysteine can only act as a radio-protector if it is present during irradiation[3]. Several theories have been put forward to explain the protection effect[4]. Under *in vivo* conditions, the penetration of cysteine from the surrounding medium into the cells is generally considered to be a prerequisite for protection. It was therefore considered to be of interest to gain more information concerning the correlation between cysteine incorporation in cells and the radio-protection effect.

Cells of the diploid *Saccharomyces* strain 211-1*a*/2 from our strain collection were used, and were taken either from the stationary growth phase (*s*-cells) or from the logarithmic growth phase (*l*-cells) in liquid nutrient medium (1 per cent Difco yeast extract, 0·25 per cent glucose) aerated by agitation. Before irradiation the cells were washed three times in M/20 potassium dihydrogen-phosphate buffer. The proportion of budding cells was reduced to about 10 per cent by fractional centrifugation, and the cell suspension diluted in buffer to an appropriate cell titre. During irradiation, the cells were either suspended in buffer or in a solution of buffer containing in addition 0·01 M cysteine (cysteine solution).

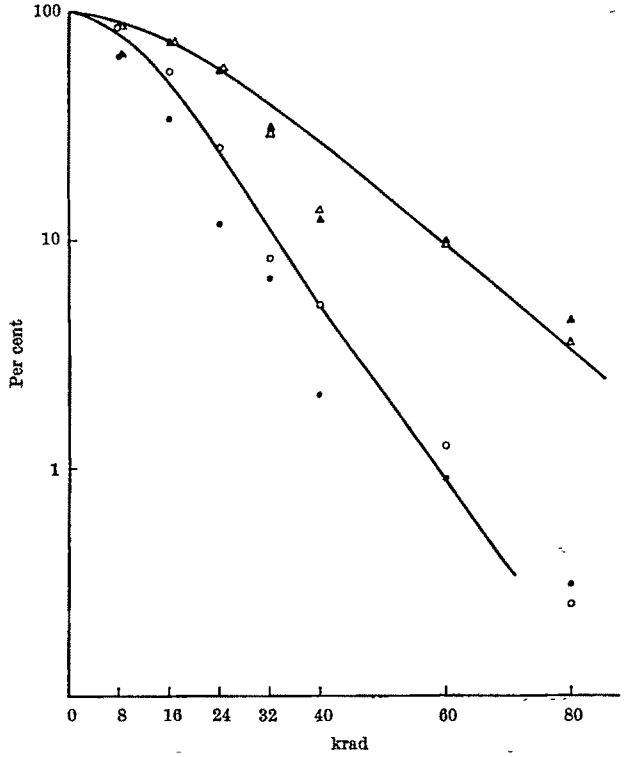

Fig. 1. Inactivation of the colony-forming ability of diploid *Saccharomyces* cells by 50-kV X-rays. The radiation source was a Machlett tube with beryllium window without additional filter. △, *s*-cells, and ▲, *l*-cells, incubated for 20 min in a 0·01 M cysteine solution before irradiation. ○, *s*-cells, and ●, *l*-cells, without cysteine treatment

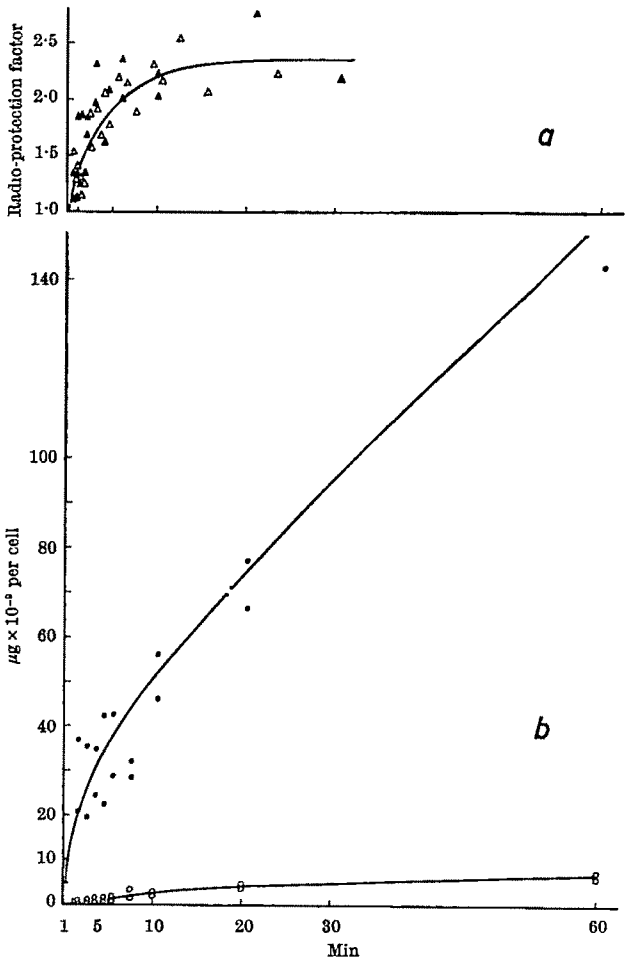

Fig. 2. *a*, Dependence of radio-protection of diploid *Saccharomyces* cells on the time of incubation in a 0·01 M cysteine solution. The absorbed dose of 50-kV X-rays was kept constant at 24 krads. Irradiation time 30 sec. The radio-protection factor is calculated from the quotient: $\frac{\text{percentage of colony-forming cysteine-treated cells}}{\text{percentage of colony-forming untreated control cells}}$. The time marked on the abscissa includes the time necessary for irradiation (30 sec). △, *s*-cells; ▲, *l*-cells. *b*, Dependence of cysteine-incorporation in diploid *Saccharomyces* cells on the time of incubation in a 0·01 M cysteine-^{35}S-solution. The time marked on the abscissa includes the time necessary for centrifugation. ○, *s*-cells; ●, *l*-cells

When *s*-cells or *l*-cells are suspended in cysteine solution for 20 min and then irradiated with 50-kV X-rays both types of cells exhibit various degrees of radio-protection, as can be seen from a comparison with controls treated in the same way but irradiated in the absence of cysteine (Fig. 1). The inability of the cells to form macroscopic colonies after incubation for 4 days at 30° C on nutrient agar (1 per cent Difco yeast extract, 0·5 per cent peptone, 2 per cent glucose 2 per cent Difco bacto-agar) was taken as an indication of radiation damage. As can be seen in Fig. 1, the X-ray dose necessary for an inactivation of 90 per cent of the cells (10 per cent survival) is nearly twice as large for cysteine-treated cells as for untreated controls. There may be a tendency for greater radio-protection in *l*-cells than in *s*-cells; however, a statistically significant difference in the degree of protection between both types of cells has never been observed.

The dependence of the effectiveness of radio-protection on the period of cell exposure to cysteine can be seen in Fig. 2*a*. The cells were exposed for different periods to a solution of 0·01 M cysteine in buffer at room temperature and then irradiated. An optimal radio-protection of *s*-cells and *l*-cells was achieved after exposure to cysteine for about 10 min. After this period, the percentage of cysteine-

treated cells of both types surviving an X-ray dose of 24 krads was about twice as great as that for the surviving untreated controls.

The dependence of cysteine-incorporation in *s*-cells and *l*-cells on the period of exposure was determined by means of labelling the cysteine with sulphur-35. The cells grown in the specified liquid medium were washed three times in buffer and suspended in solutions of buffer containing in addition 0·01 M cysteine-^{35}S (specific activity 3·3 mc./mM) for various intervals of time at room temperature. Afterwards the cells were washed three times in inactive 0·01 M cysteine-buffer solution. The radioactivity of the cells thus treated was measured with a Geiger–Müller counter *FHZ* 15*b* (Friesecke and Hoepfner) and the amount of radioactivity per cell calculated. The percentage of budding cells was kept approximately constant in all experiments with radioactive cysteine. As can be seen in Fig. 2*b*, there is a significant difference in the amount of cysteine incorporated in the *l*-cells from the *s*-cells. Saturation in the incorporation of cysteine was not achieved with *l*-cells during an exposure time of 60 min. In *s*-cells, however, the incorporation of cysteine reached a limit after about 20 min of exposure.

These experiments show that an optimal radioprotection is only achieved after a certain quantity of cysteine has penetrated into the cell. The minimal quantity of cysteine necessary for a maximal radioprotection of *s*-cells is reached after about 10 min and amounts to about 10^{-15} g per cell. This value corresponds to about 0·01 per cent of the total quantity of amino-acids per cell or to about 1 per cent of the total quantity of cysteine and cystine per cell. The considerably larger amount of cysteine incorporated in *l*-cells within the same period of exposure does not, however, result in a significant increase in radio-protection. Furthermore, radioprotection does not increase in *l*-cells during the continued cysteine-incorporation in an additional exposure period of 50 min. These observations can be explained if it is assumed that part of the incorporated cysteine is rapidly used in protein synthesis and consequently loses its radio-protective effectiveness. This assumption implies that only the pool of free cysteine acts as radio-protector. That the same degree of maximal radio-protection is observed in *s*-cells and *l*-cells may indicate that the content of free cysteine is about the same in both types of cell after exposure for 10 min to a 0·01 M cysteine solution. Synthesis of protein, however, as an effective consumer of free cysteine, should be abundant in *l*-cells, but should be strongly reduced or absent in *s*-cells. Further investigations concerning the presence of free and protein-bound cysteine in yeast cells are now under way.

GENETICS

Chiasma Frequencies and the Potential Genetic Variability of *Lolium* Populations

RECENT investigations in *Lolium* show that annual and other short-lived populations have higher chiasma frequencies than more perennial populations[1]. The variation in chiasma frequency was inferred to be adaptive. It was also suggested, however, that the variation in chiasma frequency was not directly but only indirectly dependent on the longevity of the population. The basis for this suggestion was, briefly, as follows: (1) It is well established that inbreeding species, the members of which on average carry low potential genetic variability, have higher chiasma frequencies than related outbreeders[2–4]. The high chiasma frequencies, which promote a high rate of release of variability whenever hybridization does occur, may be regarded as compensating for the low potential variability[2,3]. (2) There was some evidence in *Lolium* to indicate that the shorter-lived rye grass populations contain less potential variability than the longer-lived populations. As in the inbreeders already referred to, the inference is that their high chiasma frequencies compensate for this relatively low potential variability.

On this view the chiasma frequencies are adaptive in direct relation to the potential variability of populations and only obliquely in relation to longevity. A critical test for this view would be to survey the chiasma frequencies in populations for which data on both longevity and potential variability were available. Estimates of the latter are, however, particularly difficult to obtain. Fortunately the selection work of Cooper[5] and the more recent work of Edwards and Cooper[6] provide such information with respect to four *Lolium* populations, namely, the varieties *Kent*, *Irish*, *Italian* and *Hunsballe*. The information on potential variability is adduced from the degree of response to selection. For example, with selection for leaf size the greatest response was shown by *Irish*, then *Italian* and, last, *Hunsballe*. From this we may conclude that *Irish* has the highest potential genetic variability, then *Italian*, *Hunsballe* having the lowest potential variability. In other experiments where selection was practised for ear emergence, *Kent* rye grass gave a much greater response than *Irish*. While it is unfortunate that the selection data involve only a few characters, the results nevertheless give a reasonable indication of the order of magnitude of potential variability in the four populations. In descending order the sequence is *Kent*, *Irish*, *Italian*, *Hunsballe*. If, as is proposed, the chiasma frequencies are inversely related to the degree of potential variability of the populations, the expectation is that the order of increasing chiasma frequencies will be *Kent*, *Irish*, *Italian* and *Hunsballe*.

Fig. 1 shows the chiasma frequencies of the four populations plotted against the order of potential vari-

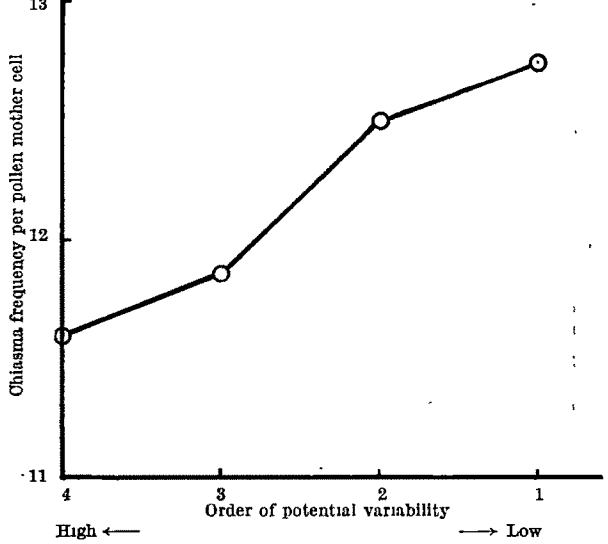

Fig. 1. Average plant chiasma frequencies of *Lolium* populations plotted against the order of potential genetic variability of the populations. Chiasma frequencies (expressed as chiasmata per cell) were estimated from counts in twenty pollen mother cells in each of ten plants in each population

ability. As will be seen, the chiasma frequency variation agrees completely with expectation of an inverse correlation with potential variability.

Turning to longevity, *Kent* and *Hunsballe* are both highly perennial; *Irish* is next in order of perenniality and *Italian* the least perennial. *Kent* and *Hunsballe* are of particular interest in that they show the same high degree of perenniality but differ with respect to potential variability. If population chiasma frequencies relate directly to longevity, the chiasma frequencies of *Kent* and *Hunsballe* should be alike at one end of the scale with *Italian* at the other. In fact, the chiasma frequencies of *Hunsballe* and *Kent* are significantly different ($P < 0{\cdot}01$) and are highest ($12{\cdot}79 \pm 0{\cdot}20$) and lowest ($11{\cdot}58 \pm 0{\cdot}31$), respectively. These chiasma frequencies vary quite independently of longevity but are completely correlated with variation in potential variability, as already mentioned.

From these comparisons it appears that variation in chiasma frequency is inversely related to the degree of potential genetic variability of populations. Finally the correlation between chiasma frequencies with longevity in many of the *Lolium* populations investigated[1] follows as an inevitable consequence of the correlation between longevity and potential genetic variability generally, but not invariably, found in *Lolium* populations.

BIOLOGY

Effect of Magnetic Fields on the Respiration of Malignant, Embryonic and Adult Tissue

WITH the development of stronger magnetic fields, a renewed impetus has been given to the investigation of the effect of these fields on biological material. Already proposed theories, elaborately expressed mathematically, appear to be far in advance of the facts.

Because energy must be involved in the effect of a magnetic field on biological material, it is natural to suppose that it is on a molecular level, and that it involves enzymes and other biochemical constituents of the cell. It has been suggested by Valentinuzzi[1] that aspects of chemical kinetics, closely related to the velocity of reactions, might significantly fit into magnetobiological phenomena. Theoretical investigations, according to Valentinuzzi, take into account that the effect due to modification of the rotational diffusion of paramagnetic molecules caused by magnetic fields could explain some of the experimental observations. It is held by Valentinuzzi (see also Setlow and Pollard[2] and Barnothy[3]) that, "If such molecules with specific reactive sites are paramagnetic, there exists the possibility that an externally applied magnetic field may either slow or stop their rotation, a fact which would imply a decrease of the probability of effective collisions, and therefore a retardation of the corresponding biochemical reaction".

Whatever the fundamental mechanism, it has been observed that either a stimulatory or inhibitory effect can be induced by exposure to a magnetic field, the plus or minus deviation from the normal depending on the kind of tissue and its metabolic or proliferative status.

Reno and Nutini[4] were perhaps the first to investigate the effect of magnetic fields on the respiration of normal, neoplastic and embryonic tissues. They observed that the respiration of cancer and embryonic tissues was depressed when they were exposed to a magnetic field, while normal adult tissues showed no significant response.

It would seem, from a review of the literature, that most, if not all, of the experiments conducted used constant fields applied to the test material over various periods of time. This procedure resulted in effects which were usually on the borderline of significance and predictability. It occurred to us that a more pronounced effect would be realized if the field could be intermittently applied so that, in effect, the tissue or cells would receive a series of pulses analogous to building up and collapsing the magnetic field in order to do work. Two methods were used: (1) a quadruple permanent magnet (6 kG) mounted on a dolly so as to bring the field to and away from the specimen; (2) an electromagnet (10 kG) which permitted the field to be turned on and off at predetermined intervals.

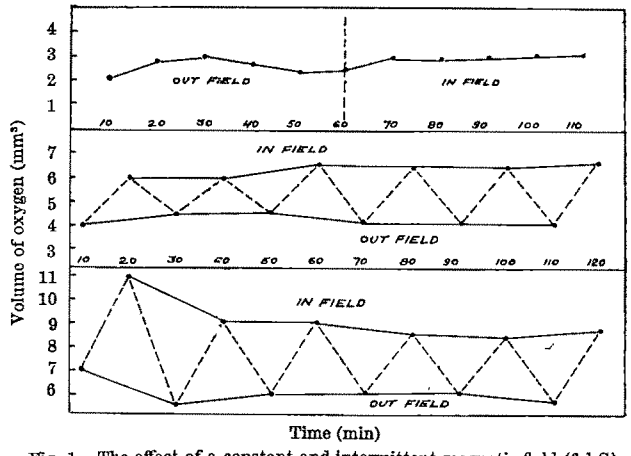

Fig. 1. The effect of a constant and intermittent magnetic field (6 kG) on the respiration of adult mouse kidney tissue

Measurements of respiration were made with a specially designed microrespirometer similar to that used by Reno and Nutini[5]. Fig. 1 (adult mouse kidney tissue) is representative of the results obtained, clearly demonstrating no effect in a constant field, whereas in experiments with an intermittent field a definite stimulatory effect was noted. The broken line, connecting the 'in-field' and 'out-field' solid lines, indicates the 10-min intervals during which the specimen was in the field and out of the field, respectively. Other tissues and cells exposed to constant and alternating fields gave comparable results. Whether or not the magnetic field stimulated the respiration depended on the kind of tissue. For example, it was found that yeast and *Bryophyllum* were stimulated, while sarcoma 37 cells, embryo heart, liver and intestine were depressed.

This work was aided by a grant from the National Cancer Institute, National Institutes of Health.

New Records of the Shrimps *Hymenopenaeus tropicalis* and *Parapenaeus americanus* from Brazil

A SMALL number of unknown shrimps were among the material obtained from one station (24° 25′ S., 44° 40′ W.), about 40 miles south-east of Punta do Boi, São Sebastião Island, in June 1962, on a muddy bottom and at a depth of 130 m. These were kindly identified by Dr. F. A. Chace, jun., of the Smithsonian Institute, as *Hymenopenaeus tropicalis* (Bouvier) and *Parapenaeus americanus* Rathbun(?). According to Dr. Chace the latter could be an undescribed species, on the basis of apparent thelycal differences, but no final statement could be made before some adult specimens were examined. The specimens of *P. americanus* (one male and two females) had a total length of 47 and 48 mm respectively. So far as can be ascertained, both species have not previously been encountered from Brazilian waters.

The occurrence of some lesser-known shrimps along the coastal waters of South America has already been described by Mistakidis and Neiva[1]. Among the species referred to were *Sicyonia dorsalis* Kingsley and *Trachypeneus constrictus* (Stimpson). Both species were obtained from hauls made near Santos (about 24° S.), and were considered as first records from Brazil.

Since then the material collected during the exploratory survey of January–February 1963 along the Santa Catarina coast has been re-examined and it is of interest to observe that the distribution of these species extended farther south than Santos.

A single female *S. dorsalis* (45 mm total length) and seven specimens of *T. constrictus* (two males and five females, 52–63 mm total length) were found in material obtained from one station (26° 53′ S., 48° 33′ W.) a few miles off the coast. The haul contained also one *Sicyonia typica*, three *Hymenopenaeus mulleri*, twenty-eight *Penaeus aztecus* and thirty-four *Xiphopeneus kroyeri*. Three female *T. constrictus* were impregnated, and the spermatophores of one male were well developed (February 1). The bottom was mud grading to sand and the depth was 21 m. Another impregnated female *T. constrictus* (50 mm total length) was obtained from another haul made about 12 miles south of this station, also on a muddy bottom, but in shallower water. In addition to the accompanying fauna the 30-min trawl haul contained three *Penaeus schmitti* and 430 *X. kroyeri*. More detailed information on the distribution and abundance of these and other species obtained during the survey has been given in a mimeographed report published by the Departamento Estadual de Caça e Pesca de Santa Catarina[2].

Records of *Macrobrachium carcinus* (Linnaeus) and *Macrobrachium acanthurus* (Wiegmann), from Santa Catarina, Brazil

AMONG unidentified material kept at the Fish and Wildlife Service Laboratory at Florianopolis, capital of the State of Santa Catarina, were several specimens of the freshwater prawn *Macrobrachium*. These were identified as *M. carcinus* and *M. acanthurus*. The two specimens of *M. carcinus*, of 200 and 210 mm total length (excluding the second pair of pereiopods, which measured 230 mm), were from Lagoa da Conceição, a brackish to freshwater lagoon on the Santa Catarina Island. The eight specimens of *M. acanthurus*, of 80–140 mm total length (excluding the second pair of pereiopods, which measured up to 120 mm in length), were from Rio Pinheira (27° 50′ S.), a small river on the mainland, about 3 miles south of the southernmost tip of S. Catarina Island. Local fishermen stated that *M. carcinus* had occasionally been taken from Rio Pinheira, but this could not be verified.

According to Holthius[1,2] the distribution of both species extends from Georgia and Florida in the United States, to South Brazil, including the West Indies. Holthius[1] lists several records of *M. carcinus* from Brazil, including the State of Santa Catarina, the southernmost locality being the Rio Itajai. As the Lagoa da Conceição is approximately 40 miles south of Itajai the distribution appears to extend farther south than was previously known.

The distribution of *M. acanthurus* extends farther south than *M. carcinus*, and it has been recorded as far south and west as Itaqui, on the River Uruguay, and from São Lourenço, Rio Grande do Sul, Brazil's southernmost state. However, the species had not previously been recorded from Rio Pinheira.

Plasminogen Activator in Saliva of the Vampire Bat *Desmodus rotundus*

IT was generally accepted that vampire bats were blood-sucking animals until 1932 when Dunn[1] observed that these animals use their tongues to lap blood from freely bleeding wounds inflicted by means of razor-sharp superior incisors. This observation was confirmed by Ditmars and Greenhall[2] and by many subsequent investigators, and it has been noticed that bites inflicted by vampire bats not only bleed very freely when the wound is first made, but also continue to bleed for several hours after the bat has ceased to feed[3]. It is therefore of interest to investigate the mechanism by which vampire bat saliva brings about this degree of interference with the haemostatic mechanism of the host animal.

The presence of an anticoagulant in saliva of *Desmodus rotundus* has been suggested by several workers including Romana[4] and Mann[3], and dissolution of blood clots containing *D. rotundus* saliva was noted by Bier[5]. DiSanto[6] reported that addition of a saline suspension of the principal submaxillary gland to fibrin brought about hydrolysis and suggested that a proteolytic substance in the gland was responsible for this. In the present investigation the effect of saliva from *D. rotundus* on platelet adhesiveness and aggregation, blood coagulation, fibrinolysis and vasoconstriction has been investigated and it has been demonstrated that the saliva increases vascular permeability and contains a potent plasminogen activator. Preliminary tests for inhibition of platelet adhesiveness to glass surfaces and aggregation of platelets by adenosine diphosphate have given negative results and tests for anticoagulant activity have been inconclusive. Some characteristics of the plasminogen activator are reported here.

Tests have been carried out on two specimens of *D. rotundus* in captivity at the London Zoological Gardens. A small drop of pilocarpine hydrochloride was applied to the buccal mucosa with a fine polythene Pasteur pipette and approximately 2 min later it was possible to collect saliva by means of a second polythene pipette. This process could be carried out without handling the animals. Saliva was obtained in a similar manner from normal laboratory mice for comparative tests. The saliva was

placed in an ice bath immediately and tested without delay.

Dilutions of saliva were prepared in 0·9 per cent saline and 0·03-ml. volumes of each dilution were incubated in triplicate on standard[7] and heated[8] bovine fibrin plates for 20 h at 37° C. No lysis occurred on heated (plasminogen-free) fibrin plates, excluding the presence of a direct fibrinolytic enzyme. On standard (plasminogen-rich) fibrin plates, vampire bat saliva produced large areas of lysis (Table 1) suggesting that a potent plasminogen activator was present. This was confirmed by testing mixtures of saliva and human plasminogen (Kabi Pharmaceuticals) on heated plates.

Table 1. FIBRIN PLATE TESTS

Source of saliva	Area of lysis/mm² Standard plates	Heated plates
Bat 1, undiluted	1,089	0
Bat 2, undiluted	2,200	0
1/10	868	0
1/100	310	0
1/1,000	38	0
1/10,000	0	0
Mouse 1	64	0
Mouse 2	0	0

Plates prepared from bovine plasma fraction I (Armour Pharmaceutical Co.) and bovine thrombin (Leo Laboratories). Results are the average of three readings.

Table 2. LYSIS OF HUMAN PLASMA CLOTS BY VAMPIRE BAT SALIVA

Source of saliva	Lysis time by saliva diluted Undiluted	1/10	1/100	1/1,000
Vampire bat 1	1·5 min	6·5 min	2 h	24 h
Vampire bat 2	4 min	28 min	4 h	24 h
Vampire bat 2 while feeding	—	2 min	4 min	25 min
Mouse	No lysis apparent after 24 h			

Clots consisted of human plasma 0·1 ml., saliva 0·05 ml., thrombin (50 N.I.H. units/ml.) 0·05 ml. Lysis was measured at 37° C.

Further experiments were carried out in which dilutions of saliva were mixed with human plasma before clotting with thrombin. Rapid lysis occurred with undiluted saliva collected at intervals between feeding a bat with defibrinated ox blood; the potency of the activator was markedly increased (Table 2). No lysis occurred of clots containing mouse saliva.

Lysis of human plasma clots by vampire bat saliva is inhibited by the presence of ε-amino-caproic acid at concentrations of 10^{-4} M and greater. The activator is stable for at least 2 weeks at −35° C, 24 h at 4° C, 3 h at 37° C and 30 min at 56° C. It is destroyed by boiling. Preliminary experiments have indicated that animals of different species vary greatly in susceptibility to the activator. Reactivity does not depend on the presence of proactivator, however, as lysis of fibrin prepared from bovine fibrinogen and thrombin takes place (Table 1).

It is not yet known if the potent plasminogen activator present in vampire bat saliva is solely responsible for the prolonged bleeding which takes place from bites inflicted by these animals. Further experiments are planned to determine if vampire bats can feed successfully from animals in which the plasminogen is not activated by vampire bat saliva.

I thank Dr. D. Morris for permission to study the vampire bats at the London Zoological Gardens and Miss Noel Lansdown and Mr. G. Nevill for technical assistance. The work was supported by a grant from the British Heart Foundation.

Eleven-month "Embryonic Diapause" in a Marsupial

THE tammar, *Protemnodon eugenii* (Desm.), is included in the marsupial family Macropodidae in which the majority of species so far studied exhibit lactation-controlled delayed implantation[1]. Tyndale-Biscoe[2] pointed out that, unlike eutherian mammals which have delayed implantation, the marsupial blastocyst does not implant as soon as development recommences, and he suggested that the term "embryonic diapause" be used to describe the marsupial type of discontinuous development of the embryo.

Embryonic diapause in a marsupial was first described by Sharman[3] in the quokka, *Setonix brachyurus*. Female quokkas fertilized at post-partum oestrus carried an unimplanted dormant blastocyst in one uterus while suckling a young in the pouch. Premature removal of that young during the breeding season (approximately January–August) was followed by resumption of development by the blastocyst. On the other hand, the dormant blastocysts of the continuously breeding red kangaroo, *Megaleia rufa*, completed development following removal of pouch young at all times of the year and at the end of pouch life of the young[4]. Most female quokkas entered anoestrus while carrying a pouch young, and Sharman[3] thought that the blastocyst then degenerated. This view was supported by Shield and Woolley[5], who demonstrated a progressive decrease in the percentage of quokkas giving birth following removal of pouch young as the breeding season progressed and a total failure of the blastocyst to develop during anoestrus.

Sharman[6] reported the occurrence of embryonic diapause in the tammar, and Poole and Pilton[7] gave the gestation period as 29 days. The mean length of the gestation period of tammars studied in this investigation was $28{\cdot}4 \pm 0{\cdot}2$ days ($N = 12$) and a breeding season extending from January to July was indicated for both wild and domestic tammars.

A sample of fifty wild tammars was shot on Kangaroo Island, South Australia, in October 1964. Most females were carrying advanced pouch young (213–245 days old) or were suckling young which had left the pouch. None was in active pregnancy but 68 per cent had dormant blastocysts in one or other uterus. The ovary corresponding to the uterus which contained the blastocyst had a resting corpus luteum similar in size and histology to the corpus luteum of lactation found during the quiescent phase of lactation in macropodids exhibiting embryonic diapause[2,3].

Twenty females without pouch young or dependent young-at-foot were taken into captivity in October 1964, and three of these were kept isolated from males. These gave birth, 3–4 months later, on January 29, February 1 and February 2, 1965. Sixteen of the remaining females also gave birth in January and February 1965 (that is, at the start of the breeding season), and although males had access to them the occurrence of mating before birth was not confirmed from the daily vaginal smear. There was no difficulty in recognizing the occurrence of post-partum mating, or of mating resulting in pregnancy in other females, from the vaginal smear.

A further sample of wild females was shot in February 1965, and from this sample, and from observations on captive females, the occurrence of post-partum fertilization and subsequent embryonic diapause was confirmed. Removal of pouch young during the breeding season was followed by development of the dormant blastocyst as happens in the quokka during the breeding season[3] and in the red kangaroo[4]. Blastocysts taken during the breeding season, from animals with pouch young, were exactly like those from females taken in the October 1964 sample. In both breeding season and anoestrous animals the blastocysts were from 0·24 mm to 0·33 mm in diameter and had between eighty and ninety cells, none of which was undergoing division in any blastocyst. Blastocysts carried by anoestrous females resumed development

following the same hormone injection procedures as resulted in the precocious development of blastocysts carried by females with pouch young during the breeding season. These experiments will be reported in full later, but are mentioned here as evidence for the viability of the dormant blastocysts of anoestrous females.

These results are interpreted as follows. Females breeding for the first time became fertilized during the early part of the breeding season. Post-partum fertilization, which leads to the production of a dormant blastocyst, occurs and loss or experimental removal of the young during the breeding season is followed by completion of development of the blastocyst, birth and another post-partum fertilization. Most females enter anoestrus carrying a pouch young, and loss of the young thereafter or its emergence from the pouch is not followed by resumed development of the blastocyst. However, the blastocyst is retained, through anoestrus, in a viable state and resumes development at the onset of the next breeding season. Thus embryonic diapause is initially lactation-controlled but the blastocyst remains quiescent, presumably because of the absence of pituitary stimuli, during the anoestrous period. The retention of a viable but totally quiescent embryo consisting of only eighty to ninety cells for a period of up to 11 months—that is, for one year minus the length of the gestation period—is regarded as established for the tammar. It may also occur in other seasonally breeding macropodids. The 11-month-long diapause is the longest known to occur in any mammalian embryo.

I thank Mr. P. C. Moore for assistance with the handling of the animals, Mr. W. E. Poole for his help in field sampling, and Dr. G. B. Sharman for supervision and assistance. The research was supported by a Fulbright research grant from the Australian–American Educational Foundation.

Bispecific Chimerid Sponges from the Antarctic

IT is not unusual to find two different sponge species growing together intimately. One sponge often uses another as substrate, either encrusting, growing up from it, or surrounding it laterally. Topsent[1] and Kirkpatrick[2] have each reported a case in which one sponge is completely surrounded by another, with only its osculae projecting to the exterior. There is, however, always a definite delineation between the two unless the substrate portion of the host is dead.

The merging of two different sponge species to form one sponge is virtually unheard of. Evans[3] once reported peculiar spiculiferous bodies within a fresh-water sponge, and thought that perhaps they were parasitic sponges. However, he did not go into great detail and his illustration is unconvincing. The only other such case is de Laubenfels's *in vitro* induced "bispecific conglomerates"[4–6], the best case of which was still alive at 21 days when a storm washed away the live-car in which it was held[6]. These re-aggregates showed considerable sorting out of component cells, by species. Had they lived, they might well have produced a truly bispecific individual sponge.

During the course of investigations into the biota of the Antarctic seas, the Department of Biological Sciences and Allan Hancock Foundation of the University of Southern California have mounted, since 1961, a continuous sampling programme aboard the U.S.N.S. *Eltanin* under the sponsorship of the U.S. Antarctic Research Program of the National Science Foundation. On the sixth cruise a bispecific sponge was collected in the Drake Passage (62° 40·7′–62° 39′ S., 57° 50·7′–57° 45·5′ W., 662–1, 119 m).

The specimen, 428–2–43 (A.H.F. 1965–2), appeared on superficial examination to be a single sponge (Fig. 1). On the basis of its gross appearance, this sponge was placed as an extra specimen in a series later identified as *Oxymycale acerata* (Kirkpatrick, 1907). Collections from this station also included many individuals of a second species, a new *Sigmadocia*[7]. The *Sigmadocia* (Fig. 2*b*) is characterized by much thinner, dendritically branched, largely parallel fibre tracts, rather than the massive, very coarsely reticulate, fibre tracts of the *Oxymycale* (Fig. 2*a*). Variation in gross appearance had led to a few specimens being misplaced in series during the initial cursory examination and sorting. However, microscopic examination quickly indicated the proper placement.

A closer look at the specimen 428–2–43 gave the impression that it was one of the initially misplaced specimens and actually belonged in the *Sigmadocia* series, but stained sections and spicule slides from one area still indicated *Oxymycale*. New sections and spicule mounts from the side opposite were *Sigmadocia*. All slides were made in quadruplicate.

Spiculation of the two species involved is as follows: *Sigmadocia*, oxeas, microxeas and sigmas (Fig. 3*b*). *Oxymycale*, oxeas about half as long again, microxeas of about the same size, and two sizes of palmate anisochelas (Fig. 3*a*). Based on lumped dermis, fibre and "flesh" samples from other representatives of both species (428–2–3, *Sigmadocia*, s.s. 100, and 428–2–1, *Oxymycale*, s.s. 150) and a 0·1 per cent level of significance ($t = 15{\cdot}33$), it is concluded that the microxeas of the *Sigmadocia* are longer, although there is considerable overlap. Lumped microxea samples, size 150, from the first spicule slide of each of the representatives in the bispecific specimen also indicated that those of the *Sigmadocia* portion are longer at the 0·1 per cent level ($t = 55{\cdot}18$).

The area between those taken for the initial sections yielded two blocks designated as *A* (*Oxymycale*) inner and *B* (*Sigmadocia*) inner. At least one section from the *A* inner block demonstrates introgression of the *Sigmadocia* into the *Oxymycale* (Fig. 4). The converse is demonstrated by spicule slide No. 3 from the "flesh" of the outer region of the *Sigmadocia* side. This slide shows 40–60 per cent contamination by *Oxymycale* megascleres as well as 197 small and five large anisochelas (Fig. 3*c*). Cross-contamina-

c, Portion of spicule slide *B*3-Flesh, showing oxeote megascleres from both species, (1) microxeas and (2) chelas; the sigmas are present but do not show up well. Scale, 114μ

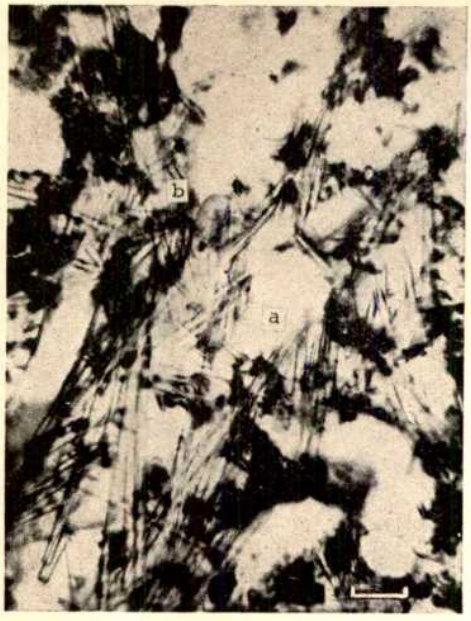

Fig. 4. Part of section from *A* inner (*Oxymycale*) block, showing (*a*) *Oxymycale* megasclere and (*b*) two *Sigmadocia* megascleres. Scale, 114μ

tion of sigmas and anisochelas in the other "flesh" mounts was minor and about the same as that found in specimens 428–2–1 and –3. The volume of material used in such preparations was about 2–4 mm³.

Further investigation yielded another such specimen, 428–2–283 (A.H.F. 1965–13), from the same station which, though much larger, is not nearly so impressive as the first. This is because the *Oxymycale* portion comprises the bulk of the specimen, the *Sigmadocia* part being about 10 per cent of the whole, and one can seemingly distinguish where one stops and the other begins. Cross-introgression, however, was repeatedly demonstrated in both directions in sections from the intermediate zone.

These specimens may be considered as the first naturally occurring "bispecific conglomerates". Two orders and families are represented, Desmacidonidae of Haplosclerina and Adociidae of Poecilosclerina.

Earlier ideas of a nearly infinite antigenic universe, and Spiegel's[8] demonstration that intercell adhesion in sponges is an antigen–antibody phenomenon, would virtually preclude the existence of such a bispecific specimen. More recent concepts of a definitely limited and even rather small antigenic universe coupled with eclipsed antigens and molecular mimicry[9,10] substantiate the possibility and even probability of such specimens in so lowly organized groups as sponges and some of the colonial protozoa.

We thank Drs. W. D. Hartman of Yale University and J. M. Savage and other staff of the Allan Hancock Foundation for suggestions and C. F. Thomas and V. D. Kach for technical assistance. This work was supported by a grant from the National Science Foundation.

A Relict Priapulid from Northern Labrador

DURING the summer of 1960 a relict population of the priapulid *Halicryptus spinulosus* v. Siebold was discovered in Tessiarsuk, northern Labrador. Tessiarsuk, at 56° 30′ N., 61° 57′ W., is a small coastal meromictic lake, 544 hectares in area, which receives periodic volumes of sea water during high tides. At depth (54 m) the maximum salinity is 21·5 ‰ while the surface salinity increases from zero in the spring to about 16 ‰ in late autumn. As the lake is permanently stratified and the bottom waters anoxic, the benthos is mainly confined to the shallower littoral zone. *H. spinulosus* was found only in a small corner of the littoral about 6 hectares in area where the depth was 4–6 m, the salinity 10–15 ‰ and the bottom sediments consisted of silt and fine sand. A total of twenty-six specimens was obtained, the largest being 16 mm in length or approximately half the maximum length of 31 mm recorded by Fischer[1]. Other members of the community were the bivalves *Mytilus edulis* and *Macoma baltica* and the polychaete *Castalia aphroditoides*.

This is the first North American record of *H. spinulosus*. In a recent paper on the zoogeography of the Priapulida, Murina and Starobogatov[2] list the known areas of occurrence as western and eastern Greenland, Spitzbergen, southern Iceland, Trondjheim Fiord, Finmark, Øresund, Kategaat, Baltic Sea, Barents Sea, Kara Sea, Matochkin Shar in Novaya Zemlya and Taymirsky Zaliv in the Taymar Strait. Théel[3] first accounted for the peculiarly broken distribution of *H. spinulosus* by suggesting that the centrum of its range was the Baltic Sea, from which it had radiated westward to occupy a variety of habitats. Wesenberg-Lund[4] and Segerstråle[5], however, put forward the more convincing theory that the species is primarily Arctic and migrated into the Baltic during post-glacial

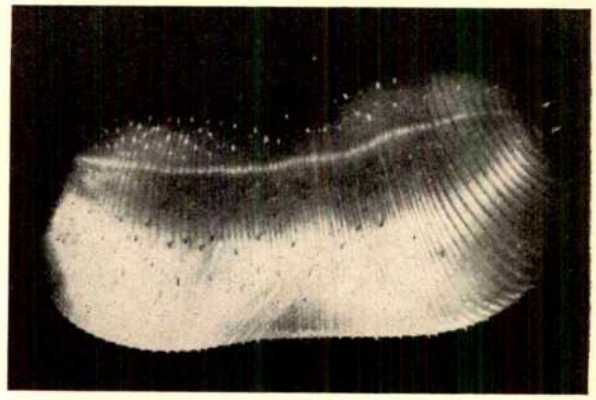

Fig. 1. *H. spinulosus*. Lateral view showing external annulations, spines and ventral nerve cord

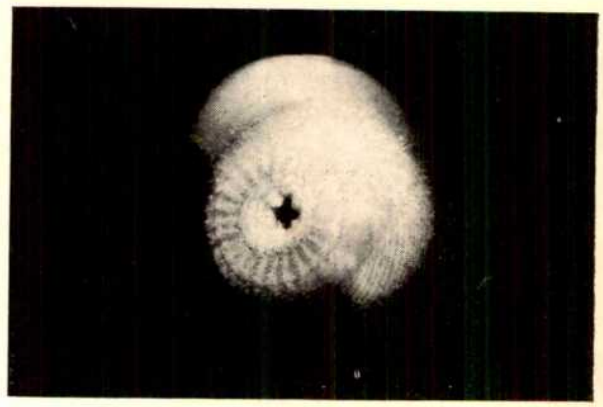

Fig. 2. *H. spinulosus*. Oral end

times when the salinity there was somewhat higher. When the salinity afterwards decreased, *H. spinulosus* was able to adapt to the modified conditions. A similar process presumably occurred in the case of Tessiarsuk, which probably contained water of a much greater salinity before the land rebounded in more recent times partially to isolate it from the sea. Since the closest recorded population is more than 500 miles distant it is probable that the range of *H. spinulosus* has shrunk considerably during the last few millennia.

Other faunistic parallels exist between Tessiarsuk and the Baltic Sea despite the great disparity in size. Besides *Macoma baltica* and *Mytilus edulis*, Tessiarsuk also contains populations of the amphipod *Pontoporeia femorata* and the medusa *Halitholus cirratus*, all common forms in the Baltic.

A Decline in the Occurrence of *Diphyllobothrium* Plerocercoids in the Trout *Salmo trutta* L. of Llyn Padarn, Caernarvonshire

A SURVEY of the parasites of the trout, char, stickleback, minnow and eel in Llyn Padarn was begun in April 1963. The trout *Salmo trutta* L. and the char *Salvelinus alpinus perisii* (Günther) were heavily infected by the plerocercoids of *Diphyllobothrium ditremum* (Creplin, 1825) and *Diphyllobothrium dendriticum* (Nitzsch, 1824) which were found encapsuled in the viscera and body wall. The parasite survey was continued in 1964 when a marked fall in the occurrence of *Diphyllobothrium* plerocercoids in the trout was noted. Observations made in 1965 showed a further fall in the numbers of the plerocercoids in the trout. The numbers of plerocercoids present in the char remained more or less constant throughout the period of investigation (see Table 1).

In 1963 and 1964 a random selection of the trout population was sampled. In 1965 only trout longer than 15 cm were examined because smaller trout were found rarely to be infected by plerocercoids of *Diphyllobothrium*. All char examined were longer than 16 cm. All capsules were opened and the living plerocercoids were relaxed in cold water and preserved for further examination. Full details of the biology of the plerocercoids will be published later.

Table 1 shows that the mean number of *D. ditremum* and *D. dendriticum* per trout fell during the period 1963–65, while the ratio of occurrence of the two species remained constant. The numbers of plerocercoids in the char did not decline.

The fall in occurrence of plerocercoids in trout indicated that a change has taken place in the numbers, habits, or reactions to the parasite of one or more of the host animals involved in the life-cycle of the two species of tapeworm. No decrease in the numbers of the definitive hosts (gulls in the case of *D. dendriticum* and cormorant in the case of *D. ditremum*) has been observed during the investigation, nor is there any indication that the planktonic fauna of the lake has radically changed. These considerations, together with the fairly constant level of infection in the char and a recorded increase, from 1963 to 1965, of the number of capsules containing dead plerocercoids in trout, strongly suggest that the trout have developed an increasing immunity to the *Diphyllobothrium*.

A review of epidemics caused by plerocercoids of *Diphyllobothrium* in trout in the British Isles was presented by Fraser[1], but it is unfortunate that the fate of these outbreaks is not known. The date of the first occurrence of plerocercoids in the trout of Llyn Padarn is not certain, but the Gwynedd River Authority officials have only noticed the worms since 1959. The infection may have been building up at this time, and have reached a peak about 1961–62. Our observations have been carried out during a decline in the level of infection in the trout. We are continuing the observations in order to see the future pattern of the infection in the trout which may follow one of three possible trends: the infection of *Diphyllobothrium* may eventually die out, or may remain at a low level, similar to that found in the trout of Llyn Tegid (Bala Lake), or there may be cyclical changes between high and low levels of infection. In Llyn Padarn the presence of the infected char will affect the occurrence of the plerocercoids in the trout, by acting as a reservoir for the infection of the definitive hosts and the continuation of the life-cycle. As there has been no marked decline in the numbers of plerocercoids in the char, it is difficult to envisage the infection dying out completely in the trout.

We thank Mr. H. Evans, Fisheries Superintendent of the Gwynedd River Authority, and his staff for their help.

MICROBIOLOGY

Observations on the Gametogenesis of *Plasmodium vinckei*

MANY authors in the past have observed the disappearance of gametocytes of certain blood protozoa as a result of their continuous and prolonged mechanical transmission. This phenomenon was especially investigated by Vincke[1], Rodhain[2], Jadin, Yoeli and Pierreux[3], and by Michiels[4] in strains of *Plasmodium berghei* maintained in the laboratory for years by 'syringe passages'. The rodent malaria parasite *Plasmodium vinckei*[5], isolated in 1952, behaves similarly.

It has recently been observed by Vincke, Scheepers-Biva and Bafort[6] that *P. berghei* (*Vinckeia* from Garnham[7]) which has lost its ability to produce gametocytes could

recover this power if kept in a state of 'quiescence'. This 'quiescence' may be obtained by transmitting the infection to adult albino rats in the metacritical phase, where it survives in a mild, latent stage, and also by keeping the parasite at low temperatures at −75° C.

We wondered if we should observe the same phenomenon in *P. vinckei*. This parasite has been maintained since its isolation by blood transfers and has long lost its ability to produce gametocytes. We received the strain on September 14, 1962, from Algeria by the courtesy of Prof. Fabiani. No precise information is available on the number of mechanical transmissions undergone by the strain before its arrival in our laboratories. Our estimation is that the strain had passed at least 400 times when we received it, assuming that one blood transfer was carried out every 10 days from the time of its discovery by Vincke in January 1952 to November 1962.

We continued to maintain the strain by weekly transfers in mice and rats. On May 20, 1965, the strain, about 13 years old, has been passed 68 times in 934 days in our laboratory: 59 times in mice, four times in albino rats, and five transfers in tree rats, *Thamnomys surdaster*. Two transfers in deep freeze at −75° C were also carried out during this period.

Tables 1 and 2 summarize the details of the successive blood transfers in the two lines of animals which originated from the *P. vinckei*-infected animals received in September 1962.

It must be emphasized that the blood of all *P. vinckei*-infected animals was regularly checked for the appearance of gametocytes and for exflagellation, but none was observed. However, after keeping *P. vinckei*-infected blood from rat 362 at low temperature (−75° C) and afterwards passing it twice through albino rats, few gametocytes and sparse exflagellation were observed in the blood of mouse 734. More numerous exflagellations occurred in the blood of mouse 901 after the strain was maintained for a second period in deep freeze.

Table 1. SUCCESSIVE TRANSMISSIONS AFTER RECEIPT OF THE STRAIN ON NOVEMBER 14, 1962: MOUSE 901

Date	No. of passage	Animal	Observations
11/14/62–11/20/62	1–2	Young mice	Weekly transfers
11/27/62–1/4/63	3–7	*Thamnomys*	Weekly transfers
1/2/63–9/20/63	8–41	Young mice	Weekly transfers
9/27/63	42	Albino rat 362	Blood in deep freeze (−75° C) tenth day after inoculation. Time of stay at low temperature 67 days (10/8/63–12/12/63)
12/12/63–2/20/64	43–53	Young mice	Weekly transfers
2/27/64	54	Albino rat	Weekly transfers
3/13/64–5/8/64	55–63	Young mice	Weekly transfers
5/15/64	64	Rat reservoir	Rat clinically cured on the thirtieth day after inoculation and sub-inoculated on the 107th day
8/31/64	65	Rat reservoir	Rat clinically cured on the twenty-first day after inoculation and sub-inoculated on the 50th day
10/20/64	66	Young mouse	
10/30/64	67	Young mouse 734	Few exflagellations of microgametocytes observed in the blood on 11/5/64, the sixth day after inoculation. The blood was kept at −75° C from 11/6/64–5/13/65, 190 days
5/13/65	68	Young mouse 901	Exflagellation observed on 5/20/65, the seventh day after inoculation

Table 2. SUCCESSIVE TRANSMISSIONS AFTER RECHIPT OF THE STRAIN ON NOVEMBER 14, 1962: MOUSE 931

Date	No. of passage	Animal	Observations
11/14/62–11/20/62	1–2	Young mice	Weekly transmissions
11/27/62–1/4/63	3–7	*Thamnomys*	Weekly transmissions
1/2/63–9/20/63	8–41	Young mice	Weekly transmissions
9/27/63	42	Albino rat 362	Blood in deep freeze on tenth day after inoculation. Time of stay at low temperature, 414 days (10/8/63–11/26/64)
11/26/64	43	Young mouse	
12/3/64–12/11/64	44–45	Albino rat	Weekly transmissions
12/18/64–5/29/65	46–68	Young mice	Weekly transmissions
5/28/65	69	Young mouse	Few exflagellations observed in the blood on 6/3/6 5, 6 days after inoculation

We also observed exflagellation in the transfers originating from mouse 931 (Table 2). This animal was also infected with *P. vinckei* blood originating from rat 362, but the infected blood was kept for 414 days at −75° C and afterwards passed in successive transfers to mice. Exflagellation of microgametocytes in small numbers was observed at the sixty-ninth blood transfer. In the five observations in which exflagellation was hitherto observed, all were carried out on the sixth and seventh days after inoculation.

It may therefore be concluded that in *P. vinckei*, as in *P. berghei*, a period of 'quiescence' at low temperature (−75° C) favours the later reappearance of viable gametocytes. This phenomenon must, however, be confirmed by further observations as it conflicts with investigations made in human malaria in which gametogony is present in acute cases of malaria. However, more importance and more attention are now given to the possibility of transmission of infections by asymptomatic cases.

We thank Prof. Yoeli, who has very kindly corrected our translation.

SOIL SCIENCE

Soils and Micro-organisms from Mount Erebus, Antarctica

WHILE conducting pedological and biological studies in the ice-free areas of East Antarctica, one of us (F. C. U.) and Dr. H. Janetschek had the opportunity in February 1962 to climb Mount Erebus. Considered the only active volcano known in Antarctica, Mount Erebus (3,721 m) consists of trachyte, kenyte, basalt and other volcanic rocks[1]. Extensive ice and snow cover limits the soil occurrence to the lower snow-free slopes, to exposed rock projections, a few areas near the hot fumaroles, and in the vicinity of the active crater.

Soil samples were secured at various locations along the mountain. This communication describes samples collected at two sites.

Sample E_3 was obtained from the vast field of active and inactive fumaroles. The area where the sample was collected is kept free from snow and ice by the hot fumarolic vapours. The dark-grey-brown soil is sandy, moist and warm to the touch in contrast to the air temperature of −26° C. A partial chemical analysis of the sample shows an acid reaction of *p*H 4·2, considerable quantities of chlorides, native sulphur and free iron oxides. Total nitrogen is 0·03 per cent, whereas total carbon is 0·1 per cent.

Sample E_4 was obtained from the edge of the active crater in an area covered by patches of sulphur. The very dry yellowish-brown soil is sandy with large loose feldspar crystals. The soil is very acid (*p*H 2·7); chlorides and native sulphur are abundant, but carbon and nitrogen are not detected. More information on the composition of these two samples has already been provided by one of us[2].

Neither site E_3 nor E_4 supports any form of megascopic plants. Bacteria, actinomycetes and fungi were not found in the material obtained from site E_4, not even the acid-tolerant sulphur bacterium *Thiobacillus thiooxidans*. Lack of micro-organisms is ascribed to the high acidity and dryness of the material. Various bacteria and fungi but no actinomycetes were detected in sample E_3 collected next to an active fumarole. Approximately 9×10^6 bacteria were found by plating on albumin agar and 6,500 fungi by plating on peptone–dextrose novobiocin agar. Among the fungi were species of *Penicillium*, *Aspergillus* and *Neurospora*, and a yeast and also a fungus that failed to produce spores and is considered to be a member of the Dematiaceae. The bacteria and fungi were as abundant in E_3 as in many fertile cultivated soils of temperate regions.

The soils of Mount Erebus are acid, contrary to the ubiquitous alkaline or neutral conditions of the soils of Southern Victoria Land. The oxidation of the native sulphur into sulphuric acid may be responsible for the low *p*H.

HORTICULTURE

Chemical Control of Vegetative Growth and Fruitfulness of Tomatoes

IN 1957, Eaton[1] described the induction of selective male sterility in flowers formed on various cotton varieties which had been sprayed with sodium 2,3-dichloro-2-methylpropionate solutions and projected the possibility of mass-producing F_1 hybrid cotton seed from rigorously inbred parents by the use of these treatments. Similar gametocidal responses to foliar sprays of this chemical have since been demonstrated by Moore[2] in eleven tomato varieties. Additional gametocidal and growth regulatory properties have been described for tomatoes, cotton and sugar beets[3]. Further experimentation on all three crops, using foliar sprays of this chemical, invariably induced an excessive amount of female sterility in the process of achieving the desired sterility in male flower parts[4]. As a result, the mass production of hybrid seed in these crops using this chemical has been impractical.

The projected termination of the California Bracero programme in 1965 has stimulated interest in developing mechanical harvesting devices for use with various crops destined for processing in that area. All experimental models developed so far for tomatoes involve the destruction of the entire plant in a single picking harvest. The presence of either prematurely ripe fruit or small developing green fruit is undesirable at harvest. Renewed interest in the gametocidal properties of this chemical has been directed to its use as a possible aid in mechanical harvesting procedures. Normally, the perfect tomato flowers are self-fertilized before anthesis, but the stigmas remain receptive to hand pollination for a variable period after anthesis (depending on variety) when selective male sterility has been induced by chemical treatments. In the absence of hand pollination, natural crossing by other agents, or parthenocarpic fruit development, sterile tomato flowers continue to abscise without setting fruit. Thus, gametocidal treatments could eliminate the presence of early overripe fruit and facilitate the mechanical harvesting operation.

Three extensive field experiments were conducted at Tracy, Stockton and Saticoy, California, during the 1964 growing season. The locations selected represented a reasonably diverse range of geographic and cultural conditions normally encountered in California tomato production. Six treatments involving a factorial combination of two gametocidal dosage-levels (0·15 and 0·25 per cent water solutions) × three spray schedules (one versus two versus three sequential sprays) were used at each location in which four to six replications were used in a randomized block design. Attempts were made to adjust fertilization practices, water management and pesticide applications to the optimum benefit of each treatment, but the random arrangement of plots precluded complete adjustment in all instances. Each plot of any single treatment at all locations was harvested by hand to simulate a mechanical operation when the onset of overripe fruit was obvious. Accurate plant response data necessary for the appraisal of treatment responses listed in Table 1 were collected at each experimental installation.

All gametocidal treatments resulted in a "blanching" of the foliage, slight leaf epinasty, and obviously retarded growth rates at all locations. The severity of foliar injury increased with increasing numbers of sprays and, to a lesser extent, with spray concentration. The injury symptoms persisted for a minimum of 3 weeks at one location, a maximum of 7 weeks at another, but eventually vanished at all locations.

All treatments at each location induced obvious sterility in floral parts with resultant abscission of flowers and delay in the onset of fruiting. As treatment effects increased markedly with the increasing number of sprays, and were relatively uninfluenced by spray concentration, the average treatment responses for three sequential sprays over the range of two spray concentrations and three locations are compiled in Table 1.

Table 1. AVERAGE EFFECTS OF TWO CONCENTRATIONS OF THREE SPRAYS AT THREE LOCATIONS

Criteria	Untreated	Treated	*L.S.D.* ($P = 0.01$)
A. Delay in onset of fruiting (days)	0	24	
B. Vine weight (oz)	21·5	37·8	10·29
C. No. of fruit set per plant	45·3	58·8	10 15
D. Yield (tons/acre)	23·5	36 5	9 67
E. Yield (tons/acre day)	0·184	0·247	0 0735
F. Percentage usable fruit* (count basis)	48 4 (44·1)	63 7 (53·1)	(8·01)†
G. Percentage usable fruit* (weight basis)	60 7 (51·4)	74 7 (60 0)	(8·98)†
H. Percentage green fruit (weight basis)	35·3 (36 1)	18·6 (25 6)	(8·89)†
I. Fruit size (oz.)	2·60	2 25	0·436

* For processing.
† Percentage of data transformed (arc sin) for tests of significance.

Three sequential gametocidal sprays obviously induced floral abscission and delayed the onset of fruiting. These responses resulted in a longer period for continued vegetative growth and larger individual vines, which eventually set a greater number of fruit per vine at a later date. Increased yields resulted in all treatments using either tons per acre or tons per unit of production time as criteria. Fruit matured in a "peaked" condition favourable for either mechanical or hand harvesting procedures. The occurrence of underripe green fruit in a single-picking harvesting operation was also reduced by the treatments. Fruit size was somewhat adversely affected by the treatments, but this response may have resulted in part from our inability to adjust completely cultural practices to the optimum advantage of each treatment at each location. All the treatment responses in growth and fruitfulness reported here are statistically reliable at substantial levels of confidence.

In view of the common relationship between vegetative growth rates and fruitfulness in flowering plants generally, it would seem reasonable to expect corresponding responses to gametocidal treatments in other crops. The gameto-

cidal attributes of this chemical have already been established for cotton and various legumes.

GENERAL

Kinematic Programming for Rain

The following statement and resolution of an elementary optimization problem may be of interest to those who, like me, have never been confident about the optimal speed and posture to adopt when caught without protection in a rain shower.

Consider a bounded rigid body B of arbitrary shape in a Euclidean space of k dimensions ($k > 1$). B is required to move one of its points, a reference point O, say, from a starting point S to a finishing point F. The space is dotted with hostile points generically denoted by the symbol R, which are all moving with the same velocity $\mathbf{v}$. It is B's object to move O from S to F in such a way as to minimize his contact with R.

An *itinerary* between S and F is specified by the triad $I = [P_0, \omega(t), \omega(t)]$, where P_0 is the initial posture of B at S, $\mathbf{u}(t)$ is the velocity of O at time t and $\omega(t)$ is the angular velocity vector. Let $\mathfrak{I}$ denote the class of available I's. Assume that, if a portion of the surface of B sweeps out a volume δV of the space, the mean contact with R is proportional to δV if δV, regarded as part of the moving space (R-space say) in which R is stationary, has not been previously swept by B. Also that, once a volume in R-space has been swept, that volume remains free of R thereafter. The problem is therefore to minimize:

$$V = \int_{(S)}^{(F)} \frac{\mathrm{d}V}{\mathrm{d}t}\,\mathrm{d}t \qquad (1)$$

where $\mathrm{d}V/\mathrm{d}t$ is the rate of sweeping by the whole surface of B of previously unswept volume. Now:

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \int \varphi\,(\mathbf{r},t)\,[\mathbf{u}(t) - \mathbf{v} + \omega(t) \wedge \mathbf{r}].\ \mathrm{d}\mathbf{S} \qquad (2)$$

where $\mathrm{d}\mathbf{S}$ is the normal vector surface element of B at the point $\mathbf{r}$ relative to O and $\varphi(\mathbf{r},t) = 1$ if the rest of the integrand is not negative and $\mathbf{r}$ is adjacent to previously unswept volume: $\varphi(\mathbf{r},t) = 0$ otherwise. Equations (1) and (2) combine to give V for any itinerary.

Fortunately, the expected is the case. As long as $\mathfrak{I}$ includes "top-speed, unrestricted posture, straight-line" itineraries along SF, then choice of I to minimize V can be made using elementary considerations. Let:

$$u_m = \max_{I \in \mathfrak{I}} \max_{t}\ u(t)$$

and let $V_t(\mathbf{p})$ be the volume in k–1 dimensions of the projection of B at time t parallel to $\mathbf{p}$ on to the k–1 space orthogonal to $\mathbf{p}$. Let $\min V_t(\mathfrak{I}) = M$ (say) $= V_t(\mathbf{p}_t)$ (say). Let $\mathbf{l}$ be the unit vector along $\overrightarrow{SF}$.

Case A. If $\mathbf{v} \cdot \mathbf{l} \leqslant 0$, then an optimal itinerary in $\mathfrak{I}$ is $I_m = [P'_0, u_m\,\mathbf{l}, \mathbf{o}]$, where P'_0 has $\mathbf{p}_0$ parallel to $\mathbf{v} - u_m\,\mathbf{l}$. To see this, Fig. 1 in R-space should be examined.

S_0, F_0 are the positions of S and F, respectively, at $t = 0$. F_T is the position of F at $t = T$ if O arrives at F_T along I_m. $F_{T'}$ is the position of F at $t = T'$ if O arrives at $F_{T'}$ using the arbitrary(dashed) itinerary I_A. Clearly I_m minimizes the time of the itinerary, whence $T \leqslant T'$ and $S_0F_T \leqslant S_0F_{T'}$ as shown. Thus, using I_A, B must

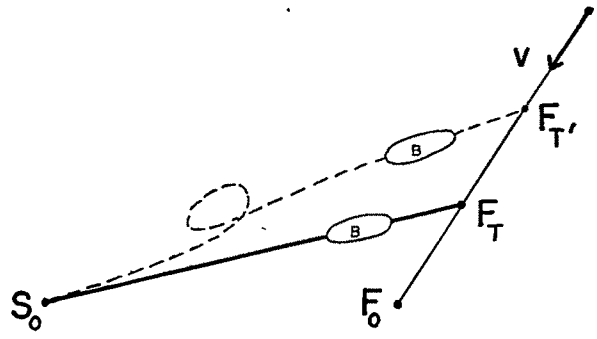

Fig. 1. Straight line and arbitrary itineraries in R-space

sweep out a volume of R-space which cannot be less than the volume for I_m. [The degenerate case of $\mathbf{v}$ parallel to $\mathbf{l}$ does not affect this finding.]

Case B. If $\mathbf{v} \cdot \mathbf{l} > 0$, then an optimal itinerary is: (i) I_m if $u_m \leqslant v^2/\mathbf{v} \cdot \mathbf{l}$; (ii) $I_0 = [P''_0, (v^2/\mathbf{v} \cdot \mathbf{l})\,\mathbf{l}, \mathbf{o}]$, where P''_0 has $\mathbf{p}_0$ parallel to $\mathbf{v} - (v^2/\mathbf{v} \cdot \mathbf{l})\,\mathbf{l}$, if $u_m > v^2/\mathbf{v} \cdot \mathbf{l}$. Case B (i) is proved in the same way as case A, because, for $u_m \leqslant v^2/\mathbf{v} \cdot \mathbf{l}$, an essentially similar figure is obtained. For case B (ii), S_0F_T is perpendicular to F_0F_T for I_0, which also establishes the result.

In cases A and B (i), the optimal itinerary is seen to be unique. Any deviation from it will increase V. However, in case B (ii) there is non-uniqueness. This is readily seen for the extreme case when $u_m = \infty$, when the solid itinerary indicated in original space in Fig. 2 has the same V as I_0.

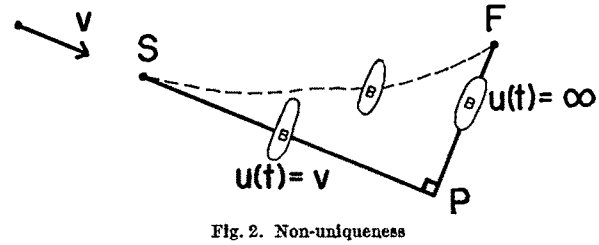

Fig. 2. Non-uniqueness

For $v^2/\mathbf{v} \cdot \mathbf{l} < u_m < \infty$, there are itineraries with O-paths interior to the triangle SPF of Fig. 2, as dotted, their characteristic being increasing distances from SP and a resolved velocity parallel to SP equal to $\mathbf{v}$.

The practical recommendations arising from these considerations are that, when rain is coming from the general direction of your destination, you should get your head down and go as fast as you can. When the rain is coming from behind, either lean backwards or walk backwards while leaning 'forwards', in neither case exceeding a certain optimal speed.

When the choice of posture is unrestricted, the only property of B affecting min V is the minimum projection M. When posture is restricted so that other properties of B affect min V, the following fact may be useful. For a given itinerary, V cannot be increased and, especially when posture is restricted, may well be decreased by filling in any concavities in B's surface with portions cut off anywhere from B.

The possibility of reducing min V by cutting B into portions and sending these portions separately to their assembly points is always available in certain applications (but not in that originally envisaged). Consider B shaped like a letter L. Break it at the angle. The flexibility thereby introduced can be used to reduce min V. However, care is needed because if B were cut into portions similar to B, it is easy to see from scalar considerations that min V would increase.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANT to assist with computation and numerical analysis—Dr. C. D. Walshaw, Clarendon Laboratory, Department of Atmospheric Physics, Parks Road, Oxford (July 30).

TEMPORARY ASSISTANT LECTURER or LECTURER IN CHEMICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (July 30).

VETERINARY OFFICERS, Grade II (aged at least 23, Member of the Royal College of Veterinary Surgeons, with one year's appropriate postgraduate experience) with the Ministry of Agriculture, Fisheries and Food—Civil Service Commission, 23 Savile Row, London, W.1, quoting Ref. 130/66/2 (August 1).

TEACHING FELLOW (with a good honours degree with specialization in palaeontology) IN GEOLOGY (Palaeontology) at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 5).

SENIOR LECTURER (with an honours degree in electrical engineering or science, preferably a higher degree, and research or design experience in electronics or communications) IN ELECTRICAL ENGINEERING (August 26); and a LECTURER or SENIOR LECTURER (with a science degree specializing in geophysics or a related discipline and some research experience or recent experience in exploration geophysics) IN GEOPHYSICS (August 5) at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

ASSISTANT EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER (chemist or biochemist, with a degree in science, H.N.C. in chemistry, or equivalent, and preferably some knowledge of chromatographic and radioactive isotope techniques) for work on mineral nutrition particularly of potassium in vegetable crops—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 6).

ASSISTANT EXPERIMENTAL (or Experimental) OFFICER (with a degree, or equivalent, in science or horticulture) FOR PLANT BREEDING WORK—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (August 6).

LECTURER or ASSISTANT LECTURER (graduate in medicine, veterinary science, dentistry or biology) IN THE DEPARTMENT OF HISTOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/136 (August 6).

RESEARCH FELLOW (with research experience in microbiology or biochemistry) IN THE DEPARTMENT OF CHEMISTRY to participate in a study of the mode of biosynthesis of antibiotics—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (August 11).

LECTURER or ASSISTANT LECTURER (with an honours degree in physiology or prepared to attend an honours course, and preferably with a veterinary qualification) IN THE DEPARTMENT OF VETERINARY PHYSIOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (August 12).

SENIOR LECTURER and a LECTURER IN PHYSICS at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 12).

SENIOR LECTURER and LECTURERS IN CIVIL ENGINEERING; LECTURERS IN ELECTRICAL ENGINEERING; and a READER, SENIOR LECTURER and LECTURERS IN MECHANICAL ENGINEERING at Ahmadu Bello University, Northern Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 12)

SENIOR LECTURER/LECTURER IN MATHEMATICS at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (August 12).

TEMPORARY ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER (with at least two "A" levels including physics, or H.N.C. in applied physics, or equivalent. A degree in electrical engineering or equivalent is desirable) at the R.N. Medical School, Alverstoke, Hants, to act as assistant to the Health Physicist in charge of the Whole Body Counter—Ministry of Defence (Navy Department) CE3(N) 368, Old War Office Building, Whitehall, London, S.W.1 (August 12).

LECTURER (science graduate preferably with experience in microbiological chemistry, microbial genetics or an applied field of microbiology) IN BACTERIOLOGY at Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee (August 13).

ASSISTANT LECTURER IN PURE AND/OR APPLIED MATHEMATICS; and a LECTURER or ASSISTANT LECTURER IN PHYSICS at the University of the West Indies, Barbados—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 15).

LECTURER or ASSISTANT LECTURER (with interests in taxonomy, morphology or plant breeding) TO TEACH THE BOTANY OF ECONOMIC PLANTS; and an ASSISTANT LECTURER to assist the Professor in teaching and research in crop physiology, crop ecology or the botany of tropical crops for two years—The Registrar (Room 39, O.R.B.), The University, Reading (August 15).

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with a first- or second-class honours degree, Dip. Tech., or equivalent or higher qualification in a natural science or technology, but, exceptionally, consideration will be given to a candidate whose main qualification is in a social science, preferably with experience in experimental psychology or with additional qualifications in natural science) in the Office for Scientific and Technical Information, London, to help promote the education and training of scientific and technical information staff at all levels and for all types of information work—Miss M. E. Gummer, Department of Education and Science, Curzon Street, London, W.1 (August 15).

LECTURER/SENIOR LECTURER IN BIOCHEMISTRY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 19).

LECTURER/SENIOR LECTURER IN MICROBIOLOGY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 19).

LECTURER/SENIOR LECTURER IN VETERINARY VIROLOGY IN THE DEPARTMENT OF VETERINARY PATHOLOGY AND BACTERIOLOGY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 19).

SENIOR LECTURERS or LECTURERS (2) (with a good honours degree and industrial or research experience in one of the following fields: circuit engineering, control, communications, microwave engineering, or power systems) IN ELECTRICAL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 19).

EXPERIMENTAL OFFICER and a TECHNICIAN (preferably with experience in mass spectrometry and/or electronics) to assist in the running of a unit for isotope geology being set up at the Reactor Centre—The Director, Scottish Research Reactor Centre, East Kilbride, Glasgow (August 20).

SENIOR LECTURER or LECTURER IN PHYSIOLOGY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 22).

SENIOR LECTURER or LECTURER (preferably with a special interest in organic chemistry) IN CHEMISTRY at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 22).

RESEARCH ASSISTANT for X-ray diffraction work—Dr. J. Zussman, Department of Geology and Mineralogy, University of Oxford, Parks Road, Oxford (August 25).

SENIOR LECTURER (with an honours degree in electrical engineering or science and preferably a higher degree, research or design experience in electronics or communications, and ability to lecture to postgraduate students and participate effectively in research projects) in ELECTRICAL ENGINEERING at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, August 26).

RESEARCH FELLOW (plant biochemist or microbiologist) to study the biochemical self-sufficiency of chloroplasts—The Registrar, University of York, Heslington, York (August 29).

CHAIR OF ANCIENT PHILOSOPHY—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (August 31).

LECTURER IN BIOCHEMISTRY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

LECTURER IN THE DEPARTMENT OF MICROBIOLOGY, Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

LECTURER or ASSISTANT LECTURER (physicist, physical chemist or others with an appropriate background) IN THE DEPARTMENT OF CERAMICS, Houldsworth School of Applied Science—The Registrar, The University, Leeds, 2 (August 31).

SENIOR LECTURER/LECTULER (preferably with interests in the field of inorganic chemistry) IN CHEMISTRY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 31).

SENIOR LECTURER or LECTURER IN THE DEPARTMENT OF PHYSIOLOGY—The Registrar, University College of South Wales and Monmouthshire, Cardiff (September 5).

LECTURER or RESEARCH FELLOW (with some experience in the area of operational research and systems analysis, and particularly interested in the mathematical techniques of optimization) IN THE DEPARTMENT OF SYSTEMS ENGINEERING—The Secretary, University of Lancaster, Bailrigg House, Lancaster (September 16).

CHAIR OF PURE MATHEMATICS IN THE SCHOOL OF MATHEMATICS AND PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, Norfolk, NOR 88C (October 15).

ASSISTANT EXPERIMENTAL OFFICER (preferably with a degree in engineering or geology, with some instrumentation and/or soil mechanics research experience) IN THE ENGINEERING GEOLOGY GROUP OF THE GEOLOGY DEPARTMENT to be concerned with the development and experimentation of advanced soil laboratory equipment, and possibly carry out field work on the engineering geology of fissuring and consolidation of fine grained sediments—Mr. E. J. Hill, Departmental Superintendent, Geology Department, Imperial College, London, S.W.7.

ASSISTANT LIBRARIAN (reference and information services) (Chartered Librarian or graduate who has passed Part 2 of the Library Association examinations)—The Staff Officer, University of Aston in Birmingham, Gosta Green, Birmingham 4, quoting Ref 0/181/N.

CELL CULTURE TECHNICIAN (preferably with experience of bacteriological techniques) for work in the Radiobiology Laboratory—Dr. R. J. Berry, Radiobiology Laboratory, Radiotherapy Department, Churchill Hospital, Oxford.

JUNIOR TECHNICAL OFFICER (with a pass degree, H.N.C. or equivalent in physics or mathematics, and preferably with mathematical or electronic experience) to assist in physical research in the application of radioisotopes to medicine including use of an analogue computer—The Director, Medical Research Council Cyclotron Unit, Hammersmith Hospital, Du Cane Road, London, W.12.

LECTURER (with a degree in metallurgy, science, or engineering, together with research or industrial experience) IN PROCESS ENGINEERING IN THE METALLURGY DEPARTMENT—Prof. A. V Bradshaw, Department of Metallurgy, Imperial College of Science and Technology, Prince Consort Road, London, S.W 7.

LECTURER (with a first- or second-class honours degree or equivalent or higher qualification in mechanical engineering and practical experience associated with that of a Chartered Engineer) IN THE DEPARTMENT OF MECHANICAL ENGINEERING to teach applied thermodynamics to students reading for London External Degree in engineering—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire.

MICROANALYST to take charge of the Macroanalytical Laboratory—The Laboratory Superintendent, Chemical Laboratory, University of Sussex, Falmer, Brighton, Sussex.

OIL SEED CHEMIST (with a Ph.D. and experience in lipid research) for duties which will include directing an oil seed laboratory and conducting research on the quality of commercial oil seed crops—Dr. G. N. Irvine, Director, Grain Research Laboratory, Board of Grain Commissioners for Canada, Winnipeg, Canada, quoting Ref. 66-10C-GO.

PROFESSOR OF APPLIED BIOLOGY—The Registrar and Secretary, Welsh College of Advanced Technology, Cathays Park, Cardiff.

RESEARCH ASSISTANT (with a chemical or biochemical background) IN THE DEPARTMENT OF PAEDIATRICS, to work on aspects of carbohydrate metabolism in the newborn infant—Dr. H. R. Gamsu, King's College Hospital Medical School, Denmark Hill, London, S.E.5.

RESEARCH ASSISTANTS IN CHEMISTRY AND PHYSICS (with a first- or second-class (upper or lower) honours degree) to undertake postgraduate research leading to M.Phil. or Ph.D degrees of the University of London—Head of the appropriate department, Sir John Cass College, Jewry Street, London, E.C.3.

RESEARCH BIOLOGIST (with an honours degree in biology) to assist in investigations of aquatic invertebrates—Personnel Officer, Trent University, Peterborough, Ontario, Canada

SCIENTISTS (2) (with experience in either of the following fields: genetics and/or biochemistry, tumour biology and/or immunology, and preferably some experience in general virology) for research on tumour viruses and related topics—The Honorary Director, Prof. M. G. P. Stoker, M.R.C. Experimental Virus Research Unit, Institute of Virology, The University, Glasgow.

TECHNICIAN/JUNIOR TECHNICAL OFFICER (preferably with experience in microbiology or tissue culture techniques) at Pollards Wood Research Station, Chalfont St. Giles, to assist in molecular biological research—The Secretary, Institute of Cancer Research, 34 Sumner Place, London, S.W.7, quoting Ref. 301/B/259.

ZOOLOGISTS (M.Sc. or Ph.D., with research experience and preferably some knowledge of histology and histochemistry) to participate in experimental multi-disciplinary programmes of basic research in the field of food additive toxicology—The Director, British Industrial Biological Research Association, Woodmansterne Road, Carshalton, Surrey.

STONEHENGE

At this time of the year, Stonehenge is crammed with tourists. The Ministry of Public Building and Works keeps the grass well cut, and will provide visitors with a guide-book for a modest fee. Refreshments are to be had in the car park across the trunk road which passes nearby, and on a sunny day those who have come to inspect the best preserved of the ancient monuments in Britain can also amuse themselves by watching the manoeuvres of the soldiers who practise incongruously with rocket weapons only a few miles away. Then, at sunrise on Midsummer Day, the Ministry of Public Building and Works will undertake to see that the monument is cleared of all who have no excuse for being there—usually the small company of eccentrics which re-enacts druidical rituals at Stonehenge once a year, and the Press photographers who come to take their pictures and that of the rising sun (when visible). The fact that this year the druids overslept and were half an hour late should not be held against them, for druids, in the twentieth century at least, are also human.

But, in spite of all the tomfoolery which it must from time to time accommodate, Stonehenge retains its trick of quickening the imagination and disturbing it. The technology of the monument, and the endless speculations about the ways in which the stones may once have been assembled, is more tangible and thus less awesome than the single-minded purposiveness of the whole enterprise. Why was it thought sensible to spend what must have been a large part of the energy of the community that built Stonehenge on this gigantic structure? To such a primitive people, this was an undertaking to dwarf the cathedral building of the Middle Ages in costliness. Surely a people preoccupied with survival would not choose to waste energy in such a lavish way merely out of superstition. But, if it is hard to conceive a superstition powerful enough, what sober purpose can there have been in building it?

Questions like these have informed speculation about Stonehenge for several decades. At the end of the nineteenth century Sir Norman Lockyer, the then editor of this journal, began to put flesh on the bones of the old assertion that Stonehenge must once have been a kind of astronomical observatory and nautical almanac office. Since then, there has been a steady stream of speculation about the way in which Stonehenge might have been used for astronomical observation and prediction. With the coming of electronic computers, it was possible to make detailed comparisons of the positions of the various stones at Stonehenge and the occurrences of conspicuous events in the movement of the Sun and Moon. Thus, three years ago, Professor G. Hawkins (*Nature*, **200**, 306; 1963) was able to claim a detailed correlation of the positions of several of the stones at the monument with the rising and setting of the Sun and Moon throughout the year and the occurrence of some eclipses. That work suggested that the men who built Stonehenge and afterwards operated the supposed observatory were able to glean a previously unsuspected wealth of detail from their observations. More recently, these conclusions have been questioned (*Nature*, **210**, 1302; 1966) on the grounds that Hawkins's alignments are not significant.

The most recent steps in the interpretation of Stonehenge as an astronomical observatory are to be found on pages 454 and 456 of this issue. Professor Fred Hoyle and Mr. C. A. Newham are both concerned to show how the post holes grouped to the north of the main circles (not accommodated in earlier interpretations) are somehow concerned in the more refined use of the circles of stones for measurement and prediction. Mr. Newham would have one group of stones function as a kind of vernier gauge. Professor Hoyle claims that it would be possible to use the array of stones for the prediction of all eclipses (which is a substantial improvement on Professor Hawkins) and also for making measurements of the regression of the line of lunar nodes in such a way as to ensure that predictions of eclipses are not vitiated by experimental errors. If Stonehenge was really designed as an astronomical instrument, the principles on which this was done accord well with the procedures by which modern experimenters pursue their craft. The scheme which Professor Hoyle describes is breathtaking not merely by its ingenuity—that of Professor Hoyle as well as of the supposed builders of Stonehenge—but by its practicality.

The cleverness which Professor Hoyle now attributes to the designers of Stonehenge is probably the most difficult part of his theory to accept. People will ask whether it is credible that people who had not then invented enduring houses in which to live, and who had not even invented the Royal Society, could possibly have been clever enough to build an optical instrument of such intricacy as Stonehenge may be. But this is not, by itself, conclusive. If archaeologists knew a great deal more than they do about life in Britain 3,500 years ago, they might be able to show that Professor Hoyle's suggestion is implausible. The difficulty, of course, is that archaeology is only able to describe a kind of lower limit to the sophistication of a society. The fact that there is no evidence of numeracy among the people who built Stonehenge is not conclusive proof that they could not predict eclipses. In the circumstances, it is only charitable that they should be given the benefit of the doubt, and that everybody concerned with their affairs should contribute to the upkeep of the monument. And, if the Ministry of

Public Building and Works should keep the grass in order, is it not appropriate that distinguished astronomers should try to puzzle out what the placing of the stones may mean ?

UNIVERSITIES WITHOUT STUDENTS

THE Collège de France is a splendid institution, and everybody will be delighted if Prof. Leprince-Ringuet's initiative (see this issue, p. 448) should eventually win for it a larger site in the centre of Paris. When institutions like this, which embody a substantial part of a nation's intellectual capital, are hampered in their work by lack of funds or facilities, the waste is every bit as real as when crops are lost through neglect or when the product of a factory is rendered useless by bad design or bad marketing. In other words, having decided that institutions like the Collège de France should exist, there is no sense in trying to run them on a shoestring.

The question remains of what place institutions like the Collège de France should assume in the modern academic world. Most often, the problems to which they were originally the solutions have long since disappeared. The Collège de France owes its existence to the wish of an ancient monarch to break down the intellectual tyranny of a medieval university. The calculation was that a group of able scholars free to pursue their interests without the restraint of conventional doctrines could not fail to be a liberalizing influence on the research and the teaching of a dogmatic university. In Paris in the sixteenth century, this expectation was most probably correct. In other words, what seems like an ivory tower can also be an intellectual Trojan horse.

At Oxford, the founding of All Souls College was similarly inspired and may, at the time, have been similarly influential. The modern equivalents of these institutions, among which the Institute of Advanced Study at Princeton is conspicuous, have more ethereal reasons for existence. They may, for example, cater for the needs of academics who hate to teach, or they may be based on the argument by which Prof. Leprince-Ringuet justifies in part the continued existence of the Collège de France at the centre of Paris—the view that the interaction between distinguished academics from widely different disciplines is likely to yield results which are qualitatively distinctive. The difficulty is that, in the modern world, these arguments are less and less convincing as justifications for what are, in essence, universities without students.

The truth is that the luxury of untrammelled intellectual enquiry is now as easy to find in a modern university as in an ivory tower on the old pattern. If a person is so engaged in his research that he does not want to confront a class of students once a week at nine o'clock in the morning, it needs very little ingenuity to escape such a commitment. Indeed, with growing size, many university departments are hard pressed to provide suitable captive audiences for all those who want to be engaged in formal teaching. In the same way, it is relatively simple for those who are so inclined to escape the chores of administration frequently thought inseparable from university life. Then the opportunities for interaction between disciplines are if anything more real and richer in a modern university than in an ivory tower. In other words, modern universities can offer scholars all the advantages of an ivory tower and also the benefits of size, and the stimulation which good students habitually provide. There are signs that the best ivory towers recognize for themselves the advantages of a vigorous interplay between research and teaching; the Rockefeller Institute in New York (which was not so much an ivory tower as a specialized research institute) has in this spirit chosen successfully to turn itself into the Rockefeller University. It is only fair to acknowledge that the contribution of the Collège de France to teaching at the University of Paris is substantial and distinguished, but it is also proper to suggest that a time when there is a chance to move to a new site may also be a suitable occasion for choosing to move some way along the road to being a university in the more usual sense. The example of All Souls is a sad proof of what happens when the integrity of an ivory tower is too successfully defended.

AT THE DEEP END

FIRST it was atomic energy; then it was aerospace. Now Washington's favourite science is oceanography. There is a danger that every project that smells of salt water is going to be so deluged with federal money that a considerable amount of research will have to be devoted to devising ways to spend it. Perhaps the explanation is to be found in this season's phenomenal heat; even in the best of summers, people stuck in Washington are driven to wild daydreams of the sea.

Whatever the cause, in the past few weeks, the result is startling. Congress has passed and the President has signed an Oceanographic Law creating, among other things, a National Council of Marine Resources and Engineering to promote "inner space" to the eminence of "outer space". Almost at the same time, a National Oceanography Association has formed itself. A new governmental body, the Environmental Science Services Administration, has unveiled a special report on the vast richness of the American continental shelf, neatly timed to impress a conference held in Washington by the Marine Technology Society. And, after all this, President Johnson last week released a report prepared by his Science Advisory Committee outlining what a national oceanographic programme should be and recommending that federal spending in this direction (now $310 million a year) be doubled.

So specific and practical is the report that it makes the new legislation, with the President's signature hardly dry, look waffly. For the new law sets up not

only the Council of Marine Resources at Cabinet level but calls for a special Commission to spend a year and a half doing what the report has done already—to decide what the United States wants from the oceans and what kind of federal agency should go after it. After that, the law would require, the Commission and the Council should both expire and a new body—what Washington wags are calling "the wet NASA"—could then emerge.

But the science advisers' report not only spells out what kind of research would be most useful—expanding the yield of food from the sea—but insists that any new agency to be formed should not be devoted exclusively to oceanography. Some new form of co-ordination is clearly needed: there are now 26 federal agencies and bureaux involved in one way or another with the salt water. These include a new Institute of Oceanography established last winter. The two biggest spenders are the Navy and the National Science Foundation, the second of which has not been swamped with applicants for the sizable sums that it has had for more than a decade to spend on oceanography. (Its budget for marine research and education for the current fiscal year is $138 million.) These would not be included in the new agency, described in the report, to co-ordinate all other efforts and to embrace all the other federal activities in the environmental sciences, land and air as well as sea.

The report recognizes that oceanography has a built-in deterrent in that scientists and students find irksome the need to go to sea, and suggests that it would be easier to do fieldwork if the research ships were clustered into fleets and made available to all universities and laboratories in a large region—the Great Lakes, perhaps, or the Gulf Coast. It also suggested that marine study centres be established, so that lawyers, economists, engineers and scientists could meet to discuss the special problems that exploitation of the oceans presents. In all these efforts, the seashore is to be given as much attention as the continental shelf (on which American oil industries are already spending about $2,000 million a year) and the deep seas. Half the American population lives near the water's edge. The shoreline needs to be restored and preserved for their recreation; in turn, they must learn to stop fouling the water. (Lake Erie is so polluted as to be in danger of turning into a swamp.)

It is hard to see how the new Oceanographic Commission will be able to improve on the Science Advisory Committee's labours. But, as long as the "wet NASA" does not emerge to lead a jingoistic race to the bottom of the ocean, the duplication may do no harm. One sensible requirement of the new law is that the President must present to Congress every year an outline of the national oceanographic plan. Perhaps by next year he may be able to report that Project Mohole has been set going again and that there are some large-scale projects of practical value to set alongside the performance of *Sea-Lab*, which has shown that men can live uncomfortably at the bottom of the sea for several weeks, and the development of clever craft which can find hydrogen bombs at the bottom of the Mediterranean.

NEWS AND VIEWS

Who Gives Most?

THE financial crisis in Britain last week kept at home most of the delegation that would otherwise have attended the meeting of the Development Assistance Committee (DAC) of the O.E.C.D. in Washington. This is entirely understandable. The calculation was not the saving of a dozen or so air fares across the Atlantic, but the need that the Minister of Overseas Development, Mr. Anthony Greenwood, should be in London to defend his department's budget against those of his colleagues bent on finding substantial economies in British public expenditure. Mr. Greenwood's counterparts from other O.E.C.D. countries will have been entirely sympathetic, for their agenda in Washington emphasized the need enormously to increase the volume of foreign aid. The fact that DAC was meeting in Washington rather than in Paris was itself a part of an attempt to increase the value of foreign aid by the advanced nations.

The league table of aid giving which informed the discussions in Washington was entirely flattering to the European members of the O.E.C.D. According to the calculations of the DAC officials, France spends a greater proportion of her national income on aid to developing countries than any other member of the O.E.C.D. Then, in order, come Belgium, the Netherlands and Britain, each of which spends more than 1 per cent of its national income on aid. By this test, the United States is surprisingly low on the list, and one of the motives of American officials in bringing the DAC to Washington was the hope that the United States Congress would be shamed by this oddly unflattering comparison into spending more on aid. Whatever the result may be, the DAC will be confirmed in its role as the keeper of objective international comparisons on aid giving; it is not, after all, so very long since the Committee pointed out that the official figures of the annual amount of British aid to developing nations should be adjusted by the amount returned as interest and capital repayments, thus converting roughly £200 million into £150 million, and also paving the way for the British Government's decision that development loans could be free of interest.

Another reason why some Americans were keen that DAC should meet in Washington was the hope that the Committee would bless the view that North American food stocks, if necessary bought with other nations' cash, will have to play an important part in foreign aid in the decades ahead. In the event, the meeting reaffirmed the need somehow to increase the capacity of developing nations to grow more food. But, one way or another, aid in the form of calories will be essential for decades to come. The O.E.C.D. brief for the Washington meeting included economic and demographic projections for the rest of this century for the advanced and the developing nations. In the developing nations (excluding China) the population is expected to multiply threefold by the end of the century, and the demand for food between four and six times. Food production, even on the most optimistic assumptions, will not grow as quickly as the population. But, in the advanced nations, food production could increase substantially, and much more quickly than the population. In other words, events seem to strengthen the

paradox first given point by Sir Arthur Lewis that, when it comes to foreign aid, the industrialized nations have most to offer in the form of agricultural produce.

Room in Paris

THE Collège de France is openly staking a claim on the site in Paris that will be vacated, possibly in five or six years, when the École Polytechnique moves out to Palaiseau in the south-west suburbs. The Collège has been in Paris since its foundation in 1530 by Francis I as part of an attempt to break the stranglehold of the schoolmen at the Sorbonne by creating a community of scholars independent of the politics of the University of Paris. The Collège de France, like many other academic institutions which are similarly placed in the hearts of capital cities, now finds the pressures of modern life—and particularly the non-academic demand for space—an increasing source of frustration. But, for one reason or another, moving out of town is unthinkable. It is no wonder that the professors of the Collège de France should be so excited by the prospect of a vacant lot in the gift of the French Government and only a few hundred metres from their present building that they have allowed themselves to express their yearnings in public.

Professor Louis Leprince-Ringuet put the claim of the Collège in an article in *Le Monde* on July 20. In the nature of things, the argument goes, the fifty or so professors who make up its membership must divide their time between research and teaching. But because their interests span the whole field of scholarship, they need facilities of all kinds. The humanists need access to the Louvre and the Bibliothèque Nationale, while the scientists—roughly twenty of them—must have their own laboratories and research assistants. Professor Leprince-Ringuet is eloquent about the great advantages which come from a system which requires distinguished men of diverse interests to work closely together in the same premises, and cites as an example the way in which Joliot-Curie and Robert Courrier worked on the study of thyroxine, using radio-iodine as a tracer. He argues quite openly that the Collège de France is "probably the only institution of higher education whose presence in Paris is almost essential", and goes on to say that, even though the Collège has no ambition to own large cyclotrons or nuclear reactors, it would gain enormously if the scientists could be gathered on to the same site rather than be scattered as at present up and down the Rue des Écoles and even farther away. Scholars everywhere will be interested to see how successfully it will be possible to sustain this claim on real estate in the centre of a capital city.

Doctors in Distress

MEDICAL manpower and utilization have been areas of debate and concern in Britain for a long time, but debate has often taken the place of action. In a pamphlet *Medical Manpower* the Office of Health Economics points out that more than 40 per cent of the hospital doctors in 1964 were born outside the country, while during the 1950's more than 5,000 doctors, the equivalent of one quarter of graduates of British medical schools, emigrated from Britain and did not return.

Coupled with these quantitative statistics, the study discusses the qualitative problems facing the hospitals; specialization has become increasingly necessary because of the complexity of modern surgical techniques and the need for medical and non-medical specialists in areas such as radiotherapy and heart surgery. Another problem facing the hospitals is the recruitment of junior staff; the incentive for staying at a hospital has usually been to reach the final goal of a consultant post. With far more registrars than consultants, more and more young doctors have gone directly into general practice so that, between 1961 and 1964, 1,000 out of the 1,100 increase in the numbers of junior hospital staff were born outside the British Isles. The Office of Health Economics blames this situation on three factors: a large error in forecasting the future need for doctors, much greater emigration from Britain than was expected or has been admitted, and a failure to take account of the rapid technological progress and changing pattern of medical care over the past twenty years when modifying medical education.

In the early 1950's there was a widespread belief in Britain that too many doctors were being trained. The Willink Committee was set up in 1955 to investigate this situation and, based on a population growth rate of 4·5 per cent—which in fact turned out to be 7·0 per cent—and assumptions about the growth of hospital staff which have proved to be half the actual growth, the committee held that student intake should be reduced by 10 per cent. This decision was reversed in 1961, but the effects are still felt in the present situation. Migration remains a major problem, yet the Council of the British Medical Association in 1958 reported that net emigration among doctors and dentists "can be considered of no special significance". Finally, while the specialized training and skills necessary for hospital staff have become less and less related to the community care demanded of the general practitioner, medical education and training have done little to recognize the variation in training that these distinct paths call for.

The study concludes that, while small advances are being made—closer links are growing between hospitals, general practitioners and local authorities—and automation and qualified auxiliaries are avenues to be explored, for the present the most pressing need is to increase the efficiency of the manpower now available.

Three Years of Data

THE National Bureau of Standards in the United States has just celebrated the third anniversary of the National Standard Reference Data System, which is the formal name for a programme intended to build up critical compilations of scientific data. Sensibly enough, the work is being co-ordinated with that of standards institutions outside the United States, most effectively by a committee of ICSU with a staff in Washington. Inevitably, however, the contribution of the United States is a very large part of the whole, and not simply because, in June 1963, the then director of the U.S. Office of Science and Technology said that the "intent is to provide an articulated system of activities under such co-ordination and direction as to ensure a compilation of data meeting quality standards and also to maintain continuous policy guidance of the system at the level of the Executive Office". The

experience of the past three years at the National Bureau of Standards is therefore a useful pointer to the problems of operating a thoroughly ambitious data system, and to some potential solutions as well.

There is no question that the plans of the National Standard Reference Data System are ambitious—and events may yet show that they have outstripped the budget. The physical sciences have been partitioned into seven fields, and separate programmes are under way in each of them. Only in nuclear physics do the existing arrangements approximate to what is thought necessary, so that the National Bureau of Standards can confine itself to the evaluation of data on elementary particles and cosmic rays. In other fields, several new projects have been started, sometimes within the Bureau of Standards but also frequently by letting contracts to independent organizations—universities, government laboratories and sometimes commercial organizations. Not surprisingly, activity is most conspicuous in thermodynamics and atomic and molecular spectra. Although the general field of "mechanical properties" is included in the brief for the reference data system, it will be hard to begin to make a start in this jungle, partly because of the difficulty of deciding what kind of information would be of value to potential users, partly because of the sheer bulk of it, and partly because of the way in which information about the mechanical properties of materials tends to depend on the method of measurement.

There is also the problem which has traditionally beset the compilers of critical tables—the frequently invidious task of deciding which published data to trust. The National Standard Reference Data System acknowledges that, in the last resort, value judgments of this kind cannot be left to machines. This is why it is good to see how it has been possible to encourage academic interest in the evaluation of data by the judicious letting of contracts. Elsewhere, scientists are still more eager to give their blessing to plans for collecting data than to undertake to carry out some of the hard work involved. But compilation is only half the story. There is also to be a huge effort on dissemination. The first of what will be a torrent of volumes of critical data have already appeared. At some stage, possibly within three or five years, a computer system will permit faster access to the files, and there will be a fast and comprehensive system by means of which individual laboratories will have access not merely to the computer files in Washington but to those in associated data centres as well.

Science Teaching Centre

THE Chelsea College of Science and Technology in London has announced a plan to create a centre intended to make a continuing contribution towards research in teaching methods in science. In a statement issued last week the principal of the College, Dr. M. R. Gavin, says that the College has in mind the possibility that there may be a hiatus in the development of new science curricula for British schools when the current plans of the Nuffield Foundation Science Teaching Project are worked out at the end of this decade. The College hopes to be able to be ready, before then, to play a full part in the development of methods of teaching science, and intends to cut its teeth in a number of fields of research and development ranging from the development of new curricula to the design of equipment and apparatus. The statement makes the point that such a centre would complement work in teacher training in a particularly valuable way, and that it would also serve as a means of providing teachers in the Greater London area with opportunities for in-service training. The first academic appointments will be made for the academic year immediately ahead. The College is evidently hoping that its plans for creating a centre for teaching science at Chelsea will match well with the secondment of the head of the Physics Department at Chelsea, Professor K. W. Keohane, to the Nuffield Foundation Science Teaching Project from July this year.

Chemical Research, Melbourne

DR. A. L. G. REES, chief of the Division of Chemical Physics, C.S.I.R.O. Chemical Research Laboratories, Melbourne, Australia, writes:

"A new laboratory for the Division of Chemical Physics has now been opened at Melbourne by Senator J. G. Gordon, minister in charge of C.S.I.R.O. The building has been named the David Rivett Laboratory after the late Sir David Rivett, for nearly 20 years chief executive officer and later chairman of the C.S.I.R.O. Sir David, a physical chemist, actively promoted the establishment of research in chemical physics in 1944 and encouraged its rapid development.

"The first steps taken in 1944 involved the establishment of specialized groups concerned with physical techniques and their application to chemical problems. Current sections include spectroscopy, electron and X-ray diffraction, electron microscopy, solid state and theoretical chemistry, and instruments and engineering services. The Division pioneered electron microscopy in Australia; its first work was largely on problems oriented towards biology. Early work on the fine histology of wool stimulated a more general interest in fibrous proteins. The Division entered the related field of electron diffraction in 1945 and its first task was the development of electron diffraction apparatus.

"Research in mass spectroscopy has been conducted in the Division since 1947. The major theme has been the elucidation, by experimental and theoretical methods, of the behaviour of molecules under electron and photon bombardment. In solid state chemistry, studies have been oriented towards establishing the significance of crystal defects in chemical behaviour. The occupation of new premises has allowed the expansion of research in this area, the most important of which concerns the low-temperature thermodynamic studies of non-stoichiometric solids.

"From the beginning, considerable attention has been paid to technique and instrumentation in chemical physics research, with the result that new techniques and new instruments have appeared as by-products. A number of these have encouraged the rapid development of the manufacture of scientific instruments in Australia. The most successful example to date is the manufacture of spectroscopic instruments. The total value of such equipment now produced each year in Australia exceeds one million Australian dollars."

Centres for Engineering

ENGINEERING education and training in Britain will have to be overhauled if it is to attract its fair share

of scientific and technological manpower. This is the conclusion of a working group on Engineering Training and the Requirements of Industry set up last year by Sir Willis Jackson of the Ministry of Technology's Committee on Manpower Resources for Science and Technology. In its report, the group calls for close co-operation between educationalists and industry to establish a programme of "matching sections" of formal education and training. By exposing engineering students to the intellectual and practical problems of manufacturing industries, they hope to maintain the interest and enthusiasm of those students who might otherwise go into research.

To co-ordinate these "matching sections", the group calls for centres of product technology, established by collaboration between an educational institution and one or more industrial units, with teaching at the former and the industrial plants used as full-scale demonstration laboratories. It envisages a training programme of approximately one or two years that would begin when a graduate enters a firm. At this time he would be exposed to possible jobs and specializations, begin to learn the principles of manufacturing engineering, and take part in a group project to expose him to the practical problems he will face. On choosing his first job and gaining some experience, he would enter a course at the centre in either product technology, manufacturing technology, or special techniques. He would then return to his firm for more supervised training.

Swings and Roundabouts

THE annual report of the British Post Office contains in microcosm the contemporary history of the balance between the different means of communication between people. On one hand, there is the traditional postal service which was introduced in Britain in 1840, with the Penny Post. On the other hand, there is the telephone system. The first of these services has had, in recent years, a tendency to run at a loss. As good luck and increased charges would have it, 1965–66 was not too bad a year. The postal services actually made a small profit—something like £0·9 million out of a total turnover of £318 million. But nobody is very hopeful about the years ahead. Already a further round of price increases has been announced.

By contrast, the telephone service is booming. In the course of a year, charges to the British public actually declined, chiefly because of the introduction of automatic dialling, yet the Post Office made a surplus of roughly 10 per cent on its telephone business. Demand from the public is at the same time growing quickly. Even local calls increased by 8 per cent in the course of a year. Trunk calls went up by 14 per cent and overseas calls by no less than 21 per cent, partly, no doubt, because of the arrival of satellite communications across the Atlantic and facilities for dialling direct to the mainland of Europe. All this, of course, is entirely to be expected. Telephones will keep on winning over posts. One practical question is whether those in charge of the Post Office should anticipate the future by weighting the odds even more heavily against the posts than the realities of handling pieces of paper entail. The second question, not quite so practical, is what will happen decades hence to all those letters written not for people now alive but for posterity.

Parliament in Britain

REPLYING on July 12 to an adjournment debate on the training of teachers, Mr. G. Roberts, Minister of State, Department of Education and Science, said that, since the announcement last year of the intention to establish departments of education in suitably located technical colleges, the local education authorities in Inner London, Birmingham, Manchester, Nottingham and Sunderland had been consulted. All had expressed a desire to participate and were preparing detailed proposals. It was hoped that the new departments of education would take their first students in the academic year 1967–68. The departments might be expected to attract to teacher training some technical college students who would not otherwise have thought of taking up teaching, and Mr. Roberts emphasized that the departments would provide courses comparable with the best afforded by the traditional college of education and the university departments of education. Initially, it was intended that the new departments should cater essentially for students taking a 3-year certificate course leading to qualified teacher status, but no doubt in due course the departments would introduce also 4-year courses leading both to degree and to professional teaching qualifications. Departments would start with about 100 students and rise to 250 to 300. For some years their main emphasis would be on training teachers for the primary schools.

REPLYING for the Government in a debate on July 8 on computers in universities, Mr. G. Roberts emphasized that the programme of the Flowers Group for new university computers, which the Government had approved, would provide for an integrated system. There would be regional centres in London, Manchester and Edinburgh. Of the 28 universities fitting into the Flowers programme, nine had delivery dates for their machines varying from July 1966 to the end of the year. Pending the establishment of the Computer Board, the membership and functions of which would be announced shortly, the University Grants Committee had made an interim arrangement for considering the most urgent cases and planning orders. Approval had already been given, at a cost of £4·8 million in the period 1966–69, for upgrading the *KDF* 9 computers at the seven universities recommended by the Flowers Group and for new installations for 21 other universities.

IN a written reply to a question in the House of Commons on July 20 regarding liaison with other countries on the courses of hurricanes, the Under-Secretary of State for Defence for the Royal Air Force, Mr. M. Rees, stated that the Meteorological Office kept in touch with other countries on hurricane research. There was liaison with the Hong Kong Meteorological Office and also with the United States National Hurricane Research Laboratory and other American weather agencies. In the near future, cloud photographs would be received at Muharraq, Gan and Singapore direct from U.S. weather satellites and would help to provide warning of hurricanes in the Indian Ocean and Far East areas. The Meteorological Office also participated in a recent North Atlantic Treaty Organization conference on cloud dynamics at which the problem of hurricanes was discussed.

University News : Bradford Institute of Technology

DR. G. D. H. LEACH, at present senior lecturer in pharmacy in the Institute, has been appointed professor of pharmacology.

Keele

DR. I. T. MILLAR has been appointed professor of organic chemistry. Dr. H. H. Greenwood has been appointed director of the University Computing Centre.

Leeds

DR. P. N. CAMPBELL has been appointed professor of biochemistry and head of the Department as from October 1, 1967.

Liverpool

DR. W. PETERS has been appointed to the Walter Myers chair of parasitology on the resignation of Prof. W. E. Kershaw.

Manchester

DR. R. B. NICHOLSON has been appointed to the newly-established chair of physical metallurgy. J. R. Moore has been appointed to the chair of oral surgery.

Southampton

THE following have been appointed to chairs: Dr. B. L. Clarkson (vibration studies); B. W. Cunliffe (archaeology); Dr. G. A. Kerkut (physiology and biochemistry). The personal title of Westland professor has been conferred on Dr. J. P. Jones, Westland reader in the Department of Aeronautics and Astronautics.

Appointments

DR. VIKRAM A. SARABHAI, a cosmic ray physicist, has been appointed chairman of the Indian Atomic Energy Commission in succession to Dr. H. J. Bhabha, who was killed in an air crash on Mont Blanc earlier this year. Dr. Sarabhai, who is 47, has been responsible in recent years for organizing Indian participation in international organizations for space research. He was a student at Bangalore and at Cambridge in the years immediately before the Second World War and took a Ph.D. at Cambridge in 1947.

THE National Science Foundation has appointed Dr. Robert Fleischer deputy head of the Office of International Science Activities. Dr. Fleischer joined the foundation in 1962, and has been programme director for solar-terrestrial research and co-ordinator for the participation of the United States in the International Year of the Quiet Sun. Between 1946 and 1962 Dr. Fleischer was professor of astronomy at Rensselaer Polytechnic Institute, where he worked on solar radio astronomy, interstellar dust and binary stars.

DR. E. A. ALEXANDER has been appointed scientific counsellor at the British Embassy in Moscow, where he will replace Mr. T. Garrett at the end of September. The post of scientific attaché was established in April, 1959; the title has recently been changed, but the purpose remains to advise the ambassador on scientific matters, to report on Soviet civil science and technology and to help visiting scientists and scientific and technological missions. Dr. Alexander, who is an Oxford physical chemist, has been with the Admiralty since 1941.

Announcements

MR. J. E. DENYER has been elected president of the Institution of Mining and Metallurgy for the session 1967–68.

MR. H. N. PEMBERTON has been elected chairman of Council of the Council of Engineering Institutions, in succession to Sir Robert Wynne-Edwards. He will take office in January 1967.

THE Royal Institution of Naval Architects has been elected a constituent member of the Council of Engineering Institutions.

THE National Bureau of Standards has established an Office of Engineering Standards Liaison and Analysis to serve as a focal point for NBS assistance to engineering standards-making bodies throughout the United States. Dr. G. S. Gordon, formerly chief of the Textile and Apparel Technology Center of the NBS Institute for Applied Technology, has been appointed chief.

THE 1966 international Industrial Diamond Conference will be held in Oxford during September 19–22. Further information can be obtained from the Organizing Secretary of the Conference, 2 Charterhouse Street, London, E.C.1.

A SYMPOSIUM on "Pyrolysis—Gas Chromatography" will be held at the Ecole Polytechnique, Paris, during September 15–16. Further information can be obtained from Dr. G. Guiochon, Ecole Polytechnique, 17 rue Descartes, Paris.

THE fourth symposium on "Chromatography and Electrophoresis", organized by the Belgian Society of Pharmaceutical Sciences, will be held in Brussels during September 12–13. Further information can be obtained from the Secretary of the Society, 11 rue Archimède, Brussels 4.

A SYMPOSIUM on "Nucleic Acids and Nucleotides in Higher Plants", arranged by the Phytochemical Group, will be held at Royal Holloway College during September 20–21. Further information can be obtained from A. H. Williams, Research Station, Long Ashton, Bristol.

A CONFERENCE on "Rare-earths", organized by the Institute of Physics and the Physical Society, will be held in the University of Durham during September 5–7. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE second international Biophysics Congress, organized by the International Organization for Pure and Applied Biophysics, will be held in Vienna during September 5–9. Further information can be obtained from Mrs. E. Weidenhaus, Wiener Medizinische Akademie, Alserstrasse 4, Vienna IX.

THE first international congress of the International Radiation Protection Association will be held in Rome during September 5–10. Further information can be obtained from the secretary-general of the congress, Dr. C. Polvani, International Radiation Protection Association, Casella Postale 2359, Rome.

A SYMPOSIUM on "Advanced Industrial Measurement and Control" will be held at the Welsh College of Advanced Technology during September 19–23. Further information can be obtained from the Organizer of Short Courses, Welsh College of Advanced Technology, Cathays Park, Cardiff.

AN international technical meeting on "The Biological Basis of Freshwater Fish Production", organized by the International Committee for the PF Section of the International Biological Programme, will be held in the University of Reading during September 1–6. Further information can be obtained from Mr. E. D. Le Cren, The River Laboratory, East Stoke, Wareham, Dorset.

ERRATUM. A note about the retirement of Prof. Eisenschitz from Queen Mary College on June 25 (210, 1314) gave the impression that Prof. Eisenschitz was retiring at the end of the current academic year. In fact, of course, Prof. J. G. Valatin has occupied the chair since September 1965.

CORRIGENDUM. In the article entitled "Memory and Spontaneous Alternation in the Rat" by A. W. Still (*Nature*, 210, 400; 1966), on page 401 in column 2, 'less' should read 'more' on line 8, 'more' should read 'less' on line 10 and 'less' should read 'more' on line 46.

OCEANOGRAPHY IN THE UNITED STATES

A RECOMMENDATION that expenditure in the United States on oceanography should be doubled is the principal conclusion of a report of a panel appointed by the President's Science Advisory Committee and now released to the public by the President with the title *Effective Use of the Sea* (U.S. Government Printing Office, $0·60). The report is likely to be influential because of the current interest in oceanography in the United States. The chairman of the panel, which was appointed in May 1965 at a time when the United States Congress was eagerly concerned to see that oceanographic research should not languish, was Dr. Gordon J. F. Macdonald of the University of California, Los Angeles. The other members of the panel were Dr. Douglas L. Brooks (Travelers Research Centre Inc.), Dr. Robert Charpie (Union Carbide Corporation), Dr. Robert Fleagle (University of Washington), Dr. Finn J. Larsen (Honeywell, Inc.), Dr. William D. McElroy (Johns Hopkins University), Dr. John Meyer (Harvard University), Dr. Walter H. Munk (University of California, La Jolla), Dr. Jack P. Ruina (Institute for Defence Analyses), Dr. Henry Stommel (Woods Hole Oceanographic Institution), and Dr. Gerald B. Whitham (California Institute of Technology).

Running through the report of the panel is the view that oceanography should be useful, and the suggestion that the U.S. Government should spend more money on oceanographic research is supported by the view that more research will bring tangible rewards. Thus it is argued that strategy requires the U.S. Navy to increase its efforts to learn more about submergence in the deep sea, partly so as the more effectively to navigate with submarines. The loss of the *Thresher* in 1963 and the loss of a hydrogen bomb off the Spanish coast earlier this year are cited as two of the reasons why the Navy should be able to recover objects from deep water.

The benefits from better use of the sea as a source of food are held to justify the considerable increase in the efforts spent on recovering edible protein from the sea. The panel would also like to see rounded studies of marine populations of organisms in estuaries and on the Continental Shelf so as to preserve the accessible parts of the ocean for fuller use by a growing population.

In pure oceanographic research the panel would like to see a shift of emphasis from the expensive survey of the oceans to an attempt to solve the specific problems related to physical oceanography and marine biology. It wants more higher education in oceanography although it questions the wisdom of proposals for granting Ph.D.s in oceanography; rather, it takes the view that oceanography is not a discipline in its own right but a field of studies to which specialists of all kinds must contribute. The panel also argues that the deployment of oceanographic research vessels needs to be planned more effectively, particularly because of the difficulty of persuading academics to go to sea. The panel therefore suggests that ships should be made available to institutions and universities on a regional basis, and grouped into fleets of reasonable size.

The argument on exploiting the oceans as a source of food is unusually specific. Comparing estimates of population with present resources of food, the panel concludes that improvements in conventional agriculture will not be sufficient to meet the future demand for protein. It points out that the fish caught in 1964 contained $17·1 \times 10^9$ lb. of protein, which would have been enough to provide 10 g of protein a day for 2×10^9 people. This, the calculation goes, would have been enough to get rid of chronic protein deficiency in the equatorial regions of the world.

The recent improvement in catches of fish from the sea is held to justify some of the panel's optimism. In the past ten years, the production of fish in the world is estimated to have increased from $60·5 \times 10^9$ lb. to 114×10^9 lb. The development of new fisheries is thought chiefly to have been responsible for the increase of production, and the fact that in 1964 nearly 20 per cent of the total production of fish was accounted for by anchovies taken off the coast of Peru is given as a sign of what new fisheries can produce.

Attempts deliberately to cultivate the sea are necessarily less well understood. The Japanese harvest is shown to have increased between 1951 and 1963 from 193×10^9 lb. to 857×10^9 lb.; even so, this is less than one-sixtieth of the total production of fish in Japan.

The panel in Washington considers that the technique of aquaculture, as it is called, needs much more development before it can be estimated what benefits are to be had. It points out that animals which feed directly from phytoplankton are likely to be among the most efficient captive sea animals. This suggests a future world in which oysters and other delectable shellfish are a part of the staple diet.

The panel plainly thinks it is easier to damage the natural ocean environment than to make it more favourable for growing things. It points to the dangers of pollution and tells the chilling story of how mussel culture in the Black Sea was brought virtually to an end by the introduction of predatory Japanese snails in 1949. To protect the oceans of the United States from disasters like this, the panel seeks to establish "marine wildernesses" in parallel with the wildernesses on dry land which have been set aside by the provisions of the Wilderness Act of 1964. It would also seek to improve food production and opportunities for recreation by cleaning some parts of the ocean and seek to win a better understanding of marine ecology so as to anticipate the effects, evil and otherwise, of interference with the natural sea.

Under the heading of what it calls "Undersea Technology", the panel argues that there is a need for better navigation, both where the Navy is concerned and as a means to exploiting mineral resources. Ideally it would

like to be able to navigate to within 30 ft. in those parts of the ocean within sight of land, and to within 150 ft. elsewhere. For drilling, even greater accuracy is necessary, and the report talks of oil companies which have been able to locate bore holes to within 2 ft. It also wishes to see more devices for producing pictures of the ocean bottom, not merely by means of better television techniques, but also by acoustic imaging. It has a number of schemes for improving survey techniques, and suggests that a surface ship should be fitted out with improved equipment, that a submarine equipped with sensing devices could do useful work, and that there is a case for developing towed submersible platforms for making more accurate and more convenient measurements of temperature near the surface of the ocean. Devices for preventing erosion, power plant that can be operated under the sea, and buoys for collecting information about weather and other physical variables need development. Then there is the programme known as "Man in the Sea" which the panel commends to the United States, and whose object is to enable people to function adequately at depths up to 1,000 ft. It seems to be acknowledged that divers will not be able to operate effectively below this depth.

In pure research, the panel argues that exploration of the oceans must become more systematic. It is concerned to have better understood the relationship between the circulations of the oceans and the atmosphere, which in turn is an essential step in formulating a theory of climate. Linked with this is the problem of sedimentation, for this is also a process governed by the same conditions within the oceans as those involved in climate.

The panel also speaks highly of new devices for following currents such as the "swallow" floats as it describes the instruments for this purpose developed by Dr. J. C. Swallow. Better data processing and telemetry have much to offer, as does the connexion between geophysics and oceanography.

The panel would like to see oceanographers turn their attention to a number of specific problems which are partly scientific and partly practical and which include prediction. For one thing, it would like to see better ways of predicting tides and exceptional oceanographic effects such as tsunamis. Predicting turbulence in the Gulf Stream, and meanders of this and other currents, is thought to be necessary and practicable. At the back of its mind, the panel let slip, is the possibility of modifying deliberately the character of the oceans—melting Arctic ice and so on.

It is argued that the work of the oceanographers which bears on geophysics ought also to be encouraged. The Benthic Boundary, at which water gives way first to ooze and then to solid mud, needs to be studied so as to understand long-range sound transmission as well as to make it easier to find things which fall to the ocean bottom. The panel gives its blessing to schemes for drilling holes into the crust of the earth as it is exposed on the sea bed, which will no doubt be welcomed by the organizers of the MOHOLE project. There is also a general commendation of studies involving floating buoys to study the circulation of the ocean, and programmes based on fixed platforms, moving buoys and aircraft to study such things as the upward mixing of layers of the sea near the surface, and the interaction between the physical and chemical environments and the biological life. The panel points out that plankton are not merely the means by which all sea populations obtain energy, but that a number of sea organisms—sea cucumbers, starfish and so on—are potentially important as sources of pharmacological chemicals.

How much will this cost? The panel is at pains to argue that it is not at this point feasible to assess the potential value of oceanographic research and development in strictly economic terms. In this sense the panel disagrees with the argument of the Committee of the National Academy of Sciences in the United States which argued, in 1964, that the case for a vigorous programme of oceanography could be strictly justified by the money it would earn. Instead the panel seeks to proceed by the prime objectives which are thought to be attainable in the not-too-distant future and then to add up the sums of money currently being devoted to these.

Outside the military field, it is thought that during the current financial year in the United States, government spending on oceanography will amount to $120 million. Of this amount, $14·5 million is being spent on better prediction services. Fisheries research in the United States seems to be using up $45 million in the year, while navigation accounts for $38 million. This sum does not, of course, include sums spent by universities and other institutions on oceanographic research. The panel argues for a steady growth of these expenditures in the next five years, with the suggestion that there should be a comparatively quick growth in expenditure on prediction and control, on marine biological resources, and on the "near-ocean environment".

How is all this to be organized? The suggestion is that there should be a major reorganization of civilian oceanography with the object of placing within a single agency all the government activities related to the description of, the prediction of, and the attempt to modify the environment—ocean, atmosphere or solid earth. The panel recommends this step because it believes there is a unity in the environmental sciences, that the development of the ocean for industrial purposes requires an ability to predict the environment, and that the effective execution of a national programme requires that one single agency should be in charge of it. The panel would form its new agency out of the existing Environmental Science Services Administration (which came into existence only at the beginning of this year), the Geological Survey, parts of the U.S. Coast Guard and the oceanographic interests in the Departments of Fisheries and of Mines.

Such a step would not, the panel argues, entail interference with the National Science Foundation in its present role of supporting academic oceanography. Similarly, the present activities of agencies such as the Office of Naval Research and the Smithsonian Institution would continue without interruption.

The operation of ships for oceanographic research is reckoned to be a special problem. Not merely are there a number of oceanographic vessels in commission, but there is a prospect of drilling platforms such as that intended for MOHOLE soon to come into commission. At present, the demand for ship time, and the complexity of modern exploration, means that schedules have to be prepared two years in advance. This, the panel argues, is extremely difficult when the cost of operation has to be met by a number of grants and contracts with individual researchers. For one thing, this means retrospective haggling about who pays what. It also means that the cost of operating an unpopular ship may seem to be more than that of operating a popular one. This in turn implies that small laboratories tend to find it hard to make proper use of their comparatively small funds. Thus, the argument goes, there is a need that ships should be operated centrally, and that the distribution of time among interested laboratories should be decided by groups of users with joint responsibility and privileges.

Among the other facilities for oceanographic research which the panel would like to create is a strengthening of the existing National Oceanographic Data Center which, the panel says, "needs upgrading very badly". The panel would also like to establish a number of special laboratories, including one in the Arctic for the study of living things at sub-freezing temperatures; a laboratory in the tropics for the study of marine environment and population; and a laboratory in the temperate zone to study the organisms involved in the food chains of food fishes.

STONEHENGE—AN ECLIPSE PREDICTOR

By PROF. FRED HOYLE
University of Cambridge

THE suggestion that Stonehenge may have been constructed with a serious astronomical purpose has recently received support from Hawkins, who has shown[1] that many alignments of astronomical significance exist between different positions in the structure. Some workers have questioned whether, in an arrangement possessing so many positions, these alignments can be taken to be statistically significant. I have recently reworked all the alignments found by Hawkins. My opinion is that the arrangement is not random. As Hawkins points out, some positions are especially relevant in relation to the geometrical regularities of Stonehenge, and it is these particular positions which show the main alignments. Furthermore, I find these alignments are just the ones that could have served far-reaching astronomical purposes, as I shall show in this article. Thirdly, on more detailed investigation, the apparently small errors, of the order of $\pm 1°$, in the alignments turn out not to be errors at all.

In a second article[2] Hawkins goes on to investigate earlier proposals that Stonehenge may have operated as an eclipse predictor. The period of regression of the lunar nodes, 18·61 years, is of especial importance in the analysis of eclipses. Hawkins notes that a marker stone moved around the circle of fifty-six Aubrey holes at a rate of three holes per year completes a revolution of the circle in 18·67 years. This is close enough to 18·61 years to suggest a connexion between the period of regression of the nodes and the number of Aubrey holes. In this also I agree with Hawkins. I differ from him, however, in the manner in which he supposes the eclipse predictor to have worked. Explicitly, the following objections to his suggestions seem relevant:

(1) The assumption that the Aubrey holes served merely to count cycles of 56 years seems to me to be weak. There is no need to set out fifty-six holes at regular intervals on the circumference of a circle of such a great radius in order to count cycles of fifty-six.

(2) It is difficult to see how it would have been possible to calibrate the counting system proposed by Hawkins. He himself used tables of known eclipses in order to find it. The builders of Stonehenge were not equipped with such *post hoc* tables.

(3) The predictor gives only a small fraction of all eclipses. It is difficult to see what merit would have accrued to the builders from successful predictions at intervals as far apart as 10 years. What of all the eclipses the system failed to predict?

My suggestion is that the Aubrey circle represents the ecliptic. The situation shown in Fig. 1 corresponds to a moment when the Moon is full. The first point of Aries γ has been arbitrarily placed at hole 14. S is the position of the Sun, the angle $\bigcirc$ is the solar longitude, M is the projection of the Moon on to the ecliptic, N is the ascending node of the lunar orbit, N' the descending node, and the centre C is the position of the observer. As time passes, the points S, M, N and N' move in the senses shown in Fig. 1. S makes one circuit a year. M moves more quickly, with one circuit in a lunar month. One rotation of the line of lunar nodes NN' is accomplished in 18·61 years. In Fig. 1, S and M are at the opposite ends of a diameter because the diagram represents the state of affairs at full Moon.

If the Moon is at N, there is a solar eclipse if the Sun is within roughly $\pm 15°$ of N, and a lunar eclipse if the Sun is within $\pm 10°$ of N'. Similarly, if the Moon is at N', there will be a solar eclipse if the Sun is within $\pm 15°$ of coincidence with the Moon, and a lunar eclipse if it is within roughly $\pm 10°$ of the opposite end of the line of lunar nodes. Evidently if we represent S, M, N and N' by markers, and if we know how to move the markers so as to represent the actual motions of the Sun and Moon with adequate accuracy, we can predict almost every eclipse, although roughly half of them will not be visible from the position of the observer. This is a great improvement on the widely scattered eclipses predictable by Hawkins's system. Eclipses can occur as many as seven times in a single year, although this would be an exceptional year.

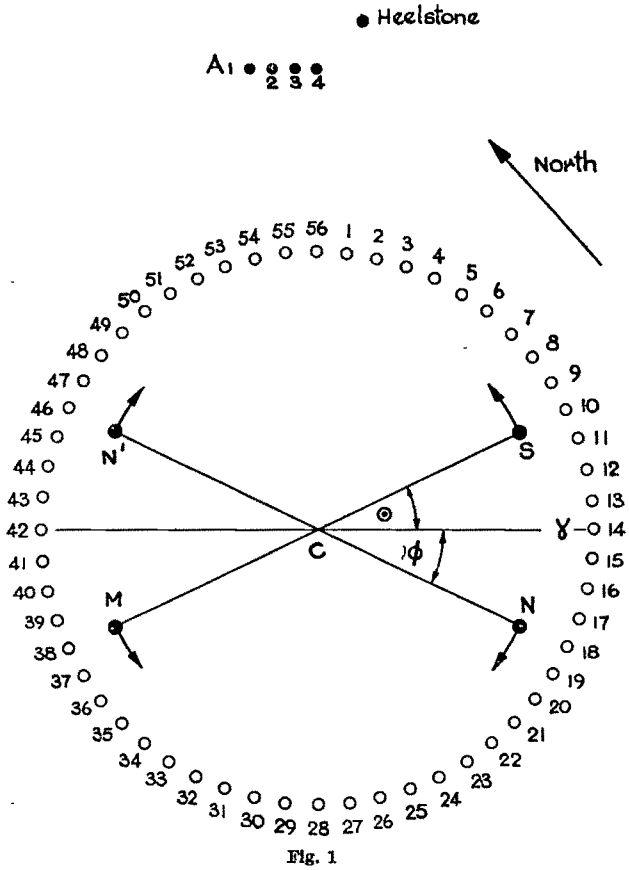

Fig. 1

The prescriptions for moving the markers are as follows: (1) Move S anticlockwise two holes every 13 days. (2) Move M anticlockwise two holes each day. (3) Move N and N' clockwise three holes each year.

We can reasonably assume that the builders of Stonehenge knew the approximate number of days in the year, the number of days in the month, and the period of regression of the nodes. The latter follows by observing the azimuth at which the Moon rises above the horizon.

If in each lunar month we measure the least value of the azimuth (taken east of north), we find that the "least monthly values" change slowly, because the angle $\varphi = NC\gamma$ changes. The behaviour of the "least monthly values" is shown in Fig. 2 for the range $-60° \leqslant \varphi \leqslant 60°$. (The azimuthal values in Fig. 2 were worked out without including a refraction or a parallax correction. These small effects are irrelevant to the present discussion.) The least monthly values oscillate with the period of φ, 18·61 years. By observing the azimuthal cycle, the period of φ can be determined with high accuracy by observing many cycles. At Stonehenge sighting alignments exist that would have suited such observations. With the periods of S, M and N known with reasonable accuracy the prescriptions follow immediately as approximate working rules.

Suppose an initially correct configuration for M, N and S is known. The prescriptions enable us to predict ahead what the positions of M, N and S are going to be, and thus to foresee coming events—but only for a while, because inaccuracies in our prescriptions will cause the markers to differ more and more from the true positions of the real Moon, Sun, and ascending node. The lunar marker will be the first to deviate seriously—the prescription gives an orbital period of 28 days instead of 27·32 days. But we can make a correcting adjustment to the M marker twice every month, simply by aligning M opposite S at the time of full Moon, and by placing it coincident with S at new Moon. The prescription for S gives an orbital period of 364 days, which is near enough to the actual period because it is possible to correct the position of S four times every year, by suitable observations made with the midsummer, midwinter, and equinoctial sighting lines that are set up with such remarkable accuracy at Stonehenge.

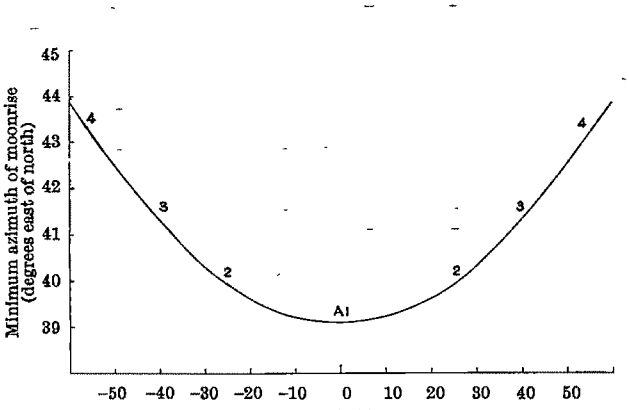

Fig. 2

Stonehenge is also constructed to determine the moment when $\varphi = 0$, that is, when N should be set at γ. The line C to $A1$ of Fig. 1 is the azimuthal direction for the minimum point of Fig. 2. By placing N at γ when the Moon rises farthest to the north, the N marker can be calibrated once every 18·61 years. The prescription implies only a small error over one revolution of N. If N started correctly, it would be out of its true position by only 1° or so at the end of the first cycle. The tolerance for eclipse prediction is about 5°, so that if we were to adjust N every cycle, the predictor would continue to work indefinitely without appreciable inaccuracy. The same method also serves to place N at the beginning.

But now we encounter an apparent difficulty. The minimum of Fig. 2 is very shallow and cannot really be determined in the way I have just described. Angular errors cannot have been less than $\pm 0·25°$, and even this error, occurring at the minimum of Fig. 2, is sufficient to produce an error of as much as $\pm 15°$ in φ.

The correct procedure is to determine the moment of the minimum by averaging the two sides of the symmetrical curve, by taking a mean between points 2, for example. The inaccuracy is then reduced to not more than a degree or two—well within the permitted tolerance.

What is needed is to set up sighting directions a little to the east of the most northerly direction. The plan of Stonehenge shows a line of post holes, $A1$, 2, 3 and 4, placed regularly and with apparent purpose in exactly the appropriate places.

The same point applies to solsticial measurements of the Sun. In summer the sighting line should be slightly increased in azimuth, in winter it should be slightly decreased.

Hawkins[1] gives two tables in which he includes columns headed "Error Alt.". These altitude errors were calculated on the assumption that the builders of Stonehenge intended to sight exactly the azimuthal extremes. The test of the present ideas is whether the calculated "errors" have the appropriate sign—on the argument given here "errors" should be present and they should have the same sign as the declination. In ten out of twelve values which Hawkins gives in his Table 1 this is so. The direction from C to the Heelstone is one of the two outstanding cases. Here the "error" is zero, suggesting that this special direction was kept exactly at the direction of midsummer sunrise, perhaps for aesthetic or ritualistic reasons. The other discrepant case is 91 → 94. Here my own calculation gives only a very small discrepancy, suggesting that this direction was also kept at the appropriate azimuthal extreme.

Negative values of the altitude error correspond to cases where it would be necessary to observe below the horizontal plane, if the objects in question were sighted at their extreme azimuths. This is impossible at Stonehenge because the land slopes gently upward in all directions. Such sighting lines could not have been used at the extremes, a circumstance which also supports this point of view.

It is of interest to look for other ways of calibrating the N marker. A method, which at first sight looks promising, can be found using a special situation in which full Moon happens to occur exactly at an equinox. There is evidence that this method was tried at Stonehenge, but the necessary sighting lines are clearly peripheral to the main structure. Further investigation shows the method to be unworkable, however, because unavoidable errors in judging the exact moment of full Moon produce large errors in the positioning of N. The method is essentially unworkable because the inclination of the lunar orbit is small. Even so, the method may well have caused a furore in its day, as the emphasis it gives to a full Moon at the equinox could have been responsible for the dating of Easter.

An eclipse calibrator can be worked accurately almost by complete numerology, if the observer is aware of a curious near-commensurability. Because S and N move in opposite directions the Sun moves through N more frequently than once a year, in 346·6 days. Nineteen such revolutions is equal to 6,585·8 days, whereas 223 lunations is equal to 6,585·3 days. Thus after 223 lunations the N marker must bear almost exactly the same relation to S that it did before. If the correct relation of N to S is known at any one moment N can be reset every 223 lunations; that is, every 18 years 11 days. The near-commensurability is so good that this system would give satisfactory predictions for more than 500 years. It requires, of course, S to be set in the same way as before. The advantage is that in the case of N it obviates any need for the observational work described above. But without observations the correct initial situation cannot be determined unless the problem is inverted. By using observed eclipses the calibrator could be set up by trial and error. This is probably the method of the Saros used in the Near East. There is no evidence that it was

used at Stonehenge. The whole structure of Stonehenge seems to have been dedicated to meticulous observation. The method of Stonehenge would have worked equally well even if the Saros had not existed.

Several interesting cultural points present themselves. Suppose this system was invented by a society with cultural beliefs associated with the Sun and Moon. If the Sun and Moon are given godlike qualities, what shall we say of N? Observation shows that whenever M and S are closely associated with N, eclipses occur. Our gods are temporarily eliminated. Evidently, then, N must be a still more powerful god. But N is unseen. Could this be the origin of the concept of an invisible, all-powerful god, the God of Isaiah? Could it have been the discovery of the significance of N that destroyed sun-worship as a religion? Could M, N and S be the origin of the doctrine of the Trinity, the "three-in-one, the one-in-three"? It would indeed be ironic if it turned out that the roots of much of our present-day culture were determined by the lunar node.

STONEHENGE—A NEOLITHIC "OBSERVATORY"

By C. A. NEWHAM
5 Sedge Rise, Tadcaster, Yorkshire

PROF. G. S. HAWKINS[1] has shown how Stonehenge could be regarded as a "computer" to predict the time when eclipses of the Sun and Moon were due, though not always visible at Stonehenge. He ingeniously relates the fifty-six Aubrey holes with a 56-year eclipse cycle. The principle is valid, but there is no evidence to support the idea that Stonehenge was intended to be a "computer" other than that the majority of main features embodied in the 'monument' unquestionably have some astronomical connexion. There are, however, a number of "post holes"; however, no satisfactory explanation has so far been put forward to explain their purpose.

An analysis of the position and number of post holes prompts a suggestion as to their purpose, and may well provide the clue to the method by which the builders of Stonehenge acquired elementary knowledge of Moon cycles, possibly including the approximate 56-year eclipse cycle.

Stonehenge post holes. Of the many post holes found in and around Stonehenge, there is one group of about forty holes situated in the "causeway" near the north-east entrance (Fig. 1). The holes seem to radiate from the centre of the Aubrey circle, and lie within a 10-degree arc north of the heelstone or solstice line. They are roughly arranged into six ranks crossing the line of the causeway.

A fairly reliable record of the behaviour of the Moon could be obtained by planting a temporary marker (wooden stake) to align on the point where the winter full-moon appeared above the horizon each year. The indications are such that this was done over a large number of years covering several 18·61-year cycles. Such a period would be sufficient to ascertain a 19-year phase or metonic cycle and possibly the approximate 56-year eclipse cycle as suggested by Hawkins (that is, $3 \times 18{\cdot}61 = 55{\cdot}83$). It should be appreciated, however, that they would have considerable difficulty in defining this eclipse cycle by their crude methods.

Starting from the premise that the post holes were used for the purpose suggested, the azimuth bearing of each post hole was first ascertained in rank order, numbered 1 to 6 counting in a north-easterly direction.

The number of holes attributed to each rank and their azimuth bearings taken from the centre of the Aubrey circle are given in Table 1.

Preliminary calculations reveal that the causeway post holes lie within the arc or sector of the most northerly limits of winter full-moon rise as seen from the centre of the Aubrey circle (C.A.C.); also, the number of holes in any one rank did not exceed the number of risings that could appear north of the heelstone or solstice line in any one cycle.

If individual bearings of moonrise in a sequence of cycles were found to agree with the "hole alignments", any doubt as to their significance would be eliminated; furthermore, dating of the post holes would be feasible. Unfortunately, the necessary data concerning the Moon are not available; to obtain such information would severely tax the ability of the most expert celestial mechanician.

Table 1

Rank No.	1	2	3	4	5	6
	–	–	(40·4)	(40·7)	–	(40 3)
	41·9	41·9	–	–	41·8	–
Azimuth	43·1	43·0	43·0	42·9	42·9	42·7
bearings	–	44·1	44·0	43·8	44·0	–
degrees	–	45·3	45·3	45·5	45·6	–
E. of N.	–	45·6	45·6	–	–	–
	46·3	46·4	46·5	46·3	46·4	46·4
	–	– *47·4	–	–	–	46·7
	–	47·8	47·5	47·2	47·6	47 5
	–	49·3	49·4	49·0	48·9	49·1
	–	49·8	–	–	49·8	–
	–	–	50·4	50·2	50·8	50 3

The figures in parentheses refer to holes beyond the line of full orb but are reached by the line of first gleam of moonrise.

* This hole is situated between ranks No. 2 and No. 3 and cannot be allocated to either rank.

However, computed moonrise bearings covering the period of 2000–1000 B.C. were first used in an attempt to determine whether any similarity existed between general grouping of the post holes and a sequence of moonrisings. The data used were kindly supplied by Prof. G. S. Hawkins. His calculations are based on first-order terms and refer to the full-moon nearest the winter solstice and also require that the instant of moonrise should coincide with the time when the Moon reaches its appropriate maximum declination. This particular feature seldom applies (see Fig. 2).

The pattern of risings that would apply to the early Stonehenge period is more truly represented in groups '*B*' and '*C*'. Even so, their arrangements could be subject to slight variations as many individual moons have possible alternative rising positions. This applies in those cases when the Moon reaches "full" during the daytime, for example, on December 12, 1875, the Moon was full at 0745 h (shortly before setting). In similar circumstances, would they regard the critical Moon as being that which rose on the afternoon of December 12, or that of the following day? If midnight was their datum, the former Moon would apply. On the other hand, it would be the latter if the critical time was on its rising. A similar condition arises in respect of those Moons which are full

14 or 15 days before the solstice and would be followed by the next Moon 14 or 15 days after the solstice.

There is no question that people of early civilizations had to contend with the same difficulty which was partly obviated by choosing the critical Moon as the one which was full after a specified time, such as the day of the winter solstice or equinox. In the second millennium B.C. the Delians regarded the critical Moon as the first one that was full after the winter solstice, and the possibility that such was the case with the Stonehenge people cannot be overlooked. However, the remarkably close relationship of the moonrise sequences and hole patterns must surely be more than a coincidence. If this suggested method of observation had been carried out by the Stonehenge people, they would have had little difficulty in recognizing the 19-year phase or metonic cycle.

It seems fair to assume that these and other post holes served a purpose in obtaining preliminary information of the behaviour of the Sun and Moon. Once satisfactory alignments had been established, markers of a more permanent kind would be installed. If the foregoing assumptions were correct, then the long period of time that elapsed between the inception of the bank, etc., and the building of the first major stone structures would be accounted for.

The position and spacing of the four large post holes near the heelstone indicate a relationship with the causeway holes, especially so in conjunction with stone '*D*' and the heelstone. The size of the holes indicates that the posts were much larger than the causeway posts and, presumably, more permanent. If stone '*B*' were also included, then the seven markers which could be observed would act as a crude 'vernier'. When correlated with the setting Sun seen in the reverse direction, it would provide a means of defining the time when an eclipse of the Moon was probable.

Whether or not Stonehenge people discovered the 56-year cycle is a matter for conjecture, but their ability to predict pending eclipses after a crude fashion was certainly possible.

It can be shown that a person assisted by nothing more than the crudest equipment in the form of a peg and line and a few stakes could acquire the necessary information. The observer, however, would have to have the necessary tenacity of purpose to undertake systematic observations over a long period of time and a simple method of recording numbers by means of tokens, for example, notches on a stick or pebbles in a bag.

Doubtless, several generations of observers were involved, and if we are to believe that the writings of Diodorus referred to Stonehenge, then the position of supervisor of the "Spherical* Temple" was held by a member of the same family from one generation to another.

The strong lunar influence with which Stonehenge must now be associated necessitates revision of hitherto

* Early Greek term for "Astronomical". Heath: *History of Greek Mathematics.*

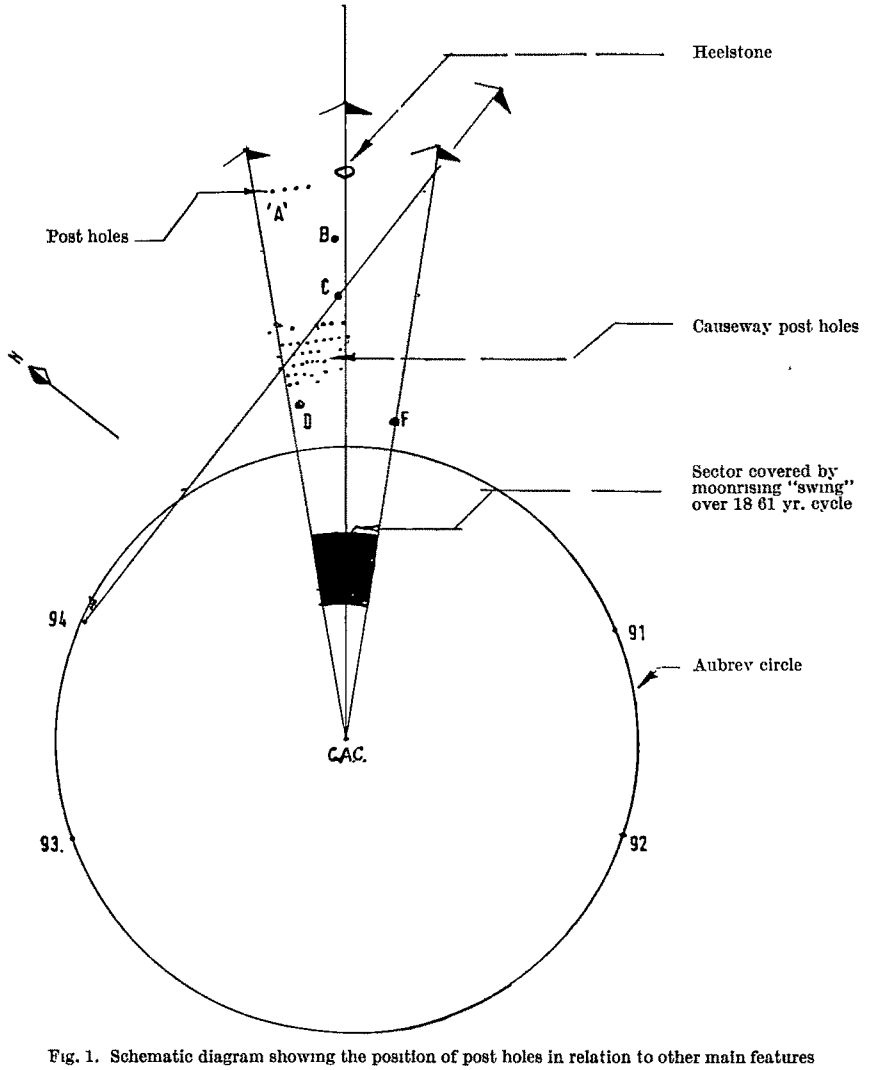

Fig. 1. Schematic diagram showing the position of post holes in relation to other main features

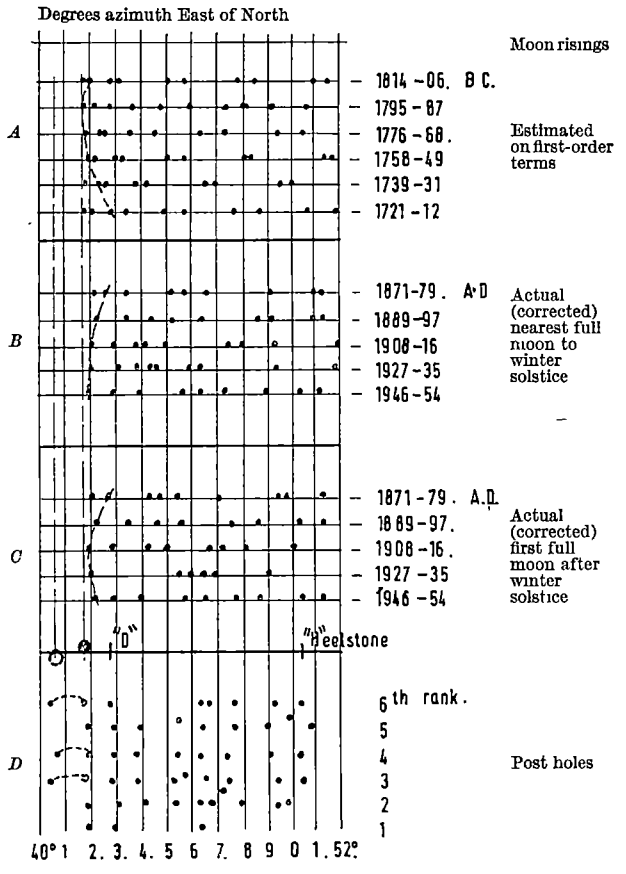

Fig. 2. Comparable azimuth bearings of winter full-moon risings. (Full-orb tangent to horizon) and post hole alignments

Group '*A*': Six cycles of moonrisings based on first-order terms as supplied by Hawkins for period 1814–1712 B.C.

Group '*B*': Similar to '*A*' but the "Moons" correspond to the known rising position covering the period A.D. 1871–1954 after correction to allow for the change in the angle to the ecliptic of the Earth–Moon system over the past 3,800 years

Group '*C*': Basically similar to '*B*', but here it applies to the first full-moon after the winter solstice

Group '*D*': Depicts the post holes arranged according to their azimuth bearings

The data connected by broken lines are all separated by a period of 6,940 days or exactly 19 years within a few hours, and differ from other similar Moons in that their rising positions are practically the same. The broken lines in group '*D*' merely indicate the position the three holes would occupy if they were aligned on full orb. The two larger circles immediately above represent the most northerly position of first gleam and full orb of moonrise. The positions of stone '*D*' and the heelstone are indicated on the same line

accepted explanations of some salient features. Until new evidence is found pointing to the contrary, it is more logical to conclude:

(*a*) That the small stone (No. 11) in the sarsen circle was intentional, and that the circle represented the 29·5 days of the lunar month.

(*b*) The double circle or spiral[2] of the '*Y*' and '*Z*' holes represented the 59 days of two lunar months. The strong possibility that there were fifty-nine blue stones inside the sarsen circle would provide a more suitable means of representing the same thing.

(*c*) The 19-year phase or metonic cycle was represented by the nineteen blue stones inside the trilithon "horse shoe".

All things considered, including other similar post holes, there seems little doubt that Stonehenge, in its early stages, was a kind of "observatory". It provided a suitable site wherein systematic observations of 'Soluna' (Sun and Moon) phenomena were carried out by these neolithic peoples.

BOOK REVIEWS

NEW CONCEPTS FOR OLD

Science, Folklore and Philosophy

By Harry Girvetz, George Geiger, Harold Hantz and Bertram Morris. Pp. xi + 547. (London and New York: Harper and Row, Publishers, 1966.) 72*s*.

THE authors of this volume seem to have run up against a common difficulty for teachers of philosophy, that of justifying to their pupils the seemingly abstract and recondite studies included in the philosophy curricula. Why study methodology, why do conceptual analysis? And in particular why read Aristotle on substance, or Locke on qualities, or Austin on performative utterances? In this book there seems to me to be exactly the right answer. It is that the growth of science has thrown up, from time to time, new ranges of phenomena which have required new concepts and systems of concepts for their understanding. The system with which the discoverers were equipped (called by the authors the "folklore") broke down in the face of the new situation and a new system was painfully forged to accommodate it. They see philosophy as the activity of forging (by critical analysis) new conceptual schemes. Their answer then to their pupils and to all who cannot see the point of philosophical studies is that philosophical issues have had to be resolved in each of the great periods of conceptual change initiated by scientific advance (or *vice versa* of course) and that the resolutions that were made by the Greeks, by the British empiricists and Descartes, by the post-Darwinians, and which are being made these days in the philosophy of mind and of behaviour, have created the system of concepts which we now use. In short, to understand our present science we operate with a system of concepts and methods of reasoning forged in the past and carelessly acquired in the present. We should understand the reasons why we have adopted in our culture the intellectual machinery that we have.

The project is quite admirable in my view and the plan of the book excellent. It is distressing then to have to say that the detailed execution of the plan leaves a great deal to be desired. There are a great many historical errors, some minor, for example that "Tycho's view [of the structure of the solar system] was too clumsy to be entertained", when that very view was not only entertained by some of the first mathematicians of Europe, such as Ursus, but was the most widely taught in the first half of the seventeenth century. There are also major errors. The most remarkable of these is the contention that science and religion parted in about 1600, their divorce being pronounced by Francis Bacon. The authors can have had very little conception of the attitude to Nature of the circle of Boyle, Locke and Newton. Indeed there is a general failure to get the historical settings quite right. Nevertheless the book has great value in showing, even in a rather unsatisfactory way, how the great philosophical problems were generated, and the place of their resolutions in our conceptual scheme.

R. HARRÉ

AN INSPIRED EXPERIMENTER

Collected Papers of P. L. Kapitza

Edited and with an introduction by D. ter Haar. Vol. 1: 1916–1934. Pp. xvi + 503 + 31 plates. 140*s*. net. Vol. 2: 1938–1964. Pp. viii + 505–993. 140*s*. net. (London and New York: Pergamon Press, Ltd., 1964–65.)

THE collection of papers under review makes fascinating reading: I have found browsing through them an enjoy-

able and educational experience. It is interesting to compare Kapitza's collected papers with those of Landau, recently issued by the same publisher, for the two men can be regarded as occupying comparable positions with respect to experimental and theoretical physics in Russia. The Landau collection occupies only one volume and contains a surprisingly large number of papers that one would read nowadays for their scientific content. While some of the Kapitza papers one still reads for their scientific content—most notably the series on superfluidity of helium—the interest of the majority is in the light they throw on the development of physics and on the character of a remarkable physicist. One can find resemblances both to his teacher, Rutherford, and to Brunel. In his love for and skill in experimental physics, and in his feeling for the important simple features of his results he resembles Rutherford. But he is also to a considerable extent an engineer, and shows something of the inventiveness, the feeling for the grandiose, and the forcefulness of Brunel. One feels that Kapitza's wide-ranging abilities and interest in practical applications would have been more at home in the Royal Society of the seventeenth century than the twentieth.

The two volumes under review neatly separate Kapitza's Cambridge period, up to 1934 (together with a few early papers from Leningrad), from his Moscow period. Kapitza came to Cambridge in 1921 and secured acceptance by Rutherford by his now famous lesson in orders of magnitude repeated in Dr. ter Haar's introduction. His work on α-particle tracks soon led to an interest in producing high magnetic fields, and his skill in orders of magnitude is very apparent in his comparison of different forms of energy storage for the production of impulsive fields, making these papers an object lesson in the design of apparatus. Kapitza's impulsive 300 kG was to stand as a record for many years, and he rapidly exploited fields of the 100 kG order in numerous measurements of magnetoresistance and magnetostriction. But Kapitza not only produced and used high fields, he also succeeded in getting the Royal Society Mond Laboratory built for his work, and built the way he wanted it—a very Brunel-like achievement. It was his decision to equip this laboratory with low temperature facilities that led to his ingenious design for an expansion engine liquefier for helium, avoiding the use of liquid hydrogen, which has proved of immense importance for low-temperature technology. Not only have large liquefiers in the U.S.S.R. descended from it, but also the Collins liquefier which has so transformed low-temperature physics since the Second World War and the giant 100 l./h liquefiers at Texan oil wells.

On Kapitza's return to Russia he created a similar laboratory (even to the marble switchboards) at the Institute for Physical Problems in Moscow, and almost at once began his pioneering work on the superfluidity of helium. Of these papers, one can select two as showing quite exceptional ingenuity and insight. In the first, before Landau's theory, he showed that heat flow from a bulb of helium is accompanied by a jet capable of moving a vane, even though the whole apparatus is full of liquid. It is interesting that he was led logically to this experiment by the idea that negligible viscosity (which he had already observed) would lead to extremely easy convective transfer of heat, and he thus came near to deducing the two-fluid model from experiment. The second experiment, after Landau's theory, was the first quantitative evidence for the two-fluid model; in a simple but ingenious experiment Kapitza measured the thermomechanical effects associated with superflow through a narrow slit. These two classic papers are required reading for anyone in the field, and it is good to have them readily available in English.

After the Second World War, Kapitza turned his attention to high-power microwave engineering. I myself have no knowledge of this field, but I was impressed by the technique Kapitza developed for calculating the essential features of the motion of electrons in electric and magnetic fields (also applied by him to the problem of a pendulum with a rapidly oscillating support, which led to a typical Kapitza demonstration experiment), and by the ingenious experimentation which accompanied these calculations. These papers (and also a few others) were specially translated for the present volumes; it is to this, no doubt, that we owe the addition to the vocabulary of microwave plumbing of the "sewerage" of microwave power. This latest work of Kapitza's is in a sense a return to his earliest. It involves the same type of original electrical engineering, and shows the same delight in taking things to extremes, as his work on high magnetic fields.

The brief introduction by Dr. ter Haar gives a useful summary and classification of the papers, but little more. A larger introduction giving much more biographical information would have considerably enhanced the interest and value of the volumes. As it is, many questions, such as the enigma of Kapitza's wartime eclipse, remain unanswered, as well as a number of fascinating sidelines—for example, the genesis of the paper on the nature of ball lightning.

At £7 per volume the books are expensive, even for collected papers, and few but libraries will afford them. Every science library should buy them, and they should be widely read. The books are well printed and open comfortably, but at the price the publishers should have managed a better cloth binding. H. E. HALL

THE IONOSPHERE *IN EXTENSO*

Physics of the Earth's Upper Atmosphere

Edited by C. O. Hines, I. Paghis, T. R. Hartz and J. A. Fejer. Pp. xiv+434. (Englewood Cliffs, N.J., and London: Prentice-Hall, Inc., 1965.) 105*s*.

To the scientist the "upper atmosphere" means broadly that part of the Earth's envelope in which physical processes are profoundly affected by the presence of charged particles, and are therefore intimately associated with the fields of electromagnetic waves and the Earth's magnetism.

Effective study of the upper atmosphere began some 40 years ago with the discovery of the ionosphere by radio sounding, and much of the early work was concerned with problems of radio communication. More recently, through the extension of observational techniques by means of rockets and satellites, the study has developed into a major discipline which embraces an astonishing variety of interlinked phenomena. There are, of course, reasons in addition to scientific interest for the scale of the present research effort, but it is to the purely scientific aspects of the subject that this book is devoted.

A wide range of topics is covered. Details of theory, and of the results and methods of observation, are generally omitted. There are plenty of diagrams, but, as a phrase from the dust jacket puts it, emphasis is on descriptive physics The account is none the worse for that. Indeed, it is hard to imagine a different approach serving better either the student just entering the field, whom the editors are particularly anxious to help, or the specialist in some part of the discipline looking for an authoritative guide to the wider implications of his work.

The various sections are written by experts in each topic. Nevertheless, the whole is remarkably well knit, and the level of exposition uniformly high; of the battle to reconcile inevitable differences over the selection and presentation of material, lightly touched on in the preface, no scar remains.

Roughly, the first half of the book is concerned with so-called "normal" or "undisturbed" conditions, and the second half with "disturbed" conditions. In this context a disturbance in the upper atmosphere means an effect

caused by a disturbance on the Sun, so that the later chapters contain a good deal about the part played by solar emission of particles or radiation.

After an introduction, there is a chapter on the solar optical radiation that affects the ionosphere below 120 km, and then, successively, chapters on the *D* and *E* regions of the ionosphere, on the *F* region, and on the outer ionosphere. The latter includes a review of the motion of charged particles in a magnetic field, prefacing a discussion of the Van Allen belts, those regions where energetic charged particles are trapped in the geomagnetic field. Next, windlike motions are considered, first of the neutral atmosphere, and then of ionization; the main topics here are tidal oscillations and smaller scale gravity waves (the only purely gas dynamic phenomena treated in the book), and the "dynamo" theory of the diurnal variations of the geomagnetic field. Discussion of the undisturbed atmosphere ends with a chapter jointly on ionospheric noise, that is, audio-frequency radio emissions which produce the delightful medley of sound known as "dawn chorus", and on geomagnetic micropulsations.

Disturbances on the Sun are divided into those emitting ultra-violet and X-radiation, and those emitting charged particles. The former give rise to "sudden ionospheric disturbances", and are dealt with in a single chapter. The latter are thought to be the origin of numerous effects, in particular, polar cap absorption, magnetic storms, and aurorae; and the discussion here occupies a further six chapters. Of these the final one, on storm theory, is an enlightening account of the different suggestions that have been put forward.

The two appendixes give some fifty pages on aspects of electromagnetic wave propagation. They might, perhaps, have been linked a little more closely to the main text. For example, they contain no reference to Faraday rotation, quoted earlier as giving a measure of electron content.

The authors rightly emphasize the incomplete state of knowledge in many of the topics under discussion, and throughout strike a fair balance between rival theories, not a few of which have been contributed by one or other of their company. Their book is to be highly recommended to a wide class of readers. P. C. CLEMMOW

SILICATE ANALYSIS AT THE BENCH

Methods of Silicate Analysis

By H. Bennett and W. G. Hawley. Second edition. Pp. xv+334. (Published for the British Ceramic Research Association.) (London and New York: Academic Press, 1965.) 63*s*.

FOR many decades there was little change in the methods of silicate analysis. Standard works such as Hillebrand and Lundell's *Applied Inorganic Chemistry*, itself based on an earlier text, served a generation of analysts. With the development of instrumental methods and the introduction of new reagents a move was made to introduce simplified methods of silicate analysis. The older, generally applicable, systematic schemes of gravimetric analysis, often lengthy and involved, were replaced by rapid direct determinations using spectro-photo-colorimetric and complexometric methods. Although this process was often accompanied by considerable loss of precision, the fresh impetus given to the subject induced many workers in the field to review methods generally with the result that many of these were simplified, often with a gain in accuracy.

Although this branch of analysis is now progressive, the once neat pattern of analysis has disappeared, so that these new simplified, but often restricted, methods of analysis exist side by side with the "classical" general methods of analysis. The task for the compiler is therefore not easy and for some time there has been a need for a critical survey of the variety of methods scattered in reference books and original literature. Bennett and Hawley, in a new and much improved edition of their work, *Methods of Silicate Analysis*, have gone a long way towards effectively summarizing the present state of silicate analysis, especially in the context of ceramic materials. The title is perhaps slightly misleading, for although materials which are not silicates but are of ceramic interest find a place in this work, certain silicates do not. The work is, in fact, directed primarily at the industrial ceramic analyst rather than the silicate analyst, although it will prove useful to the latter.

The book falls into three sections. Part I is introductory and is followed by a discussion on the basic principles behind the theory and practice of silicate analysis (Part II). The main section (Part III) deals with the analysis of materials; full practical details are given, but general comment and discussion are placed separately in Part II. This makes for easy reading of the practical text. The authors have not hesitated to duplicate material to avoid the necessity for cross-references which would be tiresome and out of place in a work clearly designed to be used at the bench. Chapters in this section of the work are classified on the basis of the material analysed and the general analytical approach adopted. The authors attempt to provide different schemes for different analytical requirements; these depend on the apparatus available, the accuracy required, and the material being analysed.

Materials discussed are those which have some bearing on the ceramic industry such as siliceous and aluminous materials, carbonates, refractories, frits, glazes, etc. Methods described include the generally applicable classical schemes of analysis, accurate direct determinations, and rapid gravimetric, volumetric and spectrophotometric procedures. There are chapters devoted to the analysis of alkalis, the determination of fluorine and to methods connected with the solubility and resistance of materials toward aqueous and acid attack.

The text is thoroughly reliable, for it is abundantly clear that a considerable amount of personal practical experience has gone into this book, and its use should steer an analyst clear of those hidden pitfalls of practical silicate analysis. Although it emphasizes ceramic analysis, the book should prove of value to all silicate analysts provided they are aware of the limitations of certain specialized methods. It is thoroughly to be recommended.
A. D. WILSON

CATIONS AND CATALYSIS

Friedel–Crafts and Related Reactions

Edited by George A. Olah. Vol. 1: General Aspects. Pp. xxxiv+1031. 220*s*. Vol. 2: Alkylation and Related Reactions. Part 1: Pp. xxix+1–658. Part 2: Pp. xxv+659–1362. 378*s*. the two parts. Vol. 3: Acylation and Related Reactions. Part 1: Pp. xxvi+1–910. Part 2: Pp. xxii+911–1606. 450*s*. the two parts. Vol. 4: Miscellaneous Reactions; Cumulative Indexes. Pp. xvii+1191. 340*s*. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1963–65.)

ONE of the ways which is in use at present to render down to digestible proportions the vast mass of chemical information is the publication of multi-author books on a wide theme. Each specialist then selects and presents his own considerations of what he considers to be significant. This procedure, if it is to be successful, requires a firm and wise editor who must be able to obtain co-operation from his authors and who must possess the vision which will ensure that the theme is well served.

Dr. George Olah has presided over the production of a magnificent work on, essentially, catalysed cationic reactions. *Friedel–Crafts and Related Reactions* is the combined effort of fifty contributors from nine different

countries. Half of these, including the editor himself, hold industrial positions; some have international reputations while others were unknown to me. As the net has been very widely cast in terms of the topics to be dealt with, the writers are by no means restricted to organic chemists.

The book, and it is to be considered as a whole, is immense. There is a total of 5,189 pages, of which 870 in Volume 4 are given over to the subject and author indexes. It has been published in parts from 1963 to 1965 and it is a tribute to Olah's editorship that such a large work should contain references as late as 1963. No claim for complete comprehensiveness is made and many references to previous reviews are given.

One might expect that, with such a wide diversity of contributors, the style of the book would be uneven. Surprisingly, this is not generally so. With few exceptions, the very variegated subject matter is dealt with in a remarkably cohesive manner. Further, a book of this size might be expected to present its own retrieval problems. These have been eliminated by carefully cutting each chapter into sections and providing very detailed plans of contents. These enable the reader to pick out a specific topic very readily and encourage the luxury of browsing. The subject index is also very detailed and provides references not only to conceptual material in the text but also to the thousands of individual compounds which appear in tables throughout the book.

Readability and overlap are two further problems in a book of this type. The first has largely been overcome by separation of the 'catalogue' material into tables apart from the text, so as to leave behind discussion of general principle and topics of specific controversy. Those chapters which conform to this pattern are best suited to the aims of the book; the others are, quite frankly, dull. Some overlapping is bound to occur in a multi-author treatment of a broad theme. There is a good deal in this book particularly with respect to discussion of mechanism, but at least the reader is spared from chasing cross-references to discussions in another part of the book. The amount of detail provided for the various topics is inevitably variable. The chapter in Volume 2 on alkylation with haloalkanes, which one might regard as the fundamental reaction, is disposed of in sixty pages. Perhaps this is all it deserves.

Volume 1 deals with general aspects. A very interesting historical introduction includes photographs of the laboratory notebooks of the originators who produced the three original papers in the summer of 1877. This is followed by Olah's own review of the entire field in which the scope of the book is defined. Olah himself contributes to eleven of the fifty-four chapters, and these are all extremely readable, critical and informative. The other chapters deal with inorganic catalyst systems, investigations of reaction mechanisms by spectroscopic and isotopic methods, and considerations of stereochemistry, selectivity and thermodynamics. The last provides a very timely reminder of fundamental principles for the less numerical reader. This volume is the only one which can well stand apart from the set. It presents the basis for the remainder and provides an excellent introduction to them.

Volume 2, in two parts, deals with alkylation. The coverage is very wide, and in addition to the well-known reactions with olefines, halides and carbonyl compounds, embraces dehydrogenative coupling and isomerization of hydrocarbons, together with consideration of the Prins reaction, hydrogen exchange and cationic polymerization. The treatment is now, of course, much broader than in Volume 1. The recitation-of-lists approach is more common and in some chapters the inclusion of practical details in the text is overdone. Pitfalls of structure numbering have not always been avoided: in Chapter 22, the Roman numerical horror CCCLXXXVIII appears. A chapter on alkylation of saturated hydrocarbons is heavy going because of its large amount of technical detail and sometimes unusual English. The reviews of hydrocarbon isomerization, alkylation with alcohols and ethers, and of hydrogen exchange are particularly interesting. The last of these could, with advantage, have been placed in Volume 1.

Volume 3, also in two parts, covers acylation and related reactions. 'Related reactions' again covers a wide range including sulphonation, halogenation and nitration. Within the theme of the book it is right that they should do so. The more conventional Friedel–Crafts acylations are dealt with in two enormous chapters by Gore and by Peto which occupy most of the first part. Gore's chapter alone contains two hundred pages of tables and two thousand references. As in the rest of the book, careful attention is paid to the pathways and mechanisms of the reactions involved. Stimulating pointers are given to the areas where further effort is required against the background of a vast amount of observation already made. Olah again displays his gift for interesting reviewing in the chapters on formylation and nitration, both of which include accounts of his own important work. A chapter on the curious perchloryl-ation reaction gives much practical information in this new field.

Volume 4 deals with eight miscellaneous topics. Olah again contributes—this time on metathetic cation-producing salts—and gives tabular surveys of this rather specialized field. The chapter dealing with ethers includes a valuable review of epoxide polymerization, and the strange reactions between carbohydrates and aromatics are also allotted a chapter. Reactions with organometallic compounds (Russell) comprise one of the topics farthest from the general theme of the work. Olah rounds off in a chapter dealing with technical applications (mandatory for academics) and future outlook. That the outlook is bright is due in no little measure to his own contributions. This volume also contains the very large cumulative author and subject indexes.

On the whole, the printing of formulae and text is good and errors trivial. One might perhaps have expected a stronger binding on books that will be much used for reference and which are as expensive as these. Contemporary book reviews frequently finish with a complaint that the price is far too high. This work costs, in all, £69 8*s*. This may be thought excessive. On the contrary, because of its wide breadth of coverage, its extremely detailed indexes and contents pages and, above all, because of the almost uniformly high quality of its contents, this book provides a direct entry to this highly topical field. The saving of time devoted to inefficient searching of the literature alone makes this book worth its cost. After all, only about one hundred hours of searching time need to be saved to pay for it.

The book is dedicated to the memory of Charles Friedel and James Mason Crafts and to the investigators who have followed them. It is a fitting tribute.

C. J. M. STIRLING

SEMICONDUCTING MATERIALS

Materials Used in Semiconducting Devices

Edited by C. A. Hogarth. Pp. vii + 243. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1965.) 105*s*.

THIS book consists of a series of articles, each by an author with experience of the particular material, reviewing the properties of several semiconductor materials which find extensive application in commercial devices. A notable omission is that of gallium arsenide; the editor states that the rapid technological development of this material would make any article out of date before it was published. In view of the time taken to publish this book, this view is perhaps reasonable. The article on selenium has no references to work later than 1962,

those on germanium, silicon and bismuth tellurides only one reference each later than 1962. The article on the lead compounds is brought up to date by an appendix; the articles on the antimonides are otherwise the only ones which are up to date as written. It would appear that the main part of the book has undergone a gestation period rather longer than that for an elephant.

Each article is roughly similar in layout; an introduction is followed by a section on methods of preparation, purification, crystal growth and doping. General properties, which include crystal structure, density, and thermal and elastic properties, are next discussed. The band structure is described and the resulting transport and optical properties are listed. The properties of alloys may then be given, and finally some comments on applications of the materials to devices. Mechanical properties, which are presumably of interest to device engineers, are completely ignored except for a very brief mention in the article by Putley, which is also the only one to give consideration to the making of contacts. Nowhere is there any serious attempt to explain the theory of semiconducting materials.

It is generally considered unfair to criticize a book for not being what its author never intended it to be. In this case, however, it is extremely difficult to determine the purpose of this book. Its lack of theory renders it useless as a text-book for students. If it is intended as a guide to the device engineer in selecting suitable materials for his devices, then a summary of the properties of all the materials in tabular form would be an invaluable aid, particularly for comparison purposes. To be really helpful to him, the sections on applications could also undergo a considerable expansion. There is such a lack of detail with regard to techniques that only someone who is already experienced with semiconductor materials would find it of use, perhaps when switching his attention to, to him, a new material. The collection of so much information into one volume is to be welcomed, but a division by properties and applications rather than by materials would be more appropriate.

The book is pleasingly produced and is very well indexed.

DAVID DEW-HUGHES

MECHANISMS OF MIND

The Nature of Psychology

By Kenneth J. W. Craik. Edited by Stephen L. Sherwood. Pp. xx+184. (London: Cambridge University Press, 1966.) 30*s*. net: 6 dollars.

KENNETH CRAIK, had he lived, would by now have been recognized as one of the most original and versatile psychologists of his generation. This selection from his unpublished writings, introduced by a brief biography from Sir Frederic Bartlett, should be welcome to all who knew him and highly instructive to those who did not. Born in 1914, a classical scholar at the Edinburgh Academy, and a student of philosophy under Prof. Kemp Smith, Craik was eventually attracted to psychology by the lectures of the late Prof. Drever. After graduating in that subject, he moved to the Cambridge laboratory to embark on a series of experimental researches on the problems of sensation. Besides attending the recognized classes on psychology, we are told, he went off to the Cambridge Technical School to take a course in engineering, and then under Lord Adrian's guidance steeped himself in the anatomy and physiology of the brain.

In 1940 he obtained the degree of Ph.D., and a year later a Fellowship at St. John's College with a thesis on "The Experimental Study of Visual Adaptation". The bibliography of his published work runs to eighty numbers —an output of almost eight papers every year. During the Second World War, so Prof. Bartlett relates, "he became a key man in the scientific service of his country". He was chairman of the Target Tracking Panel of the Ministry of Supply, and an active member of the Panel on Servo-mechanisms, of the Military Personnel Research Committee, and of the Vision Committee for the Flying Personnel Research. For security reasons, it has unfortunately been impossible to publish any of his official reports. In 1945, on the eve of V.E. Day, while cycling along King's Parade, he was knocked off his bicycle and killed by a passing car. In describing what happened the editor and his collaborators observe that they "have come upon about ten recorded presentiments of the circumstances of his lethal accident".

Of his numerous manuscripts, the earliest that survives is apparently an essay on "Immortality", written when he was only 17. Prof. Bartlett quotes a couple of short extracts, but it seems a pity it was not included in the present volume. The selection begins with "the epilogue from the Ph.D. thesis", and then proceeds to a couple of draft chapters and several isolated notes for a book on "The Mechanism of Human Action". The next two sections include reports of "experimental work" (for example, observations on a prolonged monocular scotoma, the effect of boldly fixating the noonday Sun for two minutes) and suggestions for the "quantification of sensation". Of the four papers that make up the third section—on "Aspects of Psychology"—the most noteworthy is a lecture on "Psychology for Medical Students"; this brings out with a shrewd impartiality both the weaknesses and the strong points of all the different schools, and stresses the need for an eclectic text-book of psychology specifically for the student of medicine. What he has in mind, he tells us, is a book which would omit all that is unnecessary for the practising physician and concentrate solely on topics of direct utility.

Here, as elsewhere, Craik fully recognizes the value of introspective techniques; but in almost all these papers his aim is avowedly to think first of the human mind as functioning through the mediation of brain-mechanisms. And throughout these selected excerpts, which, it must be remembered, were written more than 20 years ago, and in the ingenious "brain-models" which he describes, he reveals a remarkable anticipation of the later contributions made by cybernetics and information theory. The "standpoint of the electronic engineer" is equally prominent in his only book (on *The Nature of Explanation*) and in the last of his papers, the two published posthumously on the "Theory of the Human Operator in Control Systems".

The collection ends with a section headed "Philosophy", consisting of a dozen short papers dealing with the purely mechanistic approach. Of these perhaps the most illuminating is his reply to the criticisms urged by W. H. Barnes in reviewing his book in this journal ("Is the Mind a Calculating Machine?" *Nature*, 153, 603; 1944). Here he reverts once again to the subject of his youthful essay, and explains that his intention was "to pursue the physiological and mechanistic approach" as the most fruitful and profitable line available at the moment, and to "convey its relevance to the body–mind problem, to the explanation of thought and behaviour, and to the immortality of the soul". This fascinating set of papers, thirty-five in all, reveals the many-sided interests of Craik himself and the brilliant promise of his early work—a promise which unfortunately was never to be fulfilled.

CYRIL BURT

Dictionary of Nuclear Physics and Nuclear Chemistry

German – English/American; English/American – German. Second revised and enlarged edition. Edited by H. Rau. Pp. 351. (London: Sir Isaac Pitman and Sons, Ltd., 1964.) 55*s*.

THIS dictionary, though considerably enlarged from its first edition (*Dictionary of Nuclear Physics*, published

by Brandstetter, 1957), still gives the impression of a miscellaneous collection of words and phrases *aus der Praxis für die Praxis* (to quote the German preface; no corresponding phrase appears in the English preface). The terms in each half number about eight thousand, according to the preface, occupying some 130 fairly small pages. In addition to a reasonable selection of terms to be expected from the title, many expressions are included which have no direct relevance to nuclear science. For example, on page 335, *thread microscope, threaded sleeve, three-finger rule, throw-over switch, thymene* appear. On the same page is the extraordinary entry *time for scattering of an electron by distant encounters with ions*. Surely these entries, evidently *aus der Praxis*, are of little use *für die Praxis*. Again, '*Modell* (1 : 1)*/mock-up*' is all too obviously a reversal of the entry under *mock-up*, and indeed this seems to have been the method by which the two parts of the dictionary have been built up, every entry having its counterpart in the opposite direction.

Many terms are annotated or explained, mainly in German, in the same way in both parts. Genders are given. Obsolete or uncommon terms abound: *celtium, Chariot project* (but *Plowshare* is not given), *Contracid* (but not *Zircaloy*), *cooky* (but not *cobalt bomb*), *cubo-cubocube* (but not *power function*); *cathode ray tube* is rendered as 'Kathodenstrahlröhre' but not as the equally common 'Braunsche Röhre'. There are several misprints and one apparent misapprehension, *dyadic product* being rendered as 'dyadisches Erzeugnis'.

One good feature is the list of some fifteen hundred annotated symbols and abbreviations, including many acrostics and chemical formulae, though again one wonders at the inclusion of 'ACS' (American Chemical Society) and of 'ACTION' (American Council to Improve Our Neighborhoods), the latter with its postal address. The book ends with three pages of conversion factors.

J. B. SYKES

Agricultural Insects of Ghana

Compiled by John Forsyth. Pp. 163. (Accra: Ghana University Press; London: Oxford University Press, 1966.) 35*s*. net.

THIS is not a book for those desiring a narrative account of the insect pests of crops in Ghana, since the information is entirely in the form of lists of names, but, apart from its local use, it will be of great value to those dealing with the distribution of plant pests and their natural enemies in Africa or the pest fauna of particular crops, since it provides a compilation of authentic records of the kind that these require. It is much to be hoped that Mr. Forsyth's example will be followed in other countries.

The work is divided into five main parts, dealing with field crops and plants, stored products, parasites of plant-feeding insects, predators of plant-feeding insects, and insects associated with or attacked by fungi. Each part consists of two complementary lists, so that, for example, in the first and main part there is a list of the various plants showing the insects that attack them, and then a list of the insects arranged in their orders and families, showing the plants attacked by them, the plant part concerned and some details of local distribution. The lists are based on records dating back to 1909, and there is a useful bibliography of sources containing references to the appropriate abstracts in the *Review of Applied Entomology*, where further details can be found.

A good deal of care has been taken to see that the scientific names used are those accepted by modern systematists, and there are commendably few misprints, but a few minor inaccuracies have inevitably crept in, notably in the part on stored products. This part, however, contains something that the others do not, namely, an indication of which pests are the commonest.

R. F. AVERY

MEETINGS

CONDENSATION NUCLEI

SINCE the discovery of condensation nuclei by Coulier (1875) and by Aitken (1881) they have been of great interest to physicists and meteorologists. In recent years, with increasing awareness of atmospheric pollution, both chemical and radioactive, atmospheric chemists and health physicists have been drawn into the field and the resulting interdisciplinary exchange has proved to be very fruitful. This was exemplified at the International Conference on Condensation Nuclei held during May 9–13 at Albany, N.Y., and State College, Pa., which was the sixth of a series started by the late Prof. L. W. Pollak in 1955 at the Dublin Institute for Advanced Studies. More than eighty scientists from twelve countries attended and fifty papers were presented. Abstracts were available before the meeting and, with the exception of the invited review paper, presentations were limited to ten minutes to enable authors to stress the main points of their papers and an hour and a half was allowed for discussion of each group of five or six papers. This arrangement proved very successful and throughout the conference discussion was lively and sustained.

At its Albany session the conference had the honour of being addressed by the Governor of the State of New York, Mr. Nelson D. Rockefeller, who gave an impressive account of the measures being taken in the State to determine the causes and counteract the effects of environmental pollution.

In a review of recent work on small ions and Aitken nuclei (particles smaller than 0·4μ diameter), W. J. Megaw (Harwell) quarrelled with the view that such particles are of little importance in the atmosphere because they contribute little to the mass of atmospheric aerosol and therefore cannot act as centres of condensation at atmospheric super-saturations. The small ions were responsible for the important electrical properties and the Aitken nuclei, because of their size, tended to remain airborne for long periods. It had been shown that most of the natural radioactive decay products were carried on the Aitken nuclei and there was some evidence that they could act as carriers of radioactive effluent. Megaw described recent British and French work on small ions and concluded that, even after 50 years, little was known of the nature and constitution of the so-called "cluster ions". He stressed that care was needed in the use of radioactive tracers of high specific activity in aerosol work because of the production of additional particles by radiolytic reaction with impurities in the air.

In a preliminary report, H. Weickmann (Boulder) suggested that measurements of the concentration of Aitken nuclei in the neighbourhood of clouds could contribute to a better understanding of convective circulation in and around cloud fields, and P. Squires (Boulder) gave measurements of the concentration of both Aitken and cloud nuclei in the neighbourhood of cities. These showed that human activity results in a noticeable production of cloud nuclei as well as of Aitken nuclei. He concluded, however, that the total production of cloud nuclei by this means is small compared with the natural production by continental surfaces. J. Podzimek (Prague) discussed the relative importance of diffusiophoresis and thermophoresis, Stefan flow and Brownian motion on the binding of condensation and ice nuclei on the surface of cloud elements; he held that for slightly supersaturated air, the effect of the first three of these processes was negligible. G. Schumann (Heidelberg) derived expressions for the attachment of radioactive atoms to particles taking account of charge and size distribution of the particles and confirmed them by experiments on the atmospheric aerosol.

J. P. Lodge (Boulder) gave a valuable account of techniques for the identification of individual sub-micron particles. Chemical methods exist only for chloride and sulphate particles, but he has found that a number of species, including sulphuric acid in various stages of neutralization by gaseous ammonia and phosphate, can be identified by their characteristic appearance in the electron microscope.

V. J. Schaefer (State University of New York) described the detection of surface active molecules on airborne particles by the use of indicator oils. Pollen grains, ocean spray nuclei and many particles in industrial smog had been found to exhibit surface active properties by this technique.

Papers on electrical properties of particles were given by J. Bricard (Paris), G. Madelaine (C.E.A. Fontenay aux Roses) and by R. Siksna (Uppsala). Bricard had found that only 4 per cent of the radioactive small ions from the decay of radon and thoron have the expected mobility of 2·15 $cm^2V^{-1}sec^{-1}$; the remainder have a mobility spectrum with peaks at 0·51 and 0·81 $cm^2V^{-1}sec^{-1}$. He attributed this to the rapid formation of cluster ions, but in the discussion it was suggested that cluster ions as normally understood could scarcely have so different a mobility and that the effect was more probably due to the formation of Aitken nuclei by radiolytic reactions.

In papers on the development and use of instruments, T. A. Rich (G. E. Coy, Schenectady) described an interesting combination of diffusion and electrical techniques to investigate the size of aerosols and R. E. Davis (U.K.A.E.A., Winfrith) the use of the Nolan Pollak counter in the testing of high efficiency filter systems. G. F. Skala (G. E. Coy, Schenectady) advocated the use of ion chambers to investigate the production of particles from heated substances in conditions of temperature and pressure which would preclude condensation methods. H. Israel and N. Nix (Aachen) re-opened the question of the role of Aitken nuclei in atmospheric condensation by quoting measurements of the temperature drop recorded on expansion in the Nolan–Pollak counter. While their results are in conflict with other measurements, they suggest that the counter detects nuclei activated at a supersaturation of 2 per cent instead of the 280 per cent calculated if an adiabatic expansion is assumed.

It is hoped that the next conference of the series will be held in Prague and Vienna in 1969. W. J. MEGAW

OBITUARIES

George de Hevesy

PROF. DE HEVESY, Hungarian born, who lived latterly in Copenhagen and Stockholm, died on July 5. He was the pioneer in the use of isotopes as revealers of the paths taken by elements in chemical and biological processes—discoveries which have been of immense consequence. Born in Budapest in 1885, he took his doctorate in Freiburg before coming to England in 1911. Later he worked in Vienna before gaining a chair at Freiburg in 1926. Some years later he moved to a professorship in Copenhagen and finally settled before retirement in a research institute at Stockholm. He was the holder of many awards and honorary degrees. These included the Nobel Prize for chemistry in 1944 and the Copley Medal and foreign membership of the Royal Society. He found time to write notable books on his main subject as well as to publish a large number of papers. With Coster he discovered hafnium.

Von Hevesy, as he then was, found himself, a chemist, among the physicists who clustered around Rutherford in Manchester a few years before the Great War. His first success there was his showing that the whole of a minute amount of a radio-element deposited itself from a solution on nickel, immersed in it, even when the radio-element was actually chemically more reactive than nickel. His first failure—not at all his fault—was his complete inability to separate radium-*D* from its isotope lead. But with Von Hevesy, this failure led to success, for it showed him that minute concentrations of radio-elements must be successful tracers of their common isotopic elements in chemical and biological processes. Later he found that the tracer-isotope need not be radioactive; so long as its oddness could be characterized, an inactive isotope might do—for example, deuterium. Later still he extended possibilities by making a suitable inactive isotope reveal itself in a mixture by its being made artificially radioactive by bombardment by neutrons; the measurement of its characteristic radiation determined the amount of the element in the mixture quantitatively. His discoveries in all these fields have since had a magnificently fruitful following.

Hevesy was a European of the best sort, genial, kind-hearted, a good friend. He did not look strong, but he was a mighty worker dedicated to research. He died in Freiburg. A. S. RUSSELL

Hans Pettersson

PROF. HANS PETTERSSON, who died in Goteborg on January 25 at the age of 77, was particularly noted for his leadership of the Swedish Deep Sea Expedition in the *Albatross*, and for his many contributions to the study of the deep sea floor and its sediments. His father, Otto Pettersson, with other Scandinavian scientists, particularly Nansen, Ekman and Helland-Hansen, did much to establish the serious study of physical oceanography at the turn of the century. Hans studied physics in Uppsala under Knut Angstrom and in London under Sir William Ramsay. At first he joined his father in the study of currents and internal waves in Swedish coastal waters, but he soon developed his interest in optical and radiochemical studies. Between 1922 and 1936 he worked frequently at the Institut für Radiumforschung in Vienna, where he interested a number of specialists in marine problems. He found that although radium is concentrated in deep sea sediments, its concentration in sea water is much less than would be expected from the much greater concentration of uranium. He believed the deficit to be due to co-precipitation of thorium and ionium with the hydrated oxides of iron and manganese. He used the variation of radium content with depth in the sediments as a basis for geochronological estimates. He did much to further the development of deep sea coring devices.

His tremendous enthusiasm for the subject and the success of his work and that of his colleagues persuaded some of his successful compatriots to provide funds necessary for the founding of the Oceanografiska Institutet in 1939 and, in 1947–48, for the round-the-world expedition in the *Albatross*. The expedition was very successful, and its observations and sampling did much to stimulate the growth of interest in marine geochemistry there has been in the past 20 years. Although mainly concerned with the sea floor, studies of the transparency of the water and scattering of light at different depths were also important features of the work.

Pettersson was interested in the contribution of cosmic dust to the ocean sediments, and his latest communication to *Nature* dealt with this subject. He was elected a Foreign Member of the Royal Society in 1956, and retired in the same year from the post as director of the Oceanografiska Institutet. G. E. R. DEACON

Eva G. R. Taylor

PROF. EVA GERMAINE RIMINGTON TAYLOR, who died on July 5, 1966, at the age of 87, was bedridden for the later years of her life and almost totally blind for the last year, but she nevertheless retained her acute critical faculties to the last, and only a few weeks before her

death had dictated her doubts on the authenticity of the Vinland map.

She was educated at the North London Collegiate School for Girls and, after taking a degree in chemistry in the University of London, spent several years as a science mistress at Burton-on-Trent. Seeking to improve her teaching qualifications, she went up to Oxford to take the Diploma in Education. There she came under the influence of A. J. Herbertson and was swept into his activities in developing the 'new geography', both in the Oxford department and through his text-books in the schools. She stayed on as his assistant, working on the preparation of the famous Oxford wall maps and, on a vacation course, met J. F. Unstead. The series of text-books she produced with him had a great influence in the schools.

It was, however, her appointment as lecturer at Birkbeck College under Unstead in 1921 which marked the turning-point in her career. She turned her attention to historical geography and published *Tudor Geography* and *Late Tudor and Early Stuart Geography*. They established firmly her academic standing so that, when Unstead retired in 1930, she succeeded him as professor of geography and so remained until she retired in 1944. In those years she became not only the acknowledged expert in the maps and literature of the Tudor and Stuart periods, but also in the instruments of navigation and the work of contemporary explorers. A series of papers in the *Mariner's Mirror* and the *Journal* of the Institute of Navigation culminated in her *The Haven-finding Art*.

But Prof. Taylor was far from being immersed in the past. She threw herself with enthusiasm into physical planning and became a member of Lord Reith's Consultative Panel in 1941, with the inauguration of the Ministry of Town and Country Planning. She is still remembered by planners as the originator of the 'sieve method'—by eliminating or sieving out areas unsuitable for development for one reason or another there remains a positive field within which to work.

A woman of strong personality and trenchant language verging on abuse, there were occasions when it was easier to be on the other side, for she never minded opponents who hit back. But her positive opinions were based on wide knowledge, and the bubble reputations she delighted to prick usually deserved this treatment. She retained her maiden name throughout her life and, though proud of her two sons, she kept her domestic life entirely separate from her academic. Shortly after her retirement her work was recognized by the award of the Victoria Medal of the Royal Geographical Society, and her students, subscribing in large numbers, endowed a named lecture at the Society in her honour. L. DUDLEY STAMP

Fritz Zernike

PROF. FRITZ ZERNIKE, who died on March 10 in Groningen, Holland, was born in Amsterdam on July 16, 1888. His father was headmaster of an elementary school and his mother had been a schoolteacher. Their six children formed a lively and intellectually stimulating family. At nineteen, as a student of chemistry at Amsterdam, Zernike was awarded a gold medal by the University of Groningen for an essay on a probabilistic treatment of a certain parlour game. In 1912 he received another prize for work on critical opalescence, and in 1914 his collaboration with L. S. Ornstein resulted in the Ornstein–Zernike formula, which plays a central part in the theoretical and experimental investigation of the critical point. In 1915 he obtained his doctor's degree with a thesis, *L'opalescence critique, théorie et expériments*, in which the formula for extinction by scattering near the critical point was derived by means of the grand canonical ensemble. The experiments he reported agreed with the theoretical result and made possible a determination of Avogadro's constant to within a few per cent.

In the meantime, Zernike had become an assistant to J. C. Kapteyn, the astronomer at Groningen, but soon afterwards he was appointed a reader in theoretical physics at the same university, and then, in 1920, a full professor. He continued the investigation of the pair correlation function $g(r)$ occurring in the Ornstein–Zernike formula, and in collaboration with J. A. Prins applied it to X-ray diffraction in liquids. His interest in statistical physics also led to a study of the influence of Brownian motion on the measurement of small currents and, characteristically, he put his theoretical understanding to practical use by constructing an improved galvanometer.

Zernike's unique combination of mathematical insight and technical ability proved very fruitful when he directed his attention to optics. Rather than obscuring a problem by laborious calculations, he would reduce it to its simplest mathematical elements which would then serve as stepping-stones for his physical intuition and inventiveness. For example, he showed that the difference between the rival theories of Abbé and Rayleigh concerning the microscopic image formation is nothing but a difference in order of integration. The discovery of phase contrast microscopy in 1932 was virtually a natural consequence of this method; in fact, when Zernike explained the principle it was hard to understand why it had not been discovered earlier. Perhaps that makes understandable why, when he offered his invention to Zeiss, the leading optical industry in those days, the haughty reply was: "Wenn es interessant wäre, so hätten wir es schon längst selbst erfunden". Yet some development work was carried out at Zeiss, and the first motion picture of cell meiosis was made. Phase microscopy did not become widely known, however, until Arthur T. Bryce, of the U.S. Army, arrived in Jena in 1945 and immediately realized its importance.

Meanwhile, Zernike turned his attention to another problem in microscopy—What is the influence of small aberrations on the diffraction pattern in the image plane? As an appropriate mathematical tool he introduced "circle polynomials" and, in collaboration with B. R. A. Nijboer, the work was successfully completed in 1942. In the same years Zernike developed the concept of "degree of coherence", constructed a useful poor man's ultracentrifuge using the motor of a vacuum cleaner, published a quantitative treatment of the Senftleben effect with C. van Lier, gave an approximate treatment of the phase transition in binary alloys, and worked on the technical problem of how to manufacture the phase rings needed for his microscope.

Relativity theory and quantum mechanics were of less interest to Zernike, presumably because they lacked the intimate connexion with technical applications which made classical physics so fascinating to him. He was not easily persuaded to publish his results and ideas, but when he wrote an article it was carefully planned and lucidly written. His public addresses were full of brilliant ideas and he had a masterful way of utilizing a simple analogy to throw new light on an old problem. His contacts with other scientists were rather limited, partly because he was so much absorbed in his own research, and partly because he felt ill at ease with people who could not appreciate that the short, often witty, and sometimes caustic way in which he expressed his opinion was just another aspect of his search for unadulterated truth. Unfortunately, this gentleness made him rather defenceless in the turmoil of university politics. His friends, however, will not forget how his great knowledge, widespread interest, and penetrating and refreshingly unprejudiced views made his conversation an intellectual enjoyment.

Official recognition came late, first in the form of the Rumford Medal in 1952, and in the next year the Nobel Prize for his invention of the phase contrast microscope. Zernike was a Foreign Member of the Royal Society of London. N. G. VAN KAMPEN

IS GRAVITATIONAL COLLAPSE REALLY IRREVERSIBLE?

By DR. WERNER ISRAEL
Department of Mathematics, University of Alberta, Edmonton, Canada

Quasi-stellar Sources

IF the cosmological interpretation of their large red-shifts is accepted, the quasi-stellar sources lie near the outskirts of the visible universe and close to its origin in time—"sparks of the primeval fireball". A lower limit to the masses which must be involved (10^8 solar masses) can be obtained from the enormous energies stored in the relativistic electrons which gyrate in their magnetic fields[1], whereas the observed optical and radio variability[2,3] places an upper limit of about a light-week (10^{16} cm) on the size of the central emitting nucleus. A non-rotating ball of 10^8 solar masses becomes gravitationally unstable if its radius becomes smaller than $4{\cdot}7 \times 10^{17}$ cm[4]. It seems difficult to escape the conclusion that the typical quasi-stellar source is in a state of gravitational collapse approaching free fall.

The predicament to which this leads is well known. According to the picture of gravitational collapse which has become traditional[5], the collapse proceeds irreversibly to zero volume. An external observer sees the body asymptotically shrinking to its Schwarzschild radius. The observed time of collapse is thus infinite; but progressive dimming due to the Doppler and gravitational red-shifts, and to the falling back of light rays sent out obliquely from the surface, will render the object invisible to the external observer in a time comparable with the Newtonian free-fall time of 25 years[6]. This picture is obviously incompatible with the life-times of 10^6 years inferred from the linear dimensions of the sources ($\sim 10^6$ light-years), and the clear evidence (from the extended life-times and the variability) of repeated injections of relativistic particles.

It has been known for some years that the continued activity in the supernova remnant of 1054, the Crab nebula, confronts us with a similar difficulty[7].

In the face of this apparent impasse, it is very curious and perhaps suggestive that a naive application of Newton's theory will account in a perfectly natural way for all the major observed features of quasi-stellar sources. Imagine the Newtonian collapse of a ball of 10^8 solar masses. If support from gas and radiation pressure fails, the collapse continues until, at zero radius, there is a violent "self-collision" and rebound, with the ejection of high-speed streams of ionized gas and particles. For a radius at maximum of 10^{17} cm, the resulting pulsations have a period of about 20 years. (Observations of the quasi-stellar source *3C* 273 over the past 70 years suggest cycles of about 10 years for major fluctuations[2].) We can elaborate this model a little by imagining the ball deformed into an irregular lumpy mass. Each lump, while sharing in the oscillation of the mass as a whole, executes its own quicker pulsation. This reproduces the "light flashes" and irregular variations observed in many quasi-stellar sources.

At this point I should make it clear that I am not arguing for the reinstatement of Newton's theory. However, this model, which is based essentially on the reversibility of gravitational collapse, fits the observed facts so naturally that one cannot help asking whether, on this issue, Einstein's theory is—not wrong—but misinterpreted. Is it really true that general relativity predicts the irreversibility of gravitational collapse? The remainder of this article is devoted to a critical examination of this question.

Radial Motion in the Schwarzschild Field

The history of a particle on the outer boundary of a collapsing ball is a radial time-like curve of the exterior Schwarzschild field. Thus, many of the essential features of gravitational collapse are brought into focus by studying the radial motion of particles in the Schwarzschild vacuum manifold.

In terms of Schwarzschild's familiar r,t co-ordinates, the paths of incoming and outgoing radial light-pulses have the equations u = a constant and v = a constant respectively, where:

$$4m u^{-1}\,du = (1-2m/r)^{-1}\,dr + dt$$
$$4m v^{-1}\,dv = (1-2m/r)^{-1}\,dr - dt$$

These null curves are shown in Fig. 1, together with the future light cones which they define.

The time-like path ABC of a radially moving test particle can now be traced out qualitatively if we remember that it must always be directed into the future light-cones. The particle reaches $r=2m$ at a perfectly definite event C, attained in a finite proper time. But, because of failure of Schwarzschild's t co-ordinate at $r=2m$, the event C cannot be mapped on to the finite part of the r,t plane. We can remedy this deficiency by straightening the null lines, that is, adopting u, v as new co-ordinates. The new form of Schwarzschild's line-element is[8]:

$$ds^2 = \frac{32m^3\,du\,dv}{re^{r/2m}} + r^2\,d\Omega^2$$

with $r(uv)$ defined by (1)

$$\left(\frac{r}{2m}-1\right)e^{r/2m} = uv$$

and this is regular down to $r=0$.

Possible Interpretations of the Extended Manifold

In the new map (Fig. 2), we can follow the career ($ABCD$) of the falling particle down to $r=0$.

To proceed further, we have first to decide how to interpret the peculiar duplication which occurs in the uv

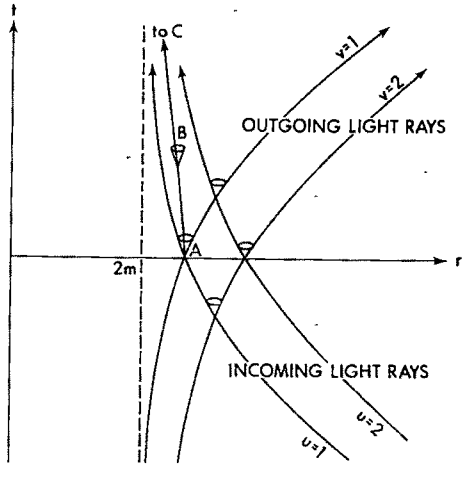

Fig. 1

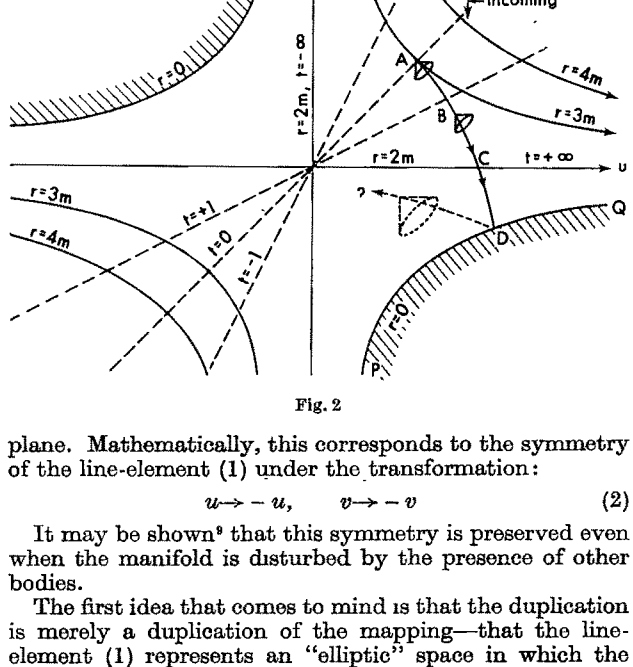

Fig. 2

plane. Mathematically, this corresponds to the symmetry of the line-element (1) under the transformation:

$$u \to -u, \qquad v \to -v \tag{2}$$

It may be shown[9] that this symmetry is preserved even when the manifold is disturbed by the presence of other bodies.

The first idea that comes to mind is that the duplication is merely a duplication of the mapping—that the line-element (1) represents an "elliptic" space in which the events (u, v) and $(-u, -v)$ are physically identical.

Actually, until very recently[10,11] this idea was not followed up. The major discouraging factor seems to have been this: Let us assume that future light cones in quadrant I of the uv plane have a south-easterly direction, as indicated in Fig. 2. If we accept the identification just proposed, then the future light cones assigned to quadrant III must point north-west. Because this assignment cannot be extended continuously into II and IV, we would be forced to admit a breakdown of the global distinction between past and future in the domain with $r < 2m$. This raises the spectre of possible causal violations.

Consequently, it has been traditional to escape these worries by the (implicit) introduction of Postulate X: Past and future can be globally distinguished throughout the extended Schwarzschild manifold.

Postulate X and Irreversibility

Postulate X permits us to mark future light cones into the four quadrants of the uv plane, all pointing (say) south-east.

On this basis, let us return to consider the fate of the particle which has reached $r = 0$ at event D. Can it rebound from the centre or pass through the centre into the radially opposite space ? Fig. 2 shows that every time-like path which emerges from the branch PDQ of $r = 0$ is directed into the past defined globally in quadrant IV, and this is forbidden. We have no alternative to the conclusion that a particle which has fallen to $r = 0$ is irreversibly swallowed up by the singularity. Correspondingly, a spherical body (boundary $ABCD$) which has collapsed under its own weight to zero radius can never re-expand: its subsequent history is the space-like singular curve DQ.

It is clear from this argument that the irreversibility of gravitational collapse is a consequence not of general relativity but of the *ad hoc* Postulate X.

Irreversibility is not required by the elliptic interpretation. As future and past are not globally distinguished in quadrant IV, it is possible—and, indeed, most natural—to assume a "bounce" at $r = 0$. (For an account of how this gives rise to an externally observed pulsation with period in agreement with Newtonian predictions, see refs. 11 and 12.)

Difficulties with Postulate X

Because the traditional picture of gravitational collapse hinges critically on the validity of Postulate X, it is important to test the soundness of this postulate. Examination reveals a number of disturbing features. I list a few of them.

(i) The imposition of a global past-future arrow on to the uv plane breaks the symmetry, since the arrow is not invariant under (2). To this extent, Postulate X is alien to the geometry and runs counter to the clear indications of general relativity.

(ii) It is unprecedented and very strange that a postulate based on the essentially statistical coarse-grained concept of a past-future distinction should need to be inserted into the foundations of the more primitive subject of dynamics.

(iii) Every slice t = constant divides the extended manifold into two sheets with $r > 2m$, joined by an Einstein–Rosen bridge. These sheets are in all respects geometrically identical, even in the presence of external disturbances. But—if Postulate X is accepted—only one is the ordinary space of our experience; the other is a physically distinct space in which each of us has an identical twin. This seems uncanny. Even more uncanny is the fact that, while no signal can pass between us, my twin appears to be in some kind of instant telepathic contact with me: when I crook my little finger he simultaneously (at the same "time" t) crooks his.

(iv) The global past-future arrow defined by Postulate X cannot agree with the direction of increasing $t = 2m \ln(u/v)$ in both quadrants I and III. This has the following curious consequence. Suppose that a sequence of slices $t = 1, 2, 3, \ldots$ shows me ageing. My twin, identical with me on each slice, will go through the same sequence of physical transformations. But, according to Postulate X, he would have to describe himself as getting younger! This drains most of the meaning from the words "past" and "future" as used in Postulate X.

(v) According to the traditional picture based on Postulate X, the final history of a collapsed star is a (singular) space-like curve. Relativistic principles would lead us to expect the history of any material body to be time-like.

Individually, the foregoing objections are perhaps not fatal, but together they add up to a formidable indictment.

The elliptic interpretation is free of these objections. Moreover, detailed investigation[11] shows that the causality bogey does not materialize under actual physical conditions. There is thus good reason to expect that the most natural interpretation of the Schwarzschild manifold is, in addition, self-consistent and concordant with the astronomical evidence.

APPEARANCE OF RELATIVISTICALLY EXPANDING RADIO SOURCES

By M. J. REES
Department of Applied Mathematics and Theoretical Physics, University of Cambridge

IN this article it is suggested that the central parts of some radio sources may expand with relativistic velocities. Relativistic effects could then have a decisive influence on the observable properties of these sources. In particular, the flux from a radio source expanding with relativistic velocity can change sufficiently rapidly to account for the variations observed in some sources, even if they are at cosmological distances. A related relativistic effect would imply that the ages of some types of radio sources may be significantly less than the usual estimates.

Variable Radio Sources

Intensity variations[1-3] have been observed in several radio sources associated with quasi-stellar objects, the red-shifts of which indicate that they are probably at cosmological distances. Well-known arguments concerning self-absorption[4,5] enable us to place a lower limit on the dimensions of a source which is at a known distance (if the radio flux is synchrotron radiation), and it has proved difficult to understand how a source at a cosmological distance can vary with the observed rapidity unless its size is less than this limit. This problem arises if the assumption is made that the 'time-scale' of the variations cannot be much less than the time light would take to cross the emitting region. If[6,7] (*a*) the variations are periodic, or (*b*) they result from changes in the brightness of a region of fixed size, this assumption is certainly necessary, but I shall describe a type of model where special relativistic effects arise which permit it to be relaxed.

In the model proposed, the source is assumed to be spherical and the radio variations are principally due to changes in its apparent diameter rather than in its surface brightness (in contrast to (*b*)). We shall show that, if the boundary of the source expands with velocity $\sim c$, the apparent rate of increase in its angular size and luminosity can be extremely high. Before discussing the physics of the model, and arguing the reasonableness of relativistic velocities, we shall illustrate its essential geometrical properties.

Consider a sphere, centre S, the surface of which expands with radial velocity v from zero initial radius. An observer O at a large distance R from S (and at rest relative to S) will observe an increase in the apparent size of the sphere.

If $v \ll c$ the observed angular diameter will be $2\frac{v}{R}t$, where t is the time measured from the moment when the expansion is seen to begin. However if $v \sim c$ this result needs modification. The locus of points from which radiation reaches the observer at time t is not a sphere, but a spheroid with S as focus, axis along SO, eccentricity v/c and semi-latus rectum vt, as shown in Fig. 1. Owing to aberration, the parts with velocity perpendicular to the observer are invisible if the sphere is opaque, and the apparent limb, in fact, has a velocity making an angle $\cos^{-1} v/c$ ($\sin^{-1} = 1/\gamma$, where $\gamma = (1-v^2/c^2)^{-\frac{1}{2}}$) with SO. Furthermore the apparent component of velocity of the limb at right angles to the line of sight is γv (which can be $\gg c$ if γ is large) and the observed angular diameter of the sphere at time t is $2\gamma vt/R$. If, for example, $\gamma = 5$, the apparent diameter of the source will increase by almost 10 light years each year. Because the observed intensity of a source, for a given surface brightness, is proportional to the apparent size, it is already clear that an expanding source could exhibit a rate of increase of flux density high enough to explain the observations.

This geometrical fact is obviously relevant to a variety of physical models, of which only one will be described here. Suppose that the source consists of a massive object (probably identifiable with a quasi-stellar object) which accelerates particles to relativistic energies. Suppose also that the surrounding magnetic field is weak, in the sense that $H^2/8\pi$ is small compared with the kinetic energy density of the particles. A burst of relativistic particles ejected from the massive object will not be confined by the field, but will expand outwards, 'dragging' the field with it (that is, there will not be an electric field in a reference frame sharing the mean outward motion of the particles, though there will generally be in other frames). This explosion will have a relativistic velocity provided that the thermal gas density is small. If we assume for simplicity that the outward radial velocity is constant, we have an expanding shell resembling the sphere already described.

The electron density and the field strength will decrease as the shell expands, and the spectrum of the synchrotron radiation will alter. The total observed flux at time t is obtained by integrating the contributions from all parts of the shell, but this calculation is complicated by the fact that the emission from different parts was emitted at different stages in the expansion. Also the Doppler blue-shift varies from γ on the limb to $\gamma(1+v/c)$ at the

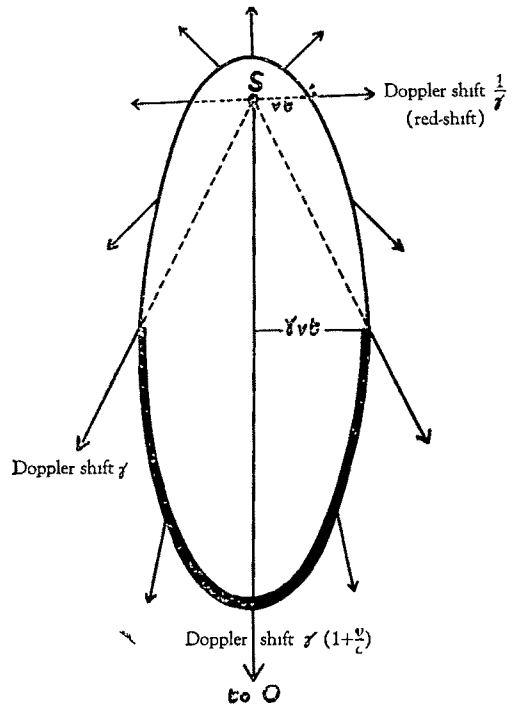

Fig. 1. If a distant observer O sees a spherical shell start to expand from S with velocity v, the locus of the points from which radiation reaches him at time t later is a spheroid. If the shell is opaque, the only visible parts are those the velocity of which makes an angle $< \cos^{-1} v/c$ with SO. These parts all have a Doppler blue-shift $> \gamma$, and the limb has an apparent transverse velocity γv

centre. The total flux from the shell obviously cannot be determined exactly without specifying the detailed behaviour of the model during the expansion. However, the problem is simpler if we restrict attention to low frequencies, for the following reason. The spectral index of the radiation from each part of the source will be 2·5 at frequencies at which synchrotron self-absorption occurs ($< \nu_c$, say). The shape of the spectrum at higher frequencies depends on the energy spectrum of the electrons. ν_c will decrease as the expansion proceeds, but at sufficiently low frequencies of observation (or for small t) all the contributions to the flux will have a spectrum of slope 2·5, and the spectrum of the whole shell will have this slope. The observed flux density will then exceed that from a static source with the same apparent size and magnetic field $\bar{H}$ (where $\bar{H}$ is a mean value of the field strength in the shell when the radiation is emitted) by a factor $\sim\gamma^{\frac{1}{2}}$.

Such a model might apply to 3*C* 273, the variability of which is well established at several frequencies. The hardest observations to explain[2] (which consequently constitute the most crucial test of any model) are the increase of ~ 6 flux units (F.U.) over a 3-year period, in the flux density at 1,400 Mc/s (the lowest frequency at which variations have been detected). Maltby and Moffet[2] have shown that this can be understood on the basis of a non-exploding model only if H has the improbably small value of $< 10^{-4}$ gauss. If, however, a source at the distance of 3*C* 273 were to start to explode with a velocity corresponding to $\gamma = 5$, and if H (measured in a frame sharing the mean particle motion) $\sim 10^{-2}$ gauss, the flux density would have risen to ~ 15 F.U. in 3 years, which is greater than is required to explain the data. The parts of the shell which would contribute most of this flux have a Doppler blue-shift > 5, and therefore the radiation received at 1,400 Mc/s would all have been emitted at frequencies below 300 Mc/s. Furthermore, after 3 years, these parts would be ~ 100 light years from S, so we would require ν_c (a decreasing function of distance from S) to be $\gtrsim 300$ Mc/s out to this distance, which is not an unreasonable requirement. The non-variable flux from 3*C* 273 at frequencies below 1,000 Mc/s must originate in a larger region surrounding the variable component, and its spectrum would mask the steep slope of the low-frequency spectrum of the exploding source. The spectrum of the shell at higher frequencies (or at later stages in its expansion when ν_c has decreased) is more difficult to calculate, because some of the radiation would come from transparent regions. We would expect the highly blue-shifted part of the source with velocity almost towards the observer to be the first to become transparent at a given frequency (though this cannot be definitely stated without detailed calculation of a precise model). It is this part which contributes most of the flux in the early stages of the expansion, so we might expect to observe a decrease in the flux density when it becomes transparent. This decrease could be almost as rapid as the original increase.

It should be emphasized that no attempt has been made to incorporate the optical frequency radiation in the foregoing model for a quasi-stellar radio source. The thermal gas which radiates the lines in the visible spectrum from which the Hubble red-shift is determined presumably has a velocity $\ll c$ relative to the massive object, in contrast to the fast-moving clouds of relativistic electrons in the model. We have, incidentally, neglected a correction factor involving the cosmological red-shift in this model.

The foregoing has demonstrated that the radio variations of quasi-stellar sources do not provide strong evidence for the so-called 'local' theory[6,8] (according to which quasi-stellar radio sources are debris from an explosion in our own or a nearby galaxy, and their red-shifts are a Doppler effect due to high peculiar velocities), since we can account for the available observations on the assumption that the sources are at cosmological distances. Nor is it necessary to invoke 'coherent' radiation mechanisms, which might permit a higher surface brightness temperature to be reached before the onset of self-absorption. If future observations should prove to be inconsistent with this model, a wider range of behaviour could be accommodated by abandoning our assumption of spherical symmetry (for which there is no physical reason, and which was adopted here merely for simplicity), and considering asymmetrical exploding sources with particular orientations.

Other Implications of Relativistic Bulk Motions

The most important feature of the model described in the previous section has been the simple fact that an object moving relativistically in suitable directions may appear to a distant observer to have a transverse velocity much greater than c. The remainder of this article is concerned with other possible implications of this fact for theories of radio sources.

Most strong extragalactic radio sources consist of two or more components separated by distances of up to 10^6 light years[9]. We may assume that their existence is due to some disturbance (of unknown nature) in the associated visible object. If the radiating regions had themselves moved bodily to their observed positions from the parent galaxy, their speed must be relativistic unless their age is $\gg 10^6$ years. Alternative theories[10,11] postulate shock waves or streams of relativistic particles ejected from the galaxy, radio sources being formed as a result of their interaction with intergalactic material or an intergalactic magnetic field. Present observations cannot prove or refute any of these hypotheses, but if more sensitive future observations fail to confirm the presence of a significant amount of intergalactic material (the existence of which is still an open question), theories of the latter type will become less plausible than those according to which both particles and magnetic fields are ejected from galaxies. These 'plasmoids' may well have velocities $\sim c$. No process capable of accelerating them is yet known, but clouds of relativistic particles could certainly be accelerated to relativistic velocities more easily than super-massive stars, as is postulated in the 'local' theory of quasi-stellar radio sources.

If these relativistic velocities exist, the possibility of apparent transverse velocities $\gg c$ implies that the minimum observed lifetime of a source can be less than its observed distance from the associated visible object divided by c. (This conclusion also holds if the radio source does not itself move, but is 'triggered' by some influence which propagates out from the visible object with relativistic velocity.) The total energy contained in radio galaxies is, however, generally sufficient to maintain their observed rate of energy output for a time $\gg 10^6$ years, so that there is no reason to suspect that their lifetimes are in fact much shorter. Quasi-stellar sources, on the other hand, radiate enormous energy at optical and infra-red as well as radio frequencies, and the problem of understanding this great power output from a small region is aggravated if their lifetime is long. Furthermore, they are more likely than other astronomical objects to be the sites of explosions violent enough to accelerate clouds of relativistic particles to high velocities. The conjectures which we shall put forward will therefore be particularly relevant to 'double' quasi-stellar radio sources such as 3*C* 273 and 3*C* 47 (refs. 12 and 13).

If a 'plasmoid' consisting of relativistic electrons and magnetic fields is ejected with a velocity $v(\sim c)$ its apparent transverse velocity relative to the quasi-stellar radio source can be as great as $\sim\gamma v$ (that is, $\gg c$) if its velocity makes an angle $\sim\cos^{-1} v/c$ with the line of sight. During t years the 'plasmoid' would appear to have moved a transverse distance $\sim\gamma\, vt$ light years, and its actual distance from its point of origin would be $\sim\gamma^2\, vt$ light years. A proper time $\sim\gamma t$ would have elapsed in the 'plasmoid' since the explosion. (If $\gamma \gg 1$ this is approximately equal

to the time it would take to reach its observed position if it had moved with a velocity $\sim c$ perpendicular to the line of sight.) Of course it is very unlikely that an object ejected at random would have its velocity oriented at $\cos^{-1} v/c$ to the direction of the observer, especially if $\gamma \gg 1$. But the associated quasi-stellar radio sources may well have ejected a large number of such clouds, which would be too faint to be detected unless they were moving almost towards us. If $\sim 2\gamma^2$ clouds were thrown out with the same velocity, for example, we would expect only $\sim\gamma$ of them to be blue-shifted, and only ~ 1 to have a Doppler blue-shift $>\gamma$; but it is the cloud which does have a large blue-shift, and is therefore bright enough to be detected, which is likely to have the greatest apparent velocity ($\gg c$) perpendicular to the line of sight. The radiation from each cloud would be emitted predominantly in a narrow beam of angle $\cos^{-1} v/c$ pointing in its direction of motion, and we would receive more radiation from the one cloud with large Doppler blue-shift than from all the others combined. These others would appear closer to the quasi-stellar radio source, though we would expect them to be too faint to be detectable individually. The energy in all the clouds (including their kinetic energy) would be no greater than the energy required by other models.

The most attractive feature of the possibility suggested here is that it enables us to adopt a lower estimate for the duration of the superluminous phase of quasi-stellar radio source. Unfortunately the model would not be tenable if the intergalactic density were as high as $\sim 10^{-5}$ atoms/c.c., since the clouds would then be braked too rapidly by the ambient gas.

The foregoing discussion has shown that bulk velocities $\sim c$ may occur in radio sources, and that relativistic effects may drastically alter estimates of the size of a source from its rate of variation, or conversely of its age from its apparent size. In this way we can resolve some of the difficulties which have been encountered in attempts to understand variable radio sources if they are at cosmological distances. It is also possible that the lifetimes of some radio sources and quasi-stellar objects may be substantially shorter than is generally believed.

I thank Dr. D. W. Sciama for advice and encouragement.

LUMINESCENCE CAUSED BY PROTON IMPACT WITH SPECIAL REFERENCE TO THE LUNAR SURFACE

By J. SCHUTTEN and TH. VAN DIJK
F.O.M. Institute for Atomic and Molecular Physics*, Amsterdam, The Netherlands

RECENTLY, Derham and Geake reported[1,2] some results of laboratory experiments on the luminescence of meteorites by proton impact in the keV-region. The figures supplied by them, however, are mainly relative. Because we are able to perform absolute measurements on excitation by proton and electron beams, we decided to carry out a similar investigation. The apparatus was calibrated by means of a standard tungsten ribbon lamp (a description of the apparatus and the calibration procedure has been given elsewhere[3,4]). Some of our results are given in Fig. 1. The graphs show the luminescence of the meteorites Holbrook, Arispe and Odessa, the lava Fuertaventura and molecular hydrogen, under proton bombardment with an energy of 30 keV. The choice of this energy results from a suggestion made by Kopal[5], who supposed that a correlation exists between solar flares and lunar luminescence. The observed time lag was between 8 and 48 h, whereas an energy of 30 keV corresponds to a time lag of about 26 h.

For the reason that our measurements gave very low excitation values, we also measured the luminescence of willemite. The results are plotted as curves 1 and 3 in Fig. 2.

The maximum number of photons obtained in this way was about 10^7 per μamp and per unit of wave-length.

If it is assumed that the normal flux of protons in the solar wind is $1{\cdot}6 \times 10^{-8}$ cm^2 s^{-1}, that the bandwidth in the optical range is 500 Å, and that there is an area on the lunar surface contributing to the luminescence of 100 km^2, a result of 5×10^{16} photons per sec is obtained. An observer on Earth with a 50-in. telescope at a distance of 385,000 km would receive on the average from this flux 1 photon per 1,000 sec.

* Formerly: F.O.M. Laboratory for Mass Separation.

As we used one of the strongest luminescent materials, we believe it very improbable that even during solar flares, when the intensity of the solar wind increases by a factor of 100, the observed excitation can be caused by proton impact in the keV-region. Even the fact that the lunar night-time is 10^4 times fainter than the normal brightness cannot be explained in this way.

For the luminescence of molecular hydrogen we find about the same values in curve 1 (Fig. 1), assuming a pressure of 10^{-2} torr (this corresponds to a density of about 3×10^{14} cm^{-3}). This seems rather high when the lack of atmosphere and the relatively low escape velocity are considered. Because our laboratory values differ considerably from those of Derham and Geake, we tried to find a reason for this discrepancy.

We believe the following two points to be worth mentioning: (1) In most cases the bombarded target consists of insulating material, so during proton bombardment it is charged up to a potential determined by the conductance of the material, the current density and the proton energy. This means that under laboratory conditions a potential drop develops across the bombarded target. Protons hitting the target surface create secondary electrons, and these electrons are accelerated to the most positive part of the target. As the efficiency of electrons in the keV-region is about 10^5 times higher than that of protons, the luminescence caused by these secondary electrons is several decades greater than the luminescence caused by protons.

This effect becomes clear from a consideration of Fig. 2, where curve 5 corresponds to the light-output by electron-bombardment, and curve 4 by proton-bombardment with an insulating target—which means that a great number of high-energy secondary electrons is formed—whereas

curve 1 corresponds to proton-bombardment on a grounded target with aluminium coating, and curves 2 and 3 with a thin insulated layer deposited on a grounded copper plate, at a proton energy of 10 and 30 keV, respectively.

(2) The background pressure in the apparatus may be a second cause for the high luminescence effects. During their passage through the gas, the protons tend to ionize the gas molecules, thus creating a number of electrons. These electrons are then accelerated to the most positive part of the target, and this results in a relatively important contribution to the luminescence. The result of the increase of background pressure in our apparatus from 10^{-5} torr to 10^{-4} torr is indicated in Fig. 3, where a thin layer of willemite was deposited on a grounded copper plate. It can be seen that by increasing the background pressure by a factor of 10 the luminescence increases by the same magnitude.

We conclude that the luminous emissions observed from some parts of the lunar surface are not caused by impact of protons from the solar wind. The high luminous yields of protons reported by other investigators are most probably due to secondary instrumental effects. We see no evidence to support the existence of a correlation between the protons from solar flares and lunar luminescence—unless some unknown storage mechanism is present.

The creation of photons on the lunar surface seems to be an established fact, and for this reason other mechanisms must be sought to explain the presence of energy and its conversion into light. We think it probable that the effect is caused by electro-magnetic radiation of short wavelength (ultra-violet, X-rays). Evidence for this supposition could be provided by an extended lunar satellite programme, in which absolute measurements of radiation intensities as a function of wave-length could be performed, and a correlation with luminescence established.

This work is part of the research programme of the Foundation for Fundamental Research on Matter (F.O.M.)

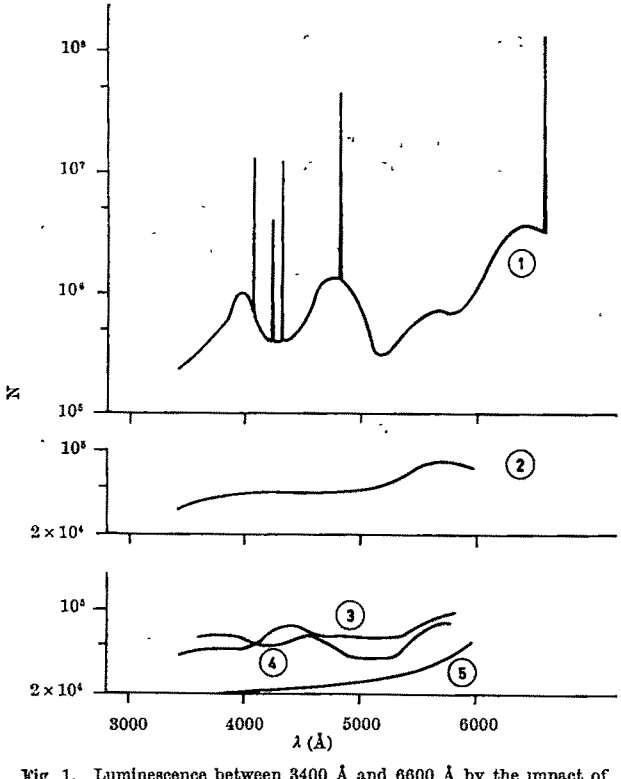

Fig. 1. Luminescence between 3400 Å and 6600 Å by the impact of 30-keV protons. The intensity I is given in number of photons per μamp beam current and per unit of wave-length (Å). Curve 1 is for molecular hydrogen (pressure 10^{-3} torr) at an observed beamlength of 25 mm; curve 2 is for the lava Fuertaventura; curve 3 for Arispe; curve 4 for Holbrook, curve 5 for Odessa

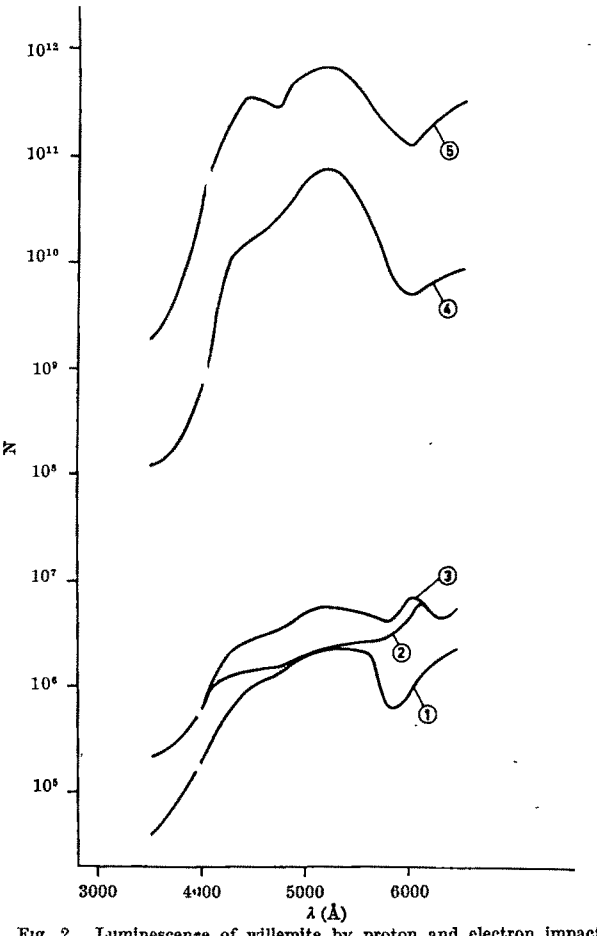

Fig. 2. Luminescence of willemite by proton and electron impact. WE should like to comment on some of the points raised by Schutten and van Dijk.

The efficiency figure of about 1 per cent which we have given[1] was for the most efficient class of meteorite we found—the enstatite achondrites. We are surprised that Schutten and van Dijk have, for comparison, taken the meteorites Arispe, Odessa and Holbrook. The first two are listed as irons, and as it seems inconceivable that almost pure nickel-iron should luminesce at all, even the weak emission they observed was probably due to surface

contamination. It is indeed difficult to make any target clean enough not to luminesce at this sort of level, especially if a large beam current is used. We find that Holbrook, a hypersthene chondrite, has an efficiency (when fresh) of about 1/25 of that of the enstatite achondrites[2], and we can only suppose that the even lower output they found was obtained from a heavily damaged sample. Indeed, the spectrum they give for it resembles ours for a damaged sample rather than a fresh one. The difficulty with this kind of measurement is that unless the proton beam current density is kept very low, the sample damages rapidly, resulting in a greatly reduced efficiency and a changed spectrum—and to obtain a spectrum at all with a sufficiently low beam current a very powerful spectrograph is needed. We find that a proton beam current density of about 1/4 μamp/cm^2 is about the most that can safely be used. Schutten and van Dijk do not give any information about their sample preparation, or state their beam current density, which is actually more important than the particle energy. Also the spectral range of their measurements does not extend far enough into the red to include the region where we have found the efficiency to be highest for the most efficient meteorites.

The second point which surprises us is the reported difference of 10^5 between the efficiencies for electron and proton excitation. Such other published evidence as is available suggests that the efficiencies are about the same. There is a shortage of this sort of data, but it is available for some scintillator materials; for example, Allison and Casson[3] conclude that for sodium iodide, protons and electrons have about the same efficiency, and even for α particles it is not much lower. Organic scintillators are known to be less efficient for heavy particles than for electrons, but even so, the figures collected by Brooks[4] from various workers only show factors for anthracene ranging from 2 to 5 depending on the energy. Silicates are likely to show much smaller differences[5], and we feel justified in taking the efficiencies as about the same for protons and electrons. We have therefore used the electron excitation figures given by Bril and Klasens[6] for the material of our comparison phosphor, as applying, within the accuracy of our measurements, to proton excitation. One effect which could produce an apparent reduction in efficiency for protons is that protons damage the target much faster than do electrons of the same energy. If a large beam current were used, the proton efficiency could become very low in a matter of seconds, although we would hesitate to ascribe the whole of the factor of 10^5 to this.

As regards the effect of secondary electrons, the process by which protons excite luminescence emission at all presumably involves the production of secondary electrons within the material as its first stage—it is unlikely that protons interact directly with the material[5]. However, the liberation of secondary electrons from the surface in large quantities, and their attraction back again by a positive surface charge, seems a very unlikely mechanism for enhancing luminescence by a large factor. All our measurements have been made with a thin dust target on an earthed metal plate, and it seems unlikely that the surface could charge up to the high potential needed to attract the electrons back with appreciable energy. Also the effect, if appreciable, should cause the apparent efficiency to vary with the surface potential, which should in turn increase with target resistance and therefore thickness. We have tried the effect of varying the thickness of the dust layer, and find the efficiency to be about the same for a thick pile of dust as for a single grain smeared out on the plate, only falling off slightly as the target becomes too thin for it to cover the beam area uniformly. Only when we put the dust on a glass plate do we notice charge effects—the beam becomes unstable and disperses convulsively, giving a wildly fluctuating luminescence output—but the peaks are still roughly at the previous steady level.

We have also checked the effect of the pressure in our apparatus. If, during normal operation, we increase the pressure by isolating the pumps, a small increase in the luminescence output indeed occurs, but this arises from a build-up of the hydrogen pressure in the ion chamber which, up to a point, increases the proton output and therefore the beam current. If, on the other hand, we increase the pressure by leaking air into the system, the luminescence output initially decreases, followed by a series of more complicated changes which we can explain, but which are in any event too small to be important. We conclude that, for a given beam current, pressure changes over the range likely to occur in our apparatus do not produce significant effects.

Unfortunately, Schutten and van Dijk do not give enough information for us to attempt an explanation of their results, except to say that they seem consistent with the use of a rather high beam current density.

ABSORPTION OF HIGH-ENERGY GAMMA-RAYS WITHIN QUASARS AND OTHER RADIO SOURCES

By DR. J. V. JELLEY
Nuclear Physics Division, Atomic Energy Research Establishment, Harwell, Berkshire

THE conspicuous absence of positive results[1] in the many attempts in recent years to detect high-energy gamma-rays from selected objects in the universe has led many to question the transparency of space to such radiations. It has gradually become apparent that high-energy γ-rays, if produced, may suffer absorption *en route*, especially by pair production, in photon–photon collisions[2] with low-energy quanta present in intergalactic and interstellar space. Collisions with the photons of intergalactic starlight[3] and radio-frequency fields[4] were first considered, and it is now realized[5,6] that the recently discovered, and supposedly universal, microwave thermal radiation[7,8] may be sufficiently strong to produce significant attenuation of γ-rays even within the Galaxy. There is now also indirect evidence[9,10] for this universal microwave radiation, from interstellar CN absorption spectra from stars in our own Galaxy.

The cases of γ-ray absorption considered so far have all been concerned with the attenuation in the relatively weak photon fields between the sources and the Earth. The purpose of this article is to point out that the same absorption process may be significant within the sources

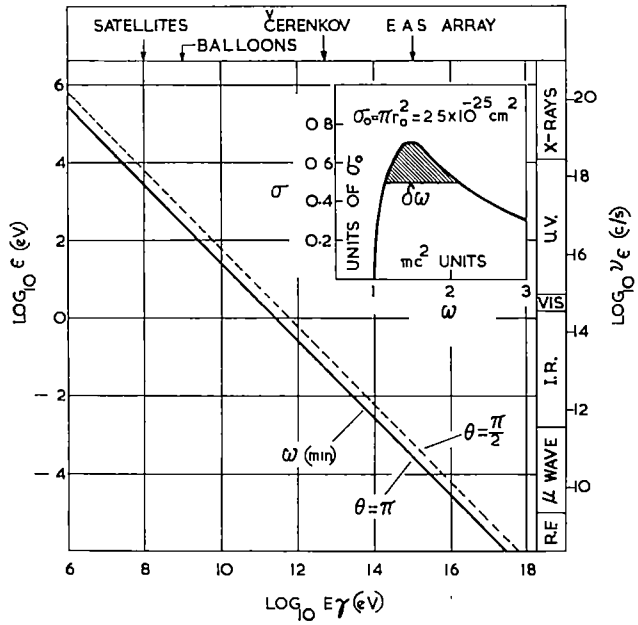

Fig. 1. A plot of the threshold condition for pair production by photon–photon collisions, between high-energy γ-rays and local radiations of low quantum energy ε. Inset: the form of the cross-section σ close to the threshold. $\omega = (E_\gamma \varepsilon)^{1/2}/m$

themselves. This idea is prompted by the realization that the potential sources of high-energy radiations are in general also intense sources of radiation of low quantum energy. In such cases the high photon density of the local fields of the lower-energy quanta may more than compensate for the relatively short interaction path lengths, as the γ-rays move through and away from the sources.

The absorption of a γ-ray of energy E_γ by pair production[2], on collision with a photon of energy ε, has a threshold at $E_\gamma \varepsilon\,(1-\cos\theta) = 2\,m^2$, where m is the rest-energy of the electron, and θ the angle between their directions of motion. This threshold is lowest for head-on collisions, $\theta = \pi$, when $E_\gamma = (m^2/\varepsilon)$. To the accuracy required here, we consider only head-on collisions, for which the threshold condition is shown in Fig. 1. The cross-section σ for the process (see insert) rises from zero at the threshold to a maximum just above it, where it attains an absolute value $\simeq 0{\cdot}7\,\pi\,r_0^2$, where r_0 is the classical radius of the electron. If $\omega = (E_\gamma.\varepsilon)^{1/2}/m$, σ is significant (that is, $> 0{\cdot}5\,\pi\,r_0^2$) over a band-width $\delta\omega \simeq \omega$, or $\delta\varepsilon \simeq 2\varepsilon$, for a given E_γ; a value of $\sigma = 10^{-25}$ cm^2 will be used throughout this article. If u_r is the energy density of the soft quanta, the numbers-density of these quanta $n = (u_r/\varepsilon)$, and the mean free path against photon–photon absorption is $L = (1/\sigma n)$.

For our purpose here we make the important assumption that the volume occupied by the lower-energy quanta is the same or larger than that from which the γ-rays may originate, and that the flux of the soft quanta is distributed approximately isotropically, so that we will ignore the variation of threshold and absorption cross-section with θ. In this model it is therefore implicitly assumed that in general the photon (and particle) energies decrease monotonically with radial distance from the core. If the source has a core and halo, as for example in the model of Rees and Sciama[11] for the quasar *CTA* 102, we would assume that the γ-rays originate in the stellar object at the centre, and not appreciably in the halo. It should be emphasized that if the energy distribution is reversed, so that some higher-energy particle and radiation fields occur in the outer halo regions, for example through the inverse Compton process, the conclusions deduced in this paper will be invalid, or will at least have to be modified (N. A. Porter, private communication).

Assuming the volume occupied by the low-energy photons to have an effective radius R, then, if the source is at a distance d, and s is the flux of these quanta at the Earth, per unit bandwidth, $u_r = (4\,s/c).(d/R)^2.\delta\nu$ erg. cm^{-3}, in a bandwidth $\delta\nu$. Taking an effective bandwidth $\delta\nu = 2\nu$ (since $\delta\varepsilon \simeq 2\varepsilon$), where $\nu = (\varepsilon/h)$, the numbers-density of photons over this effective band, is:

$$n_\varepsilon = (8\,s/c).(d/R)^2.h^{-1} \text{ quanta cm}^{-3}$$

which, we note, is independent of ε. s is assumed to be approximately constant over $\delta\nu$.

Existing techniques in γ-ray astronomy cover broadly three energy regions, with thresholds $\sim 10^8$–10^9 eV in satellite[12] and balloon-borne experiments[13], $\sim 5\times 10^{12}$ eV by the Čerenkov technique[14], and $\sim 10^{15}$ eV by large air shower arrays[15]. Let us now consider possible source absorption in these three energy regions, and for three markedly different types of object, namely quasars, galactic supernova remnants, and 'peculiar' galaxies. The main interest attaches to the 5×10^{12} eV and the 10^8–10^9 eV bands, since the microwave absorption will preclude the observation of all but local galactic objects at $E_\gamma \sim 10^{15}$–10^{17} eV. First take the case of 5×10^{12} eV γ-rays:

Quasars warrant special attention in view of their present-day interest and high energy content. 3*C*273 has been selected, as it is one for which both flux limits have already been obtained[16] and for which there is at the same time adequate information on its energy content at lower frequencies[17,18]. It is appreciated that in some respects this choice is not ideal, in view of the complex structure[19] of this particular quasar.

Of the many models proposed we consider three; the first two are simplified theoretical models, and the third is based on interferometric measurements[19] on structure, at $\lambda \simeq 21$ cm.

Model 1. Consider first the recent model of Hoyle, Burbidge and Sargent[20], in which it is assumed the object is extragalactic but local, with $R \simeq 10^{17}$ cm (determined by its light variations) and $d \simeq 10$ megaparsec (Mpc). At $E_\gamma = 5\times 10^{12}$ eV, from Fig. 1, $\varepsilon = 0{\cdot}052$ eV ($\nu = 1{\cdot}26\times 10^{13}$ c/s, $\lambda \simeq 24\mu$). Extrapolating from the infra-red measurements[18] at $\lambda = 10\mu$, we find $s \simeq 2\times 10^{-22}$ erg. cm^{-2}sec^{-1}(c/s)$^{-1}$, $n_\varepsilon = 7{\cdot}7\times 10^{11}$ photons cm^{-3} and thus $L \simeq 1{\cdot}3\times 10^{13}$ cm, that is, only $\simeq 1{\cdot}3\times 10^{-4}\,R$.

Model 2. Assume instead that the source has the same linear size, but that it lies at its cosmological distance of 470 Mpc (for Hubble's constant, $H = 100$ km sec^{-1} Mpc^{-1}). n_ε is then $1{\cdot}7\times 10^{15}$ photons cm^{-3} and $L \simeq 6{\cdot}1\times 10^9$ cm, only $\sim 6\times 10^{-8}\,R$, again at $E_\lambda = 5\times 10^{12}$ eV.

Model 3. Now take the linear dimensions of 3*C*273, as measured at $\lambda = 21$ cm (ref. 19). This source has two components of which one, component B, coincides with the optical source, and this in turn has two parts. The other and larger component, A, does not emit in the optical region. Because at $E_\gamma = 5\times 10^{12}$ eV the effective value of ε falls in the infra-red spectral region which is nearer to the optical than to the decimetre band, we will assume the observed infra-red[18] arises from one or both parts of component B.

The radio measurements set a limit of 0·1 sec arc for the size of either of the two parts of component B. This, in turn, implies $R \leqslant 2{\cdot}5$ pc or $\leqslant 114$ pc on the 'local' and cosmological models respectively, again with $H = 100$ km sec^{-1} Mpc^{-1}. Because this component B has not been resolved optically, we will assume the infra-red radiation divided equally between the two parts, in which event we deduce $n_\varepsilon \geqslant 6{\cdot}5\times 10^7$ quanta cm^{-3} and thus $L \leqslant 1{\cdot}5\times 10^{17}$ cm, that is, $\leqslant 0{\cdot}021\,R$ on the local model, or $\leqslant 4{\cdot}5\times 10^{-4}\,R$ on the cosmological model. From Low's extrapolated spectrum of 3*C*273, the infra-red yield of component A is at least three orders of magnitude lower than that from component B, so that any γ-rays ($E_\gamma \sim 10^{12}$ eV) generated in A would doubtless survive the local infra-red fields in this component.

We conclude from these arguments that if 3C273 is typical of quasars, and if the real object resembles any of these three models, it is unlikely that γ-rays in the 10^{12}–10^{13} eV energy region will be observed from quasars —at least if such γ-rays are emitted in the region of the core. This is consistent with the observations[16], with the exception of 3C147 for which there remains a suggestion of a positive effect.

Consider now the absorption of lower-energy γ-rays within this quasar. At $E_\gamma \simeq 10^8$ eV (typical of satellite experiments), $\varepsilon \simeq 2{\cdot}5$ keV which occurs close to the 3 keV X-ray band, for which galactic and intergalactic space are transparent. This band has already been explored in rocket experiments, for example, by the American Science and Engineering, Inc.–Massachusetts Institute of Technology[25], and U.S. Naval Research Laboratory[26] groups. Although no X-rays have as yet been observed from quasars, a flux limit has been quoted[1], $s_x < (1/20)$ of that from the strong source *SCOX*–1, for which $s_x = 1{\cdot}6 \times 10^{-7}$ erg. cm^{-2} sec^{-1} over a band $\delta\varepsilon = 1$–10 keV. Taking $\bar{\varepsilon} = 3$ keV and $\delta\varepsilon = 2\bar{\varepsilon}$, we find s_x (quasars) $< 3{\cdot}7 \times 10^{-27}$ erg. cm^{-2} sec^{-1} (c/s)$^{-1}$. For the local model, model 1 ($R = 10^{17}$ cm, $d = 10$ Mpc), one obtains from this figure $n_\varepsilon \leqslant 1{\cdot}4 \times 10^7$ X-ray photons cm^{-3}, or $L \geqslant 7{\cdot}2 \times 10^{17}$ cm, or $\geqslant 7R$, that is negligible attenuation. On the other hand, with this same limiting flux, on the extreme model 2, one finds $L \geqslant 3{\cdot}2 \times 10^{14}$ cm or $\geqslant 0{\cdot}003\,R$, in which case the absorption is very heavy. On model 3, that is $(R/d) < 0{\cdot}05''$, we have $L < 535R$ and $< 11R$, for the local and cosmological models, respectively.

There is no observational evidence so far for γ-rays from 3C273, or from any other quasar either in balloon-borne or satellite experiments, and the recent search[13] at $E_\gamma > 10^9$ eV with an angular resolution $\sim 2°$ unfortunately did not embrace the co-ordinates of this source.

Crab nebula. This object has always been, and remains, an object of special interest in γ-ray and X-ray astronomy. We shall assume a distance $d = 1{\cdot}1$ kpc, and that it has a diameter of $\sim 5'$ at optical and radio frequencies. Its spectrum is known over a wide range of frequencies[21], and has been discussed in detail by Gould[22]. At $\varepsilon \simeq 0{\cdot}052$ eV, appropriate to $E_\gamma = 5 \times 10^{12}$ eV, we find $s = 4{\cdot}8 \times 10^{-22}$ erg. cm^{-2} sec^{-1} (c/s)$^{-1}$, which leads to $n_\varepsilon \simeq 37$ photons cm^{-3}, and thus $L \simeq 2{\cdot}7 \times 10^{23}$ cm or $\sim 10^5\,R$, implying negligible absorption within the source. Photon–photon absorption cannot therefore be responsible for the apparent absence of γ-rays from this object[16,23] at this energy. Moreover, it will not frustrate the search for γ-rays at the lower energy $\sim 10^{11}$ eV which it is hoped to attain with a giant mirror system proposed[24] by the Smithsonian Astrophysical Observatory.

For 10^{15} eV γ-rays which could be observed with the BASJE array[15], and which would survive the universal microwave field, the corresponding figures are: $\varepsilon \simeq 2{\cdot}6 \times 10^{-4}$ eV ($\lambda \simeq 4{\cdot}8$ mm), $s = 2{\cdot}85 \times 10^{-21}$ erg. cm^{-2} sec^{-1} (c/s)$^{-1}$, $n_\varepsilon \simeq 220$ photons cm^{-3} and $L \simeq 4{\cdot}5 \times 10^{22}$ cm, or $1{\cdot}8 \times 10^4\,R$; again the attenuation is negligible.

It is readily shown that the attenuation of 10^8–10^9 eV γ-rays within the Crab nebula, owing to the observed X-rays from this object, is quite negligible, even allowing for the fact that these X-rays are concentrated within a relatively smaller volume, of angular diameter $\sim 1'$ as deduced from the occultation experiment[27]. While many of the known X-ray sources are exceedingly strong on the basis of total energy, they are relatively impotent for this absorption process, as the large bandwidths lead to correspondingly small values of s.

Galaxy M87. This object has attracted considerable attention as it is believed that much of the optical as well as the radio-frequency radiation arises from synchrotron radiation[28]. The optical emission, moreover, is concentrated in a thin jet the volume of which is small compared with that of the main Galaxy. We will assume that γ-rays may be generated in the region of the jet, the dimensions of which, following Burbidge[28], are those of a cylinder of length 20″ and diameter 2″. With a revised distance $d = 11{\cdot}4$ Mpc ($H = 100$ km sec^{-1} Mpc^{-1}), this jet has dimensions 1,100 pc × 110 pc, so that $R \simeq 55$ pc. The total optical emission from this jet is $6{\cdot}8 \times 10^{41}$ ergs. sec^{-1} (over 4000–5500 Å), so that for $\nu_{opt} = 6{\cdot}5 \times 10^{14}$ (c/s), the source strength S_{opt} is $\simeq 1{\cdot}0 \times 10^{27}$ erg. sec^{-1} (c/s)$^{-1}$.

For $E_\gamma = 5 \times 10^{12}$ eV, $\varepsilon \simeq 0{\cdot}052$ eV and $\nu_\varepsilon \simeq 1{\cdot}3 \times 10^{13}$ (c/s). The spectrum of the radiation from M87 can be written as a power law $P(\nu) = k\nu^{-\alpha}$, for which, in the optical band, $\alpha = 0{\cdot}65$ (ref. 28). The infra-red source strength S_{IR} is then $(\nu_{opt}/\nu_\varepsilon)^{0{\cdot}65} S_{opt} \simeq 1{\cdot}3 \times 10^{28}$ erg. sec^{-1} (c/s)$^{-1}$ and, at the Earth, $s = 8{\cdot}7 \times 10^{-25}$ erg. cm^{-2} sec^{-1} (c/s)$^{-1}$. For $\delta\nu = 2\nu_\varepsilon$, we deduce $n_\varepsilon \simeq 1{\cdot}51 \times 10^3$ quanta cm^{-3} and hence $L \simeq 6{\cdot}6 \times 10^{21}$ cm, or $\simeq 39R$ if R is here the radius of the jet. Absorption within the jet is thus insignificant, but not by such a large margin as in the case of the Crab. Burbidge has predicted the γ-ray fluxes which might be expected from M87. While these figures are clearly model dependent and cover a broad range, they fall in the general region of sensitivity of existing equipment. No radiation has been observed at $E_\gamma \simeq 5 \times 10^{12}$ eV although a limiting flux has been obtained[23].

While X-rays have now been observed from M87 (ref. 29), the first such source known definitely to be extra-galactic, their effect on 10^8–10^9 eV γ-rays is again quite negligible, for the same reasons already discussed for the Crab nebula.

Finally, consider the survival of high-energy γ-rays as they traverse the solar radiation on their last stages to the top of the Earth's atmosphere. The highest radiation flux to which these γ-rays are exposed in the solar system occurs at $\varepsilon \simeq 2{\cdot}5$ eV (corresponding to $E_\gamma \simeq 1{\cdot}0 \times 10^{11}$ eV). At the Earth's orbit, the solar flux is $\simeq 1{\cdot}4 \times 10^6$ erg. cm^{-2} sec^{-1} over the optical band, so that $n_\varepsilon \sim 1{\cdot}2 \times 10^7$ photons cm^{-3} (for $\delta\varepsilon = 2\varepsilon$), and thus $L \simeq 8 \times 10^{17}$ cm or $\sim 6 \times 10^4$ a.u., which represents negligible absorption. It is worth noting, however, that if γ-rays are generated in the early phases of a supernova, during which the light intensity rises to $\sim 10^9$ times that from the Sun, it is possible that this same absorption mechanism may prevent or reduce their escape from the source; in such a case, however, the energy thresholds and the photon–photon collision frequencies will be modified owing to the small values of θ.

To summarize, it would appear that γ-rays in the energy region 10^{11}–10^{13} eV may not be able to escape from the core regions of quasar sources, though they may be free to do so from the more extended halo regions. It is concluded, however, that the recently discovered X-ray emissions from various 'point' sources, strong though they are, are unlikely to frustrate the escape of lower-energy γ-rays in the energy region 10^8–10^9 eV. The survival of γ-rays of $\sim 10^{12}$ eV energy over interstellar and intergalactic distances depends critically on the level of infra-red background radiations in the energy region $\sim 0{\cdot}26$ eV, that is, for $\lambda \simeq 4{\cdot}8\mu$; it is therefore most important for the future of γ-ray astronomy that the extra-terrestial flux of infra-red radiations should be established as soon as satellite-borne equipment of adequate sensitivity can be flown.

DATING PLEISTOCENE EVENTS IN SOUTH-WEST WALES

By Dr. D. Q. BOWEN
Department of Geography, University College of Wales, Aberystwyth

Recent investigation has revealed a broadly identical stratigraphy of coastal Pleistocene deposits between Cardigan Bay and Gower (Fig. 1). The key to this stratigraphy occurs in Gower where a cave earth yielding a mammalian fauna together with a ubiquitous palaeosol enables the west Wales stratigraphy to be dated independently of recent radiocarbon dates[1] which are not as unequivocal as could be hoped and which, in the light of investigations reported here, seem misleadingly young. It seems likely that the shells from which Dr. John obtained his dates have been contaminated by ground water percolation through the gravels in which they lay.

The last glaciation of south-west Wales, with the possible exception of a small area in north Pembrokeshire and south Cardiganshire on which a Weichselian Irish Sea glacier moving down St. George's channel may have impinged[2–4], would now appear to be Saale (Riss) in age and not Weichselian (*c.* 28,000 B.P.) as suggested by Dr. John[1].

In 1932 Prof. George described a four-fold stratigraphy at Minchin Hole cave, Gower: (i) *Patella* beach; (ii) a cave breccia 8 ft. (2·44 m); (iii) marine sand, the *Neritoides* beach—1–3 ft. (0·30–0·91 m); (iv) blown sand merging laterally with limestone head. Since that date the section has receded and a recent investigation revealed:

(6) Upper head 1 22 m	(Weichsel)
(5) Cemented sand 2·31 m	(Eem)
(4) Loose sand (the *Neritoides* sand) 0 46 m	(Eem)
(3) Stratified cave earth 114 m	(Eem)
(2) Lower head 2 m	(Saale)
(1) *Patella* beach 0 51 m	(Hoxnian)

The *Patella* beach (1) is ubiquitous in Gower[5] and rests on shore platforms between 4·88 m (16 ft.) and 15·24 m (50 ft.) *O.D.*[6], the episode it represents having been one of multiple sea-level within that height range. From its included erratics it has been inferred that it is interglacial in age[7]. The lower head (2) described by George as a cave breccia "very similar to normal head" and believed by Hinton[8] to have accumulated in a 'temperate' period by virtue of its fauna, is a periglacial deposit produced by thermoclastic processes as is shown by the angular and sub-angular sharp-edged nature of its constituents. It is not unlikely that the fauna contained was derived from a previous warm period to which the *Patella* beach may be referred. The mammalian fauna yielded by the cave earth, which included *D. hemitoechus*, is similar to that recovered from the Upper Flood Plain (Ilford) terrace of the lower Thames and is regarded by Dr. A. J. Sutcliffe as Last Interglacial (Eem) in age[9]. For Minchin Hole this provides a horizon which can be dated and to which the other members of the stratigraphy can be related. The lower head (2) is suggested to be Saale (Riss) in age, the upper head (6) to be Weichselian, and the *Patella* beach deposit (1) to be Hoxnian.

Resting on the cave earth is the 'gritty marine sand' (4) of George which contained species of *Neritoides*. This was believed to indicate a higher and younger sea-level than that recorded by the *Patella* beach. Dr. M. R. Dobson kindly undertook an analysis of the sand, and on the basis of available parameters for distinguishing beach and dune sands[10], it would seem to be wind blown. It is just possible, however, that the sand may have been reworked by the sea after wind deposition.

Elsewhere, as for example between Shirecoombe and Minchin Hole, where George recognized the *Neritoides* beach, it can be shown that it is merely a facies of the lower head, beach pebbles, shells and sands having been incorporated within the limestone head. In short, the evidence from Minchin Hole and elsewhere suggests that the concept of a *Neritoides* beach indicating a specific sea-level must be rejected. The sea-level contemporaneous with the accumulation of the Minchin Hole cave earth and sands is adduced in the following.

Resting on *Patella* beach and lower head at many sites in Gower is a *terra fusca* palaeosol. George described it as a "fluvioglacial deposit"[11], but Wirtz first recognized its interglacial character[2]. Later, Ball described it at Worms Head and from its fabric concluded that it had formed under conditions similar to those of the present day but with warmer summers[12]. At many sites the lower head has been weathered and under Pwll-du head the *Patella* beach has been completely weathered. On the basis of the position of the palaeosol (that is, resting on both *Patella* beach and lower head and covered by later upper head) it is correlated with the cave earth and sands of Minchin Hole which are also considered to indicate a warm period, namely the Last Interglacial (Eem). It is unlikely that the palaeosol is any younger, for it is overlain by the thickest Pleistocene deposits in Gower, the upper head, which must be referred to the Weichselian, and from what is known of the non-glacial phases of the Last Glaciation it is unlikely that summer temperatures would have been sufficiently warm for its development[13]. At Mewslade the palaeosol rests on a shore platform at 4·88 m (16 ft.) *O.D.*, suggesting that the platform pre-dated the Last Interglacial. This, however, may not be conclusive because here, as elsewhere, the palaeosol has been subject to solifluction and may not be *in situ*.

Overlying the palaeosol occur the thickest Pleistocene deposits of the area, the upper head. Without exception in Gower they accumulated by solifluction and the 'glacial' horizons discussed by George and Wirtz consist of solifluted glacial deposits. Nowhere does till occur *in situ* in the coastal sections. This is shown by the fabric of the deposit, the long axes of stones showing a remarkable preferred orientation parallel to and changing in sympathy with local slope changes; the included head masses of local bedrock material; the cryoturbated silt horizons; the well-developed bedding; the lateral merging of glacial material with local bedrock head; and finally the intimate relationship between local topographic depressions and accumulations of solifluted till material. At several sites, for example at Horton, the surface of the upper head is

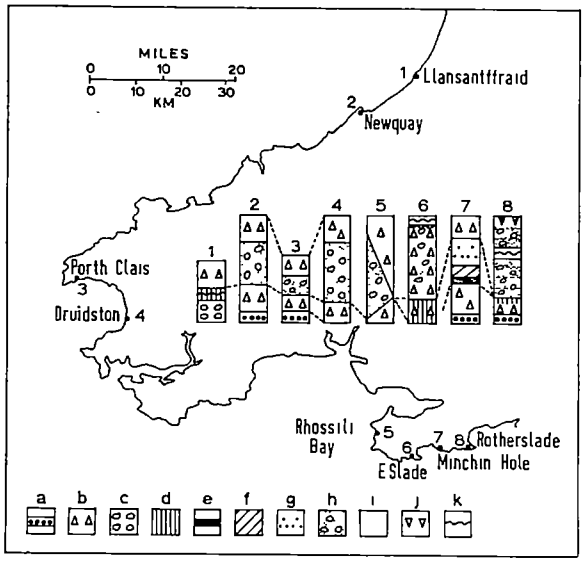

Fig. 1. Sections not to scale. Key: *a*, *Patella* beach; *b*, head; *c*, till; *d*, weathering horizon or interglacial palaeosol; *e*, cave earth; *f*, Minchin Hole sand; *g*, Minchin Hole cemented sand; *h*, solifluсted till (part of the upper head); *i*, silt horizon; *j*, frost wedge casts; *k*, involutions

frost heaved, and frost wedge casts occur at Rotherslade. Capping most of the coastal sections is the upper loam of George[11], a periglacial deposit which sometimes reveals a three-fold stratigraphy, the two lower members having been frost heaved. The upper loam is probably Late Glacial in age.

The Heatherslade beach rests on the 'modern' shore platform and, because it contains larger and a higher percentage of erratics than does the *Patella* beach, George inferred that a glaciation occurred between the formation of the two beaches. It seems likely that this glaciation was a later manifestation of the cold period which commenced with the accumulation of the lower head. The deposits of this glaciation were solifluсted during a later cold period which post-dated the formation of the palaeosol. The last glaciation of Gower must, therefore, be referred to the Saale (Riss/Gipping) Glaciation, and the changing facies and frost structures within the upper head indicate changing environmental conditions during the Weichselian. These are being investigated.

The sea-level of the Last Interglacial is probably indicated by the height of the undercut notch at the inshore margin of the Heatherslade beach shore platform and lies at 1·52 m (5 ft.) *O.D.* It is unlikely that the shore platform is any younger for radiocarbon dates suggest that, during the Weichselian, world sea-level was below the present[14], and as the platform passes beneath the solifluction terrace at Eastern Slade it cannot be Flandrian. This suggestion is consistent with a belief that the Minchin Hole sands were not flung up any great distance.

The Gower stratigraphy is repeated in west Wales where, at Porth Clais, Leach recognized a four-fold stratigraphy resting on a shore platform: raised beach, head, boulder clay (solifluсted), head[15] (Fig. 1). At Druidston Haven, John described a calcareous till, which I believe has been solifluсted, resting between two heads[16], while at Newquay, a calcareous solifluсted till occurs between two deposits referred to by Mitchell as local boulder clays[17], but considered to be head deposits by Watson[18]. The lower head rests on what might be raised beach gravels[17]. Finally, at Llansantffraid a cryoturbated interglacial palaeosol developed on weathered till is overlain by periglacial torrent gravel[7].

With the possible exception of a small area in north Pembrokeshire and south Cardiganshire[2–4], Weichselian ice did not reach the shores of south-west Wales. The basic stratigraphy is identical over wide areas and in particular within and outside Prof. Charlesworth's end moraine line[19] which has been subject to doubt recently as an ice margin by investigations of fluvioglacial features[3,4] and periglacial phenomena[20]. In Carmarthenshire the limit of local Weichselian ice may be marked by well-defined valley moraines and related outwash[6,17].

I thank Dr. M. R. Dobson, who undertook the analysis of the sand sample, and Prof. C. Kidson and Mr. E. Watson, who read the manuscript and offered helpful advice.

FORMATION OF QUARTZ SAND

By Dr. I. J. SMALLEY
The City University, St. John Street, London, E.C.1

Quartz sand is the universal continental detrital material and, as Kuenen[1] has noted, its abundance has led to its relative neglect. It is generally accepted that quartz sand is derived from quartz crystals in granitic rocks; this is a view of respectable antiquity, for example, it was stated by Sorby[2] and by Dawkins[3]. A careful modern statement has been made by Kuenen[4]: "It is assumed that the bulk of non-volcanic and non-organic sands is derived from weathered coarse crystalline rocks, mainly granites and gneisses".

There does not seem to be any acceptable alternative source and, in fact, Nemecz[5] has shown experimentally the similarity between quartz crystals in granite and sand grains found nearby.

There are two aspects to the study of the formation of sand grains; the first concerns the formation of the quartz crystals in the granite and leads to a field rich in controversy, the second concerns the release of the quartz crystals from the granite matrix by weathering.

The chemical composition of most granites is such that they can conveniently be represented on the silica–nepheline–kalsilite diagram as shown in Fig. 1. This is based on the dry diagram determined by Schairer and Bowen[6] and revised by Schairer[7]. The quaternary silica–albite–orthoclase–water is perhaps more significant and useful where the formation of the granite is being considered. Sorby[8], from his investigation of the liquid inclusions in quartz, came to the conclusion that the

magma of granite had solidified in the presence of water under great pressure but at low heat. This still appears to be a reasonable assumption. Turner and Verhoogen[9] state that the mineralogy and coarse holocrystalline fabric of granites suggests origin by slow crystallization of siliceous magma. This will be taken as the starting point in the process of sand formation.

It appears that the quartz crystals in most granites are part of a coarse eutectic of quartz and feldspar. In most granites (or at least those formed by crystallization from magma) large feldspar primary crystals are formed and then the quartz–feldspar eutectic. The other minerals (mica, apatite, etc.) at the beginning of the Rosenbusch succession have been ignored. It has been suggested that the graphic granite structure is a eutectic structure[10]; if it is, its existence would lead one to expect the existence of granites with primary crystals of silica. Very large crystals have been reported in pegmatite structures and some of these have been extensively investigated, in particular by Jahns[11], but they do not appear to form part of a primary silica plus eutectic system. The eutectic crystals must be the major source of quartz sand and the granites containing them all have compositions very close to the silica–feldspar boundary in Fig. 1.

Fig. 2 is based on a figure by Tuttle and Bowen[12] and shows the system silica–albite–orthoclase at various pressures of water vapour. The silica–feldspar boundary does not move much with increased pressure, but high quartz replaces tridymite as the silica form at the liquidus. Tuttle and Bowen also show a section through the 1,000 kg/cm² isobaric prism from $Ab_{50}Or_{50}$ to the silica apex in the silica–albite–orthoclase diagram, and this shows the temperature of the eutectic valley to be of the order of 710° C. The eutectic temperature in the dry system is of the order of 1,000° C, but in actual rock systems the lower temperature probably applies. The high pressures and the presence of water suppress the formation of tridymite and cristobalite and the silica crystallizes as high quartz with an axial ratio of the order of 1·092 and hexagonal symmetry.

At the inversion temperature the high quartz crystals undergo a displacive transformation[13] into low quartz. This transformation is characterized by the change in bond angle at the oxygen atoms. If, at the transformation temperature, the bonds all change simultaneously the low quartz crystal suffers a uniform stress. If, however, the change in the bond angle is a progressive phenomenon, there will be a time when part of the crystal is high quartz and part is low quartz. If there is any sort of temperature gradient in the high quartz crystal the low quartz will

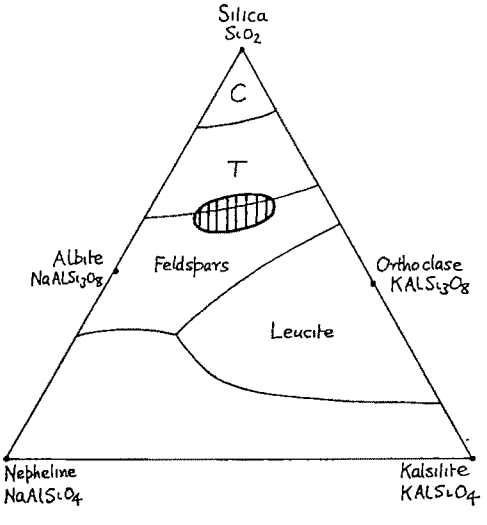

Fig. 1. The ternary system nepheline–kalsilite–silica. The shaded area represents compositions similar to those found in granites. (*C*, cristobalite, *T*, tridymite)

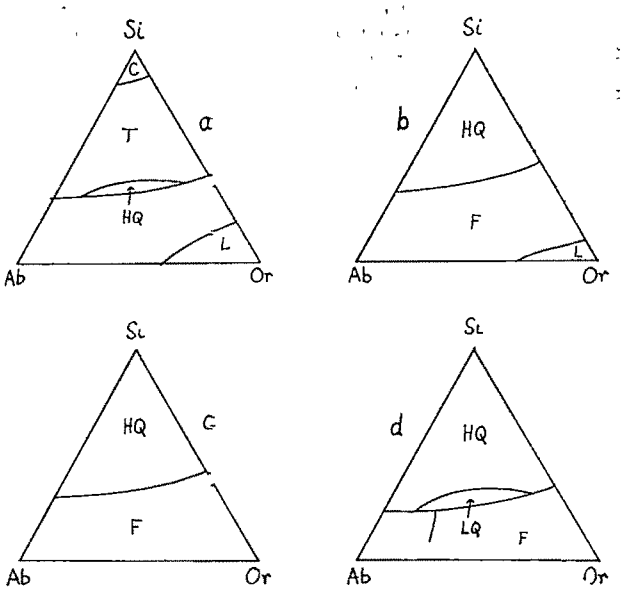

Fig. 2. Stability fields at the liquidus in the system albite–orthoclase–silica–water for various pressures of water vapour; *a*, 200 kg/cm²; *b*, 2,000 kg/cm², *c*, 3,000 kg/cm²; *d*, 4,000 kg/cm²

start to form at the lower end. The existence of an influential temperature gradient does not seem likely. It is observed that in most granites the quartz is among the last part of the system to solidify and could therefore be under some constraint; there could be compressive crystallization stresses. For the maximum relief of well-distributed compressive stresses a uniform contraction is indicated, starting at a point at which the stresses are concentrated. This will be somewhere in the interior of the crystal and from this point the low quartz structure will develop. The high–low interface will spread until it encompasses the entire crystal. There are several types of interface which may occur between separate structures in solid systems. Fine[14] has defined three kinds of interface between two crystalline phases (α and β): (1) Incoherent interface; there is no similarity in the arrangements of atoms in the α and β planes facing each other across the interface. (2) Coherent interface; here there is a perfect match in the arrangements, angles and spacings of atoms in the α and β planes facing each other across the interface. (3) Semicoherent interface; this is the case in between 1 and 2. The high–low interface is probably type 2. Nabarro[15,16] has considered the system in which the interface between α and β is coherent and all the strain caused by the phase change is taken up by the matrix. The new phase β is hard, the matrix α is soft. Nabarro, using the elasticity theory assuming elastic isotropy, computed the strain energy for expanding different-shaped holes hydrostatically. The holes were taken to be ellipsoids of revolution with a the long axis and b the short axis of the original ellipse. The axis of revolution is about b. The result of Nabarro's calculation is:

$$E \text{ (per unit vol.)} = K(\Delta V)^{1/3} f(b/a)$$

where K is the compressibility, ΔV is the difference in volume between the two phases and E is the energy.

E is least for a disk and maximum for a sphere. A low interfacial energy tends to favour a sphere; a large change in volume favours a disk. The equation appears to be applicable for an expansion or a contraction caused by the phase change. In the case of the high–low transformation the system is contracting. The volume change is relatively small, and being a simple displacive transformation the interfacial energy is probably low. It seems reasonable to expect low quartz to be slightly harder than high quartz; it has the same bonding system but a

more compact structure; high pressures certainly favour low quartz more than high quartz as the pressure–temperature diagram for silica shows. Both forms are, however, markedly anisotropic and this would influence the shape of the interface. An ellipsoid with three unequal axes would appear to be the most likely interface shape. This would influence the stress distribution in the crystal and the shape of the eventual sand grains.

If the alternative and apparently more likely assumption is accepted and a more or less simultaneous change of all relevant bond angles is postulated, a different approach must be made to the problem. It is observed that during the displacive high–low transformation the *c*/*a* ratio changes considerably. Fig. 3 shows the change in *c*/*a* ratio with temperature; the data are from Frondel[17]. As quartz cools from 800° C to about 50° C the *c*/*a* ratio changes from 1·0916 to 1·1000. If it is assumed that *c* stays constant, the volume change due to the change in *c*/*a* ratio can be calculated. The volume change is calculated with reference to a hexagonal prism and found to be 1·5 per cent. The value quoted[17] for contraction occurring at the high–low transformation is 0·86 per cent. This contraction can be accounted for by an increase in the *c*/*a* ratio from 1·0916 to 1·0950. This could virtually be achieved with an isothermal transformation at the high–low inversion point. It appears that the observed contraction at the high–low transformation could be accounted for by contraction about the *c*-axis caused by the change in bond angle at the oxygen atoms. The stresses caused by this type of contraction would act in a tensile manner perpendicular to the *c*-axis and would tend to cause cracks parallel to the *c*-axis and lead to elongated sand grains.

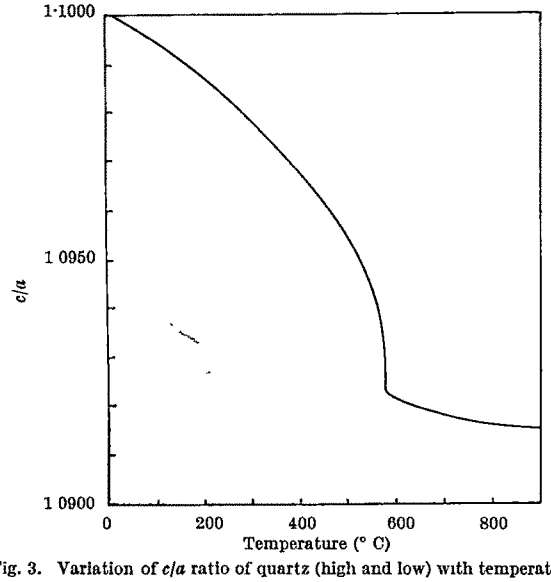

Fig. 3. Variation of *c*/*a* ratio of quartz (high and low) with temperature

Wayland[18] and Rowland[19] have observed that the quartz grains in sandstones tend to be elongated, and Wayland has noted a correlation between elongation and *c*-axis direction. Their observations and the suggestion that quartz particles fracture parallel to the *c*-axis led Ingerson and Ramisch[20] to carry out a series of abrasion tests on quartz. They also performed a statistical survey of the angles between *c*-axes and long axes of the grains of freshly crushed quartz and determined the relation of elongation to optic axis for much weathered but undisturbed quartzose rocks. They inferred that (1) quartz has no pronounced tendency to fracture parallel to the *c*-axis, (2) elongation parallel to the *c*-axis is not likely to be developed by differential abrasion, and (3) unbroken and unworn quartz grains show elongations parallel to the *c*-axis and the rhombohedron faces. They conclude that the elongation of quartz sand grains is due to the original shape rather than to fracture and differential abrasion during transport.

It may be that forces applied externally do not tend to fracture crystals parallel to the *c*-axis but that internal forces generated while the quartz crystal is part of a granitic system do cause this type of cracking. As a result, quartz grains would tend to be elongated in the *c*-axis direction.

There appear to be three factors which could influence the shape of quartz sand grains: (1) the shape of the original crystal in the igneous rock; (2) the possible distortion of this crystal by metamorphic action; and (3) internal stresses due to the high–low transformation and external stresses due to weathering. Abrasion during transportation does not materially affect the shape of the sand grain. Bokman[21] analysed the shapes of quartz crystals in source rocks and found that the mode elongation of quartz in granite was of the order of 1·3. The elongation of crystals in schists was much more marked. The elongation is expressed as an elongation quotient; this is the long axis/short axis ratio.

The metamorphic action which creates schistose rocks will account for the higher proportion of elongated quartz crystals and will therefore exert an influence on the shape of the eventual sand grain. The quartz crystals in granite are not shaped by such external forces but have more chance to form random shapes. A crystal growing in a magma system has a three-dimensional existence, and a measure of its shape can be gained by three measurements of length taken at right angles and referred to three orthogonal axes *a*, *b* and *c*. An ideal case can be considered where a limited number of lengths is possible. If each of *a*, *b* and *c* can have any integral value from 1–10 units the relative abundance of the different shapes can be calculated; the total number of solid figures possible is $(10)^3$; ten choices for each of three measurements. These can be classified into shapes using the Zingg system. There are ten configurations which fulfil the condition $a = b = c$; these fall into Zingg class 2. There are 720 configurations which fulfil the condition $a \neq b \neq c$; these fall into class 3. The remaining 270 configurations have tetragonal shapes and fall into classes 1 and 4. Thus, in this random model, Zingg class 3 shapes predominate; with an increasing number of available values for *a*, *b* and *c* the fraction of class 3 shapes increases.

If observations are made on crystals which have grown in a magma system or sedimentary particles formed by some random process one would expect the majority of them to possess the elongated shapes of class 3. This is what Bokman observed in granite. The random conditions required are more likely to be encountered in the formation of particles than in the formation of crystals, where the atomic structure and bonding of the crystal have considerable influence on the external form.

The size and shape of sand grains are largely determined at the moment the eutectic quartz solidifies in a cooling granite magma. The crack system encouraged by the stresses generated by the high–low transformation ensures a correlation between elongation and *c*-axis direction.

Schubert[22], among others, has stated that "sand is produced by continuous abrasion and action of sedimentary processes". There seems to be some confusion over the role of abrasion in the formation of sediments. Rogers, Kreuger and Krog[23] set out to show that abrasional methods of production of sand and silt are qualitatively different. If abrasion is caused by the mechanical action of one sediment unit on another it is difficult to see how it can contribute effectively to sand formation.

It is observed that there is a scarcity of certain particle sizes in sediments. Tanner[24] quotes 0·03–0·12 mm and 1·0–8·0 mm as the particular values. These effectively divide sediments into different types: gravel, sand and silt. The relevant units may be called blocks, grains and flakes. The experiments of Rogers *et al.* were designed to explain the scarcity of 0·03–0·12 particles by proving

that there are two distinct modes of abrasion, one giving sand (grains) and the other giving silt (flakes). So far as quartz sand is concerned, it seems more reasonable to suggest that abrasion plays no effective part in its formation. Its size is determined by the size of the eutectic quartz crystals in granites; its shape is determined largely by chance; its separation from the granite matrix and its final shaping are due to the combination of internal and external forces. The separation is materially aided by the tensile stresses in the quartz crystal caused by the contraction at the high–low transformation. If these stresses are concentrated inside the quartz crystal they will ensure that the grain splits cleanly away from the matrix when the crack caused by the weathering agency arrives. The glacier provides a powerful and efficient rock splitting action[25] and it seems likely that most of the quartz sand found in Britain and N. Europe is of glacial origin[26]. The problem of abrasion has been aptly summarized by Guilcher[27]: "There is no progressive change from one grade to another by gradual attrition: in particular, sand appears to be derived only to a small extent, if at all, from the reduction of shingle". Blocks and grains and flakes are formed by completely different mechanisms and it would be very surprising if a continuous distribution of size were observed.

The origin of sand cannot, with any confidence, be traced further back in time than the granite stage. From the sedimentological point of view this is a satisfactory starting point. A safe maxim is that the formation of a sediment should be traced back as far as is needed to establish the factors which influenced the properties of the detrital particles; this article is an attempt to do this, in outline, for quartz sand.

ARRANGEMENT OF ATOMS IN THE FIRST MONOLAYER OF NICKEL ON TUNGSTEN

By DR. J. P. JONES

Metallurgy Division, National Physical Laboratory, Teddington, Middlesex

AN investigation of the properties of adsorbed layers of copper on tungsten by field emission microscopy led to the suggestion that copper atoms in the first monolayer conformed exactly to the tungsten structure by taking up positions offered by the array of potential wells present at the tungsten surface. The observed maximum work function was attributed to the formation of a complete monolayer of copper–tungsten dipoles[1]. Some support for these suggestions has now been obtained by ion microscopy applied to nickel layers adsorbed on tungsten; for, like copper, nickel produces a maximum work function which can be attributed to a complete dipole layer (Fig. 1).

A bakable field ion microscope of conventional design has been used to obtain helium and neon ion images of nickel condensed on tungsten. A source of nickel was formed by enclosing a 3 mm length of Johnson-Matthey 'Specpure' nickel wire 0·5 mm diameter in a closely fitting helix of tungsten wire 0·25 mm diameter. The helix, supported on a tungsten-through-glass press seal, was situated 1·5 cm from the tungsten point. The tip, supported on a tungsten loop, was heated by direct current and temperatures were estimated by measuring the resistance of the central portion of the loop. The tip shank consisted of a length of tungsten wire 2 mm × 3 × 10^{-4} mm which constituted a thermal barrier, so that during evaporation of nickel at $T \sim 1{,}200°$ K radiant heating is calculated to have raised the temperature of the tip by 40° K at room temperature and somewhat less at 78° K.

After preliminary bake-out to attain a pressure $< 5 \times 10^{-9}$ torr, the tip was maintained at 1,600° K for 2 h in 10^{-2} torr pressure of purified hydrogen. Following bake-out at 400° C, helium was admitted, and the tip heated to 1,500° K for 2 min before final cleaning by field evaporation at 78° K, to produce the familiar evaporation end-form of tungsten. The helium was then pumped out and the surface examined by field emission to obtain Fowler–Nordheim data at pressures below 2×10^{-9} torr. With no field applied, nickel was then condensed on the tip maintained at a pre-selected temperature, and after

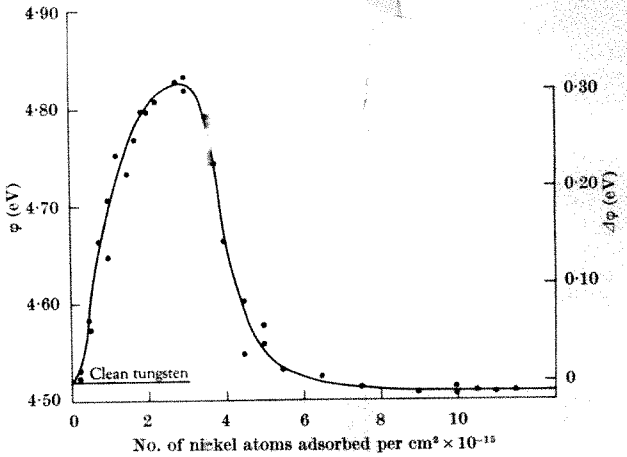

Fig. 1. Change in work function φ with amount of nickel condensed on to a clean tungsten point and spread uniformly over the surface

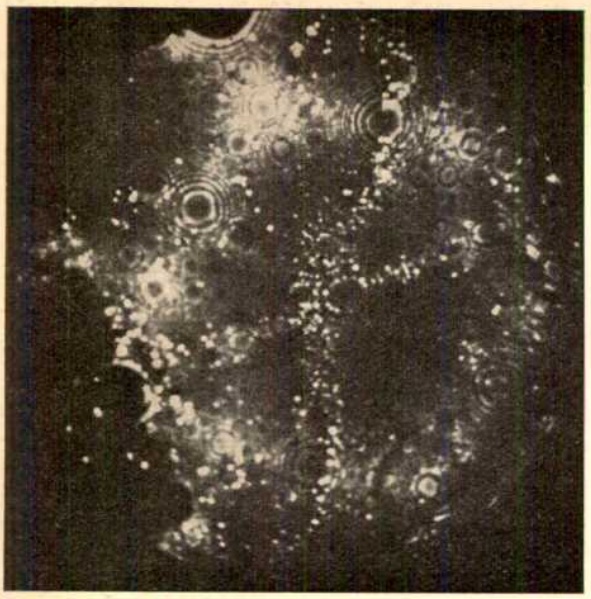

Fig. 2. An ordered nickel layer formed by condensation of vapour on to a tungsten tip cooled to 78° K. Second and higher layers of nickel are disordered and have been removed by field evaporation. Due to radiant heat from the nickel source the tip temperature during evaporation is calculated to have risen to ~118° K. (×1·2×10⁶)

examination of the deposit by field emission the tip was cooled to 78° K, neon admitted to $P \sim 2{\cdot}0 \times 10^{-3}$ torr, and the deposit examined by field ion microscopy.

Nickel condensed on to the tip cooled to 78° K showed no detectable order in the third and higher layers, and these fields evaporated at less than 9·5 kV to reveal a second layer having some degree of order. The second layer field evaporated at 10·5 kV, revealing a further layer of nickel which had a high degree of order and resembled closely the tungsten substrate except at the leading edge of the deposit (Fig. 2), where the adatom population decreased. With the tip held at room temperature, nickel atoms, which condensed to form the first monolayer, diffused forward to form a perfectly ordered layer over much of the visible surface. Second and higher layers exhibited little order and field evaporation revealed the final layer. Field evaporation of this final layer occurred first from {111} (Fig. 3*b*) at a field strength of about 3·1 V/Å and progressed inwards towards the central 110 plane as the field was increased (Fig. 3*c*). Gold condensed on tungsten has been observed to form a similar well-ordered layer[2]. The surface remaining after complete evaporation contained atoms that were clearly not part of the original surface but which nevertheless withstood fields up to that required to evaporate tungsten itself. They are thought to be tungsten atoms, but their origin is uncertain.

In order to obtain Fowler–Nordheim data, nickel was condensed on to the tip at 430° K. This temperature allowed complete coverage of the emitting areas by nickel and was sufficiently low to ensure stability of the tungsten surface during the experiment[3]. Considerable order was observed in the second and third layers, and the first layer was readily isolated by field evaporation of those overlying it. The first layer exhibited slightly less perfection than first layers formed at lower temperatures. Fowler–Nordheim data on clean tungsten obtained before and after deposition of nickel, together with data obtained for the isolated monolayer, showed that the nickel layer

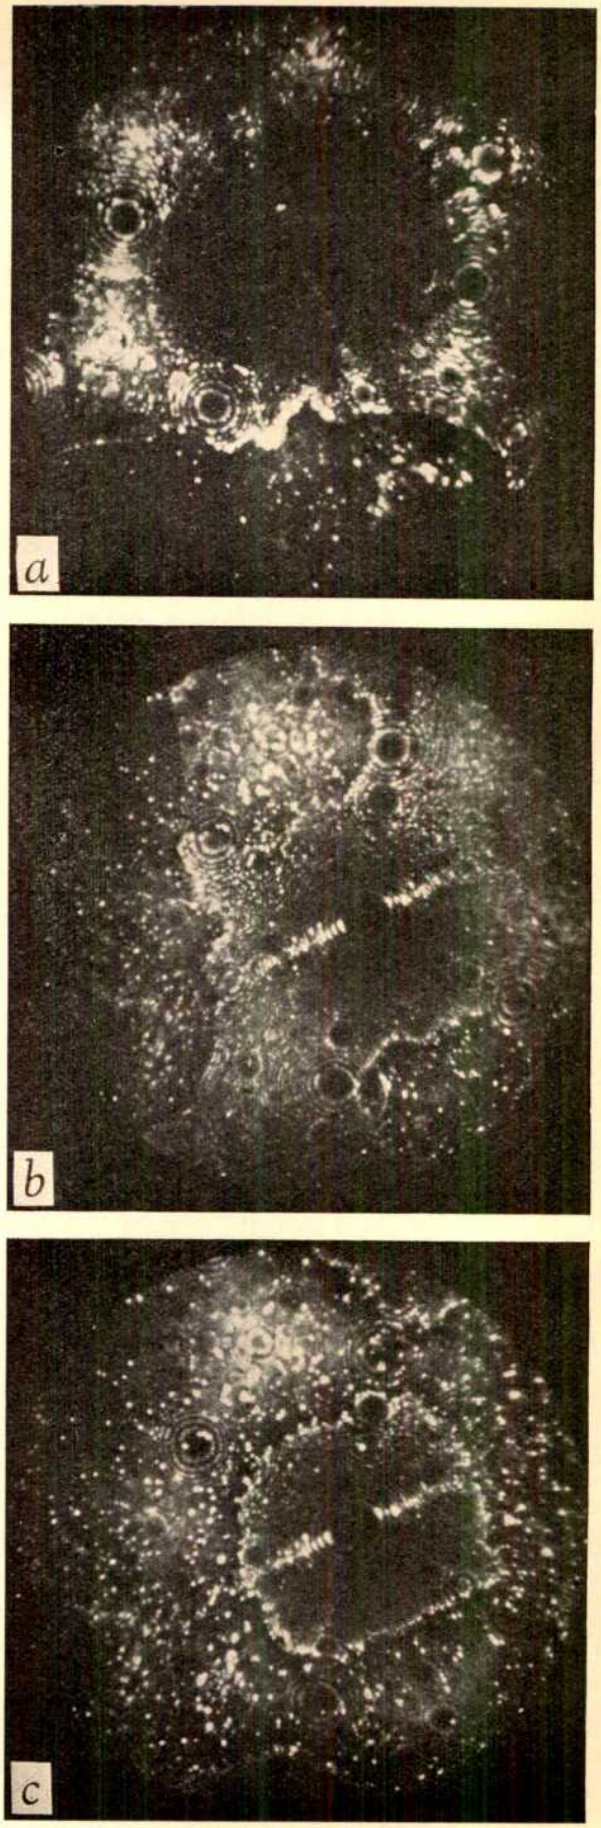

Fig. 3. *a*, The first monolayer of nickel, obtained by condensation on to a tip at 300° K, retains its ordered appearance up to the leading edge of the layer, which has spread by diffusion beyond the directly accessible target area. *b*, Field evaporation of the first monolayer at 78° K has removed nickel from {111} and their environs at a field strength of ~3·1 V/Å. *c*, With increasing voltage, field evaporation progresses by removal of atoms from the edges of the nickel layer which thus shrinks in towards the central 110 plane. (*a*, *b* and *c*, ×1·2×10⁶)

increased the work function by 0·27 ± 0·03 eV. This supports the belief that the maximum in Fig. 1 resulted from adsorption of one monolayer of nickel. It should be added that the good agreement between the work function change obtained on field evaporated tungsten and that observed on thermally cleaned tungsten (Fig. 1) is consonant with other observations of the similarity between the two forms of surface[4].

Current nucleation theory[5,6] is based on the belief that condensed material forms isolated nuclei which have the structure of bulk condensate. As applied to the condensation of gold[2] and nickel on tungsten the theory now requires some modification to take account of the formation of at least one, and possibly more, continuous monolayers of condensate on the surface, before nucleation takes place. The ordering achieved at 118° K would seem to imply that condensing nickel atoms make at least one atom jump before finally coming to rest on the tungsten surface[7].

I thank Dr. T. I. Barry for helpful discussion.

PHOTO-OXIDATION OF ORGANIC MATTER IN SEA WATER BY ULTRA-VIOLET RADIATION, ANALYTICAL AND OTHER APPLICATIONS

By F. A. J. ARMSTRONG*, P. M. WILLIAMS and J. D. H. STRICKLAND
Institute of Marine Resources, University of California, La Jolla, California

Following on the observations of Beattie *et al.*[1] that organic matter in fresh water could be oxidized to carbon dioxide on exposure of samples to radiation from a medium-pressure mercury vapour lamp, we found that exposure of sea water to such a light source caused a decrease in the extinction coefficient at 2000–2500 Å, characteristic of the presence of organic matter. This behaviour, indicative of the rapid oxidation of at least some of the organic material in sea water, led us further to examine the laboratory applications of high intensity ultra-violet radiation to analytical and other problems associated with the presence of dissolved organic matter in the sea. These preliminary findings may be of interest to workers investigating sea water chemistry as well as to others concerned with dilute aqueous solutions of organic matter.

In the work described here samples were irradiated by a 1,200-W mercury arc tube (Hanovia Engelhardt '189 *A*'), 30 cm in length mounted axially in a vertical aluminium cylinder 50 cm high and 20 cm in diameter. An air extractor fan at the lower end of the cylinder provided cooling. Dimming of the discharge through excessive cooling of the lamp was avoided by using a 4·5-cm diameter jacket of fused silica around the lamp. A small-bore silica tube delivered a stream of filtered air to the bottom of this jacket to carry off some of the heat produced by the lamp. Samples for irradiation were contained in stoppered fused silica tubes 35 cm long and 2·5 cm in diameter (containing about 110 ml.), twelve of which could be set parallel to the lamp and equidistant 7 cm from it. The temperature of samples stabilized at 60°–80° C at the tops of the tubes after prolonged irradiation.

The actinic energy incident on the samples was measured by oxalate actinometry[2] and was found to lie between 0·20 and 0·25 W/cm², some variation between tubes being found. The total actinic energy intercepted by twelve full tubes was therefore about 200 W out of some 400 W radiated in the range 2000–4400 Å (from the manufacturer's data). However, since the absorption of sea water is only appreciable below about 2500 Å, it can be calculated that only some 10 per cent of the incident actinic energy can be absorbed by the samples, at least one-half of this being at wave-lengths shorter than 2500 Å. That this was the more effective radiation was demonstrated by irradiation of samples in a 'Vycor' tube, which cuts off radiation of wave-lengths shorter than about 2400 Å. The oxidation reactions described here were then markedly slower.

* On leave from the Marine Biological Association, Citadel Hill, Plymouth.

Oxidation of Carbon in Organic Matter

The method of Menzel and Vaccaro[3] for the determination of dissolved organic carbon in sea water, rarely present in amounts outside the range 0·4–1·5 mg carbon/l., has been used by us to check the amounts of carbon left in sea water after irradiation with ultra-violet light.

In sea water the oxidation of organic matter followed first-order kinetics with respect to carbon, with a rate constant of about 0 05/min. Oxidation was effectively complete within 1 h with all samples of sea water that we have investigated.

To assess the percentage oxidation of various classes of organic compounds these were added to give concentrations of 1–2 mg of carbon/l. in artificial sea water Samples were irradiated and the residual organic carbon determined.

The following compounds were oxidized substantially to completion with a 2–3 h irradiation period: pyridine, 2,2'-bipyridine, adenine, ethyl alcohol, methyl alcohol, glucose, glucosamine, acetic and oxalic acid, formic acid, palmitic acid, dimethylamine, casein, glycerol, phenylalanine and "humic acid". Urea, on the other hand, was decomposed only to the extent of 50 per cent or less, even with the addition of hydrogen peroxide to the water as a source of excess oxygen The surprising behaviour of this compound was confirmed by the low oxidation rate of nitrogen. Palit and Dhar[4] reported incomplete oxidation of urea in experiments on the photodecomposition of organic compounds sensitized with zinc and ferric ions aerated and exposed to sunlight over long periods, but we would not have predicted our results and cannot explain them. Simple hydrolysis of urea does not occur to any extent at the hydrogen ion concentrations used here (*p*H 8).

The use of photosensitizers, such as Fe^{3+} and UO^{2+}_2 was not investigated. Heckler[5] has shown that carbon dioxide is the main product in the UO^{2+}_2-sensitized photodecomposition at 2537 Å of organic acids in solution, where carbon monoxide, hydrogen, methane and ethane are produced in lesser amounts.

The presence of appreciable quantities of end products other than carbon dioxide is contra-indicated in our work. Measurements of the decrease in *p*H after irradiation of known compounds in sea water gave values which corresponded with those calculated for the stoichiometric addition of carbon dioxide to the system. For example, the change in *p*H for sea water samples having a concentration of 1 mg of carbon/l. was of the order of 0·250 *p*H units.

If corrections are applied for the increase of hydrogen ion concentration due to the oxidation of dissolved organic nitrogen to NO_3^- and NO_2^-, then *p*H changes may be used as a rapid and fairly precise measure of dissolved organic carbon in sea water samples and such a method would be applicable to monitoring continuous flow systems.

Liberation of Inorganic Phosphate from Organic Phosphorus Compounds

Organically combined phosphorus in sea water (generally present between zero and about 30 μg/l.) has till now been estimated from the difference between two determinations of inorganic phosphate, the one on a sea-water sample after the destruction or hydrolysis of organic matter and the other on an untreated sample. Organic matter is generally destroyed by modifications of methods requiring wet oxidation with perchloric acid[6] or necessitating an autoclave treatment with sulphuric acid[7]. These methods are tedious and their precision is poor because of the difficulties of controlling contamination introduced by the reagents used to destroy organic matter. It has never been certain whether or not these procedures give interference from any inorganic polyphosphates that might be present in the sea, as these compounds would be depolymerized by the processes used to degrade organic matter and would then react with molybdate.

By contrast, exposure of sea water to ultra-violet irradiation liberates phosphorus as inorganic phosphate from organic matter rapidly and without the necessity of adding any reagents except one or two drops of 30 per cent hydrogen peroxide introduced to ensure the presence of an excess of oxygen. The method of Murphy and Riley[8] now enables *ortho*phosphate to be determined in sea water with a high precision (σ of 0·2 or less on 10 μg of phosphorus/l.) so that the differences of phosphate concentration found between irradiated and non-irradiated samples give a measure of the organically combined phosphorus present in filtered sea water with a precision far exceeding that of any analyses previously obtained. Even in deep ocean water one can detect with confidence as little as 0·5 μg organically combined phosphorus/l.

The method has been checked by us by adding phosphorus-containing organic matter to artificial sea water at concentrations of about 100 μg of phosphorus/l. and irradiating the solutions for known times before determining *ortho*phosphate in the water. Solutions of RNA were completely degraded to give the theoretical yield of inorganic phosphate after about 20 min of irradiation. For surety, 1–2 h exposure has been used with natural samples. After such a period we found complete mineralization to *ortho*phosphate of the phosphorus present in known additions of β-glycerophosphate, ribose-5-phosphate, RNA, choline phosphate and 2-aminoethanephosphonic acid (containing a carbon–phosphorus bond). In view of the destruction of these compounds, in particular the last two, it seemed pointless to test many other substances, but a trial was made with several linear inorganic polyphosphates with between three and seventy phosphorus atoms in the chain and also adenosine triphosphate with a polyphosphate group attached to an organic molecule. None of these compounds liberated any *ortho*phosphate, so that it can be assumed that ultra-violet radiation of the wave-lengths used does not bring about a significant degree of depolymerization and hydrolysis of inorganic phosphate polymers and that the phosphate liberated in sea water by ultra-violet irradiation must be present initially only in the form of organic esters. A detailed profile of organically combined phosphorus present in the sea off southern California is shown in Fig. 1.

Oxidation of Organic Nitrogen Compounds

Soluble nitrogenous matter and the ammonium ion in sea water were oxidized by dissolved oxygen, under the influence of the ultra-violet radiation used here, to give what we believe to be initially a quantitative yield of the nitrate and nitrite anions.

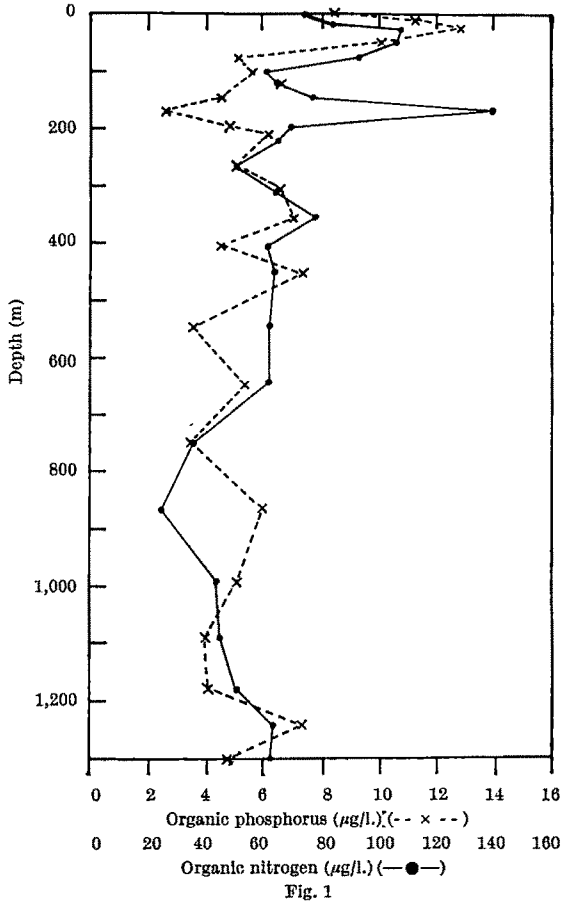

Fig. 1

It has been reported that ammonia can be photo-oxidized to nitrate and nitrite[9,10] and, therefore, because oxidative deamination occurs at an early stage in the photolysis of organic nitrogen compounds[11] nitrate and nitrite can be expected as end products of the irradiation experiments.

There are reports in the early literature[12,13] that sea water samples enriched with ammonium ion and exposed to sunlight yield nitrite, but a more recent investigation[14] did not confirm this.

The reduction of nitrate to nitrite is well documented for photolysis of solutions with or without ammonia or organic compounds present as reducing agents[15–18]. Such reactions have often been promoted by the presence of surfaces of tin, iron or titanium oxides[19,20] or by adding uranium or transition metal ions to the solution as photosensitizers. There is no information available in the literature on the products of exhaustive irradiation of small concentrations of organic matter in the presence of excess oxygen such as was undertaken in this work.

The method of Morris and Riley[21] for nitrate in sea water as modified by Strickland and Parsons[22] enables a rapid analysis to be made for this anion with high precision (σ of 3 or less on 200 μg of nitrate nitrogen/l.). The method consists essentially in passing sea water through a column of amalgamated cadmium filings and determining the resulting nitrite colorimetrically. Nitrate is reduced to nitrite with a yield in excess of 90 per cent, but any nitrite present initially in the sea water passes through the column unchanged.

The nitrogen in organic nitrogen compounds is first oxidized almost completely to nitrate which is then slowly reduced to nitrite on further irradiation. After 3 h about

30 per cent of the total nitrogen is present as nitrite. We have no explanation for this behaviour, which we have confirmed, but which clearly requires a major investigation for its elucidation.

We have made a preliminary investigation of the kinetics of the oxidation of organically combined trivalent nitrogen to give nitrate, using 2-2′-bipyridine, a convenient nitrogenous base in which the element is strongly bonded in a cyclic system. The rate of oxidation of amounts equivalent to about 200 μg organic nitrogen/l. in well-oxygenated water was found to be first order with a rate constant of about 0·03/min, which is appreciably slower than the carbon oxidation. The formation of nitrate was effectively complete in 2–3 h. Hydrogen ion concentration had no effect below *p*H 8, but above this value the reaction rate decreased, as if the ammonium or a similar ion, but not the corresponding hydroxide, were being attacked. (The ammonium ion, however, when added as such to sea water was oxidized considerably more rapidly than was organically combined nitrogen.)

Oxygen is required for nitrate formation and neither nitrite or nitrate is produced unless sufficient dissolved oxygen is present to oxidize all carbon compounds. Excess oxygen then becomes available for nitrate production by a reaction which is rate dependent on oxygen concentration raised to a fractional order of about 0·25. It is desirable, therefore, to have solutions saturated with oxygen and to this end we have added one or two drops of 30 per cent hydrogen peroxide of analytical reagent quality to each 100 ml. of sea water. This addition ensures the supersaturation of all samples with oxygen. Excess hydrogen peroxide appears to be rapidly decomposed and after 1 or 2 h of irradiation it cannot be detected.

Under these conditions solutions of ammonium chloride, 2-2′-bipyridine, casein, thiourea, adenine, guanidine, and even pyridine were quantitatively oxidized after 3 h of irradiation and, especially in view of the refractory nature of pyridine, we feel little doubt that most likely nitrogenous compounds dissolved in the sea would be transformed to give nitrate. It was interesting, however, to note that the behaviour of urea was again anomalous and this compound was only partially oxidized to give nitrate after an exposure time found adequate for the other substances. The resulting method is incomparably more rapid and precise than any existing method for determining organic nitrogen in sea water and enables detailed and reliable profiles like that shown in Fig. 1 to be obtained easily.

Other Uses

Several important applications of this technique for the destruction of organic matter in sea water can be envisaged, some of which have already been given a preliminary trial in our laboratories.

The ability to destroy all organic matter is of particular value in culture, nutrition and vitamin assay studies; water which is free from all organic growth factors and inhibitors can easily be delivered from a suitably constructed assembly at a rate of many litres an hour. The irradiated water contains no oxidants capable of liberating iodine from acidified iodide and appears to be usable for culture purposes with no further treatment or, at most, after only a brief treatment in an autoclave.

Most metallo-organic complexes should be readily decomposed by ultra-violet irradiation making for more definitive analyses of the total concentration of metal ion in sea water. By liberating metal ions in this manner from organic complexes they would be easily removed by subsequent complexing with standard organic reagents such as dithizone and separation of these new complexes by solvent extraction. Any excess of organic reagent could then be destroyed by irradiation in the presence of excess hydrogen peroxide, giving a sample completely free from organic compounds and from specific inorganic ions of nutritional significance.

We anticipate using ultra-violet irradiation in a continuous-flow system to combust the dissolved organic matter in several thousand litres of sea water in order to obtain carbon dioxide for radioactive dating. The problem of scavenging this organic material quantitatively from sea water in sufficient amounts for the purpose of dating has not, until now, been solved.

Finally, algal suspensions (marine diatoms) in the presence of peroxide can be destroyed and the carbon and nitrogen oxidized quantitatively during an overnight irradiation in the apparatus herein described. This technique has interesting possibilities for the rapid elemental analysis of cell suspensions without the necessity of preliminary filtration and washing which can lead to cell destruction and other difficulties.

We thank Patricia M. Strack for analytical assistance. This work was supported in full by a contract from the U.S. Atomic Energy Commission.

Use of Ultra-violet-irradiated Sea Water in the Preparation of Culture Media

SERIOUS difficulties are encountered in the culture of marine bacteria and algae, as well as in investigations of their physiology, on account of the toxic effects of natural sea-waters[1–5]. In order to overcome such effects the use of 'aged' sea-water in the preparation of media has been recommended[6]. However, such 'aged' water still contains unspecified amounts and types of organic matter and its behaviour is far from being reproducible for physiological investigations. In attempts to obtain reproducible organic-free media, artificial sea-waters have been used[3,7], but it has recently been demonstrated that artificial sea-water can also be inhibitory[8,9]. More recently, a charcoal-treatment of sea-water has been shown to be an effective method of preparing waters free from certain classes of metabolites[10]. However, this method has limited application as the complete removal of organic matter is not possible. Armstrong *et al.*[11] irradiated sea-water with a high-energy ultra-violet light source and found that its content of organic matter was reduced below detectable levels. It seemed reasonable to suppose that if this treatment produced no toxic by-products it would have application to investigations now in progress in these laboratories on vitamin B_{12} assays of natural waters and the kinetics of organic matter uptake by marine bacteria, as well as to the culture of marine bacteria and algae in general.

Sea-water was irradiated with ultra-violet light in the manner described by Armstrong *et al.*[11] for 2–4 h. This irradiation sterilizes the water and all subsequent handling of the water was, therefore, performed aseptically. Samples were not autoclaved unless specifically noted.

As a preliminary investigation into the possible toxicity of irradiated water, cultures of marine bacteria and algae were grown in media prepared with natural and irradiated natural sea-waters and observed for gross differences in growth behaviour. Shake-tube cultures of a marine pseudomonad were made in a medium containing glucose, ammonia and inorganic phosphate. The cultures were incubated at room temperature and their growth determined turbidimetrically. Growth curves of bacteria in the irradiated water showed no significant deviations from those observed in the natural sea-water cultures. Cultures of the diatom *Skeletonema costatum* and chrysophyte *Monochrysis lutheri* were grown in the same medium used for their routine maintenance in this laboratory. The medium was prepared with enriched natural sea-water, which had been shown to be suitable for their culture, and with an enriched irradiated sample of the same water. On one occasion there appeared to be a slightly lower initial growth rate in the medium made with irradiated sea-water, but this effect did not appear in subsequent experiments. Microscopic examination showed the algae cells to be normal in all respects in both experiments.

Sea-water samples are routinely assayed in our laboratories for the presence of vitamin B_{12} using the marine centric diatom *Cyclotella nana*. External standards of known B_{12} concentrations serve as the calibration values and are prepared in charcoal-treated[10] sea-water. Known amounts of crystalline vitamin B_{12} were added to media prepared with irradiated sea-water, irradiated sea-water which had been autoclaved (5 min at 15 lb.), and charcoal-treated sea-water. The growth response of *C. nana* in each of these waters was determined by measuring the incorporation of carbon-14 dioxide after a 2-h exposure to the isotope following a 47-h incubation. The growth response was shown to be a function of vitamin B_{12} concentration[10]. At all the concentrations tested there was little difference in the carbon-14 dioxide uptake rate in each of the media. In an earlier experiment, however, the uptake rate of carbon-14 dioxide in irradiated sea-water had been found to be about 80 per cent that in charcoal-treated sea-water. The slight inhibition found with this irradiated sea-water was overcome by a short autoclaving which may be a desirable precaution when using irradiated water for preparing standards for vitamin bioassaying.

An investigation into the kinetics of the uptake of organic matter by marine bacteria is in progress in this laboratory. The methods being used are similar to those described by Wright and Hobbie[12] where the velocity of substrate assimilation is measured over a range of substrate concentrations. The curves thus obtained and the mathematical constants describing them are extremely sensitive to the physiological state of the bacterial cells. Artificial sea-water has been used because of the possible presence of the metabolite under investigation in natural sea-water. We have compared the uptake velocity by a pure culture under rigidly standardized conditions in artificial and irradiated natural sea-waters. The two curves were identical at lower substrate concentrations. At higher concentrations, however, there was a slightly lower maximum velocity in media made with irradiated sea-water. It is probable that a short autoclaving treatment, as was performed with the B_{12} assay media, would have eliminated this effect.

While it is acknowledged that these results are preliminary in nature, they indicate that sea-water treated by the method of Armstrong *et al.*[11] may be used in the preparation of media for marine microbiological studies. On the basis of two different tests, both of which were extremely sensitive to inhibitory effects, it appears that the level of toxic by-products is very low or non-existent. Irradiation produces water of a quality equivalent to that obtained by charcoal treatment for vitamin B_{12} bioassay. There appears to be no reason why waters treated by this method could not be used, in preference to artificial and charcoal-treated sea-waters, in investigations of marine microbial physiology.

EFFECTS OF ULTRA-VIOLET ALONE AND SIMULATED SOLAR ULTRA-VIOLET RADIATION ON THE LEAVES OF HIGHER PLANTS

By DR. MORRIS G. CLINE
Division of Biology, California Institute of Technology,
Pasadena, California
AND
DR. FRANK B. SALISBURY
Plant Science Department, Utah State University,
Logan, Utah

ONE of the factors often cited[1,1a] to support the idea that earth-type organisms could not survive the environment on Mars is the postulated occurrence of relatively high levels of ultra-violet radiation in the light which impinges on the surface of the planet. This, together with the recent *Mariner* photos of Mars, and the possible use of plants in bio-regenerative systems in space, adds new impetus to the question of the relative resistance of plants to ultra-violet radiation, as the ultra-violet light present in unfiltered solar radiation occurs at levels which are considered harmful to most living organisms. The deleterious effects of ultra-violet light on higher green

plants have been investigated for nearly three-quarters of a century[2,3].

Leaves and flowers are generally the most sensitive plant organs. Leaves respond to ultra-violet light by turning a bronze or dark colour and sometimes appearing shiny. If the radiation dose is sufficient, the leaf will die. Despite this, many plants will recover by sending out new shoots when they are returned to a normal environment. Ultra-violet radiation does not penetrate deeply; thus roots and, to a lesser extent, stems are protected by soil and by bark. Extended periods of high-intensity ultra-violet radiation will eventually kill most plants, but the exact cause of injury is not known. Present lines of investigation indicate that it may involve the formation of poisonous peroxides[4] and the deactivation of nucleic acids[5] and proteins.

Investigations[6] are being carried out at Colorado State University to determine the relative resistances of a wide variety of plants to ultra-violet alone and to a high-intensity simulated solar spectrum. Possible adaptive mechanisms are also being considered. Although several approaches are being taken, the present article is concerned with two leaf survival experiments involving a total of sixty-seven species with special emphasis on *Xanthium pennsylvanicum*, *Zea mays* and *Pinus nigra*.

The first experiment was concerned with a survey for resistance among widely diverse species of the plant kingdom carried out with a germicidal lamp (Sylvania 15 W, low-pressure mercury arc—90 per cent of its energy is at 2537 Å). The second experiment was an investigation of resistance to ultra-violet in the presence of a complete, simulated solar spectrum (high-pressure xenon arc). The total emitted radiation has been measured with a thermopiler adiometer (Colorado Research and Engineering Inc., Boulder, Colo.). So far as is known, these are the first such surveys of this type which have been made since the development of the germicidal lamp and the xenon arc.

In the first experiment there was an extremely wide variation in the resistance of the sixty-seven different species tested. Leaves of young seedlings of *Pharbitis nil* were killed with less than 1 cal/cm² of germicidal light, whereas leaf blades of week-old corn seedlings required over 33 cal/cm². The lethal exposure for young needles of ponderosa pine was about 800 cal/cm². It should be emphasized that these lethal exposures do not refer to that quantity of radiation necessary to kill all foliage on the plant but only the uppermost leaves or needles. For corn it refers only to the exposed portions of the leaf blade and not to the sheath. Leaves were examined for damage within several days after irradiation. A leaf was considered to have been killed if it showed significant signs of curling, of colour change to yellow or brown, and of drying.

In the second experiment, a 2,500-W high-pressure xenon arc lamp (Osram Co.) was used as the light source. The spectral distribution of emitted light (especially in the ultra-violet) was quite similar to that of unfiltered solar radiation above the Earth's atmosphere[7]. The radiation emitted from the lamp was projected on to the plants (*Xanthium*, *Zea* and *Pinus nigra*), placed in a wind tunnel. In this experiment no filters were used. The total radiation levels used were 0·86, 2·00 and 3·82 cal/cm²/min. These intensities occurred at various distances from the focus of the arc and are equivalent to those above the atmosphere of Mars, Earth and Venus, respectively[8]. Two pots of plants could be tested at each of the three radiation levels simultaneously. A total of eighteen cocklebur plants (eighteen pots), about eighty corn plants (nine pots), and six 11-in. pine seedlings (six containers) were tested.

The only purpose of the wind tunnel in this experiment was to keep the leaf temperatures below a lethal level. Air temperatures ranged between 21° and 23° C. Wind velocity averaged about 6 m.p.h. Leaf surface temperatures (Table 1) were well below the lethal point for the three species. The plants were usually irradiated for 13–16 h each consecutive day. No attempt was made to simulate precise photo-periods, gravity effects, or gas composition or pressure of the Martian or other environments.

Table 1. LEAF SURFACE TEMPERATURES (°C) IN SECOND EXPERIMENT AS MEASURED BY COPPER-CONSTANTAN THERMOCOUPLES

	Radiation-level (cal/cm²/min)	*Xanthium*	*Zea*	*Pinus*
Martian	0 86	24	22–23	22·5–25
Terrestrial	2·00	27–32	25–28	22·5–26
Venusian	3 82	24–30	24–28	23–27

It was sometimes difficult to determine the exact radiation exposure necessary for the death of an entire leaf. Thus, the values presented in Fig. 1 are approximate. *Xanthium* leaves were killed after only 1·8 h of Venusian-level radiation, whereas leaf-kill by Martian-level radiation required about 4·5 h. The shoots of week-old *Zea* plants were significantly more resistant. The destruction of the exposed portions of these corn leaf blades required 8 h of Venusian radiation and about 32 h of Martian radiation. *Pinus* seedlings were exceedingly resistant. The newly-sprouted Austrian Pine shoots did not show serious

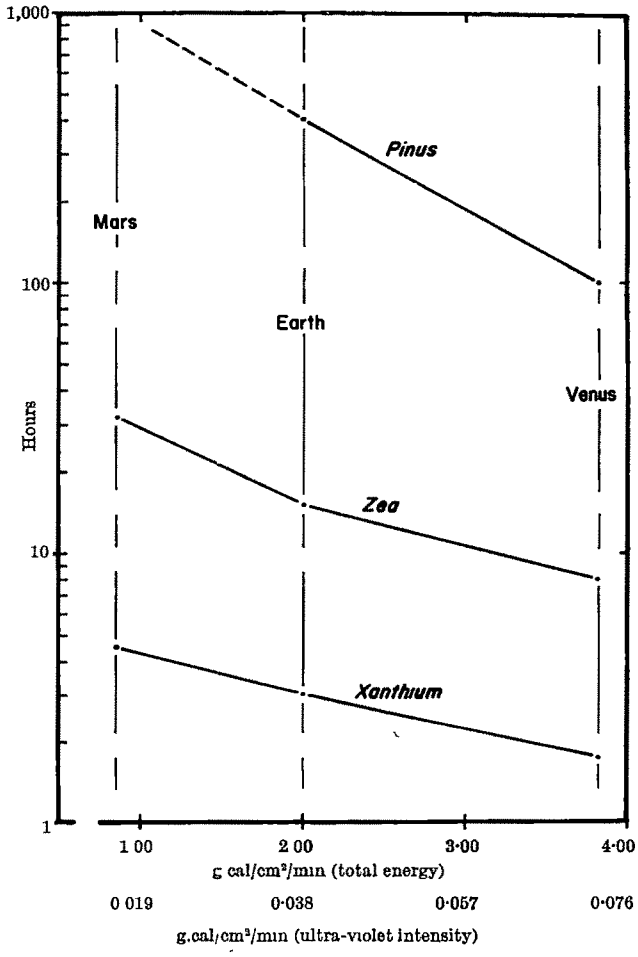

Fig. 1 Leaf survival time under different intensities of extra-terrestrial solar radiation in the second experiment. The values on the upper scale refer to the total simulated solar energy as measured; whereas those below refer only to the ultra-violet portion ($\lambda = 2000$–2900 Å) which was 1·9 per cent as determined by an analysis of the xenon spectral curve published by the General Electric Co. for 5-kW lamps (Large Lamp Dept, Nela Park, Cleveland, Ohio, 1962). The *Pinus* curve has been extrapolated to indicate its probable resistance to higher doses based on the fact that there was only slight damage after 635 h at the termination of the experiment

damage until after nearly 100 h of Venusian radiation. In this case there appeared to be evidence suggesting that a significant portion of the injury was not due to ultra-violet light but rather to water stress in the needles. Thus, the estimate is probably low. Nearly 400 h (30 days) were required to bring about serious damage to the needles of the plants at terrestrial radiation-levels, but at the Martian level there was an almost complete absence of damage in seedlings after 635 h (44 days) of irradiation.

In both experiments, nearly all tests were repeated except for the long investigation with *Pinus nigra*. For most species the results of the second treatment closely duplicated those of the first.

A fascinating aspect of the role of possible protective adaptations against ultra-violet damage in plants is the reversal of such damage by subsequent visible light. This is known to occur in a wide variety of organisms[9]. In the present investigation, photoreversal was found by the method of Tanada and Hendricks[10] in *Xanthium* leaves with both germicidal light (0·019 cal/cm of ultra-violet alone) and xenon light (8·4 cal/cm² total energy including ultra-violet, high-intensity visible and infra-red) followed by about 4 h of outdoor sunlight. The ultra-violet exposures already mentioned were near the maximum for reversal. When the exposures given were much larger than these values then the damage was not reversed. The significance of photoreversal in space is still largely unknown, but the effect could be an important one.

An interesting feature of the Martian atmosphere is the presence of a high violet layer (the 'blue haze') which is thought to be opaque to a considerable portion of the ultra-violet component of sunlight[11,12]. Occasionally this blue haze clears for a week or so, apparently allowing a considerable increase in the ultra-violet penetration through the atmosphere. A 10-day clearing in the blue haze (14·5-h days) would represent about 145 h of irradiation, or less than a fourth of the total time (635 h) used in this experiment. Furthermore, the total radiation on any particular Martian 'plant' would average considerably below 0·86 cal/cm²/min, mainly owing to the diurnal fluctuation, but also owing to latitudinal differences on the planet, some remaining atmospheric scattering, and mutual shading. Even certain earthly plants could, then, be expected to survive the ultra-violet bombardment during a blue clearing on Mars. Some of these (such as *Pinus nigra*, *Pinus ponderosa*, and *Agave* sp.) might even survive well if the blue haze were less opaque than is at present assumed[1a].

These investigations were supported by a grant from the National Aeronautics and Space Administration. We thank G. I. Connor for his valuable assistance.

DISCRIMINATING POWER OF RODENT DEOXYRIBONUCLEIC ACID ON INCUBATION IN AGAR

By DR. ANNE McLAREN
Agricultural Research Council Unit of Animal Genetics, Institute of Animal Genetics, Edinburgh
AND
DR. P. M. B. WALKER
Chemical Biology Unit, Department of Zoology, University of Edinburgh

THE discovery[1] that denatured deoxyribonucleic acid (DNA) from higher organisms can be trapped in an agar gel, and used to combine specifically with DNA fragments from similar or different sources, enabled the genetic approach, pioneered by Doty and his group[2] in bacteria, to be extended to mammals. Using this technique, Hoyer, McCarthy and Bolton[1] demonstrated a difference between radioactively labelled DNA fragments from mouse and man: human fragments bound better than mouse on to human or monkey DNA; mouse bound better than human on to mouse, rat or hamster DNA.

We have been concerned to explore further both the limitations and the possibilities of this technique[3,4]. There seems little doubt that the degree of binding between samples of DNA from different organisms at least in part reflects similarities in base sequence, which in turn reflect genetic relationships. The failure of more than about a third of the fragments to be bound to the trapped DNA, even when both are derived from the same source, is due to a true heterogeneity among the initial population of fragments[3]. For this reason, the proportion of fragments bound cannot be relied on to give a quantitative estimate of genetic relatedness. Further, different samples of DNA differ non-specifically in their binding capacity for fragments from any source[4]. Two species can therefore only be compared if labelled fragments are available from both, so that within-species and between-species binding can be tested on the same sample of DNA-agar. In the initial study of Hoyer *et al.*[1], labelled fragments were available from mouse and man only; thus the relationships between the various rodent species could not be examined.

Despite these drawbacks, the technique has made it possible for the first time to make qualitative distinctions between the DNA from different vertebrate species. But if common ground with traditional genetic methods is to be sought, the discriminating power of the DNA-agar technique will need to be very greatly increased, so as to bring more closely related groups within its scope. To this end, we have selected a single pair of fairly closely related species, laboratory mice (*Mus musculus* L.) and rats (*Rattus norvegicus* L.), and used it as a model on which to test a number of possible approaches to the problem of increasing the resolving power of the technique.

DNA is extracted[3] from liver or testis, from primary cell cultures of embryonic tissue, or from long-established cell strains; it is then denatured, trapped in agar,

sieved and washed[1]. To prepare DNA fragments, the cell cultures are labelled with radioactive phosphorus or tritium and, once extracted, the DNA is broken up with ultrasonic treatment and then denatured. DNA-agar is mixed with fragments in a water-jacketed column, kept usually at 60° C, and incubated overnight[3]. Unbound fragments are washed off at a high salt concentration; the temperature is then raised and the salt concentration lowered so as to elute the bound fragments. The result of an incubation is expressed as the percentage of the total radioactivity which is washed out at the higher temperature.

Discriminating between Mouse and Rat DNA

Initially we tried two approaches, which we termed "blocking" and "fractionation". If the DNA trapped in agar is exposed to an excess of unlabelled fragments from the other species, all shared binding sites should in theory be blocked. Labelled fragments added afterwards from the other species should be unable to find binding sites, and should therefore be rejected, while those from the same species should still be bound, though the number of available sites will, of course, be reduced. The discriminating power of the technique should thus be increased. In practice this proved to be so[4], but only to a rather small extent, owing to the difficulty of saturating more than a small proportion of the shared binding sites.

Table 1. Binding Ability and Discriminating Power of DNA Fragments during Three Successive Cycles of Incubation

Fraction selected from between-species incubation		Cycle 1	2	3
Bound	Within-species binding (per cent)	33	42	48
	Between-species binding (per cent)	23	35	47
	Discrimination (per cent)	30	17	2
Unbound	Within-species binding (per cent)	33	20	17
	Between-species binding (per cent)	23	8	5
	Discrimination (per cent)	30	60	71

For the second and third cycles, either the bound or the unbound fraction from the previous between-species incubation was taken. For each within- or between-species estimation in this and other tables, both mouse and rat fragments were used, and the binding percentages averaged. "Discrimination" is calculated as the percentage by which between-species binding falls short of within-species binding.

More effective discrimination was achieved when the DNA fragments were fractionated by means of successive between-species incubations. Those fragments which are bound by the DNA of the other species should preferentially contain shared sequences, and should therefore discriminate less well on a second incubation, while those which are rejected should include the species-specific regions which might be expected to discriminate maximally. Table 1 shows the results of three successive incubations, testing at each step for discriminating power, defined as the percentage by which between-species falls short of within-species binding. As predicted, the level of discrimination of the bound fragments declined at each successive incubation, and was virtually non-existent by the third cycle. By contrast, the rejected fraction increased in discriminating power at each successive cycle. Some asymmetry was evident, in that the rat fragments tended to discriminate less well than the mouse ones (see later).

More recently, we have found that the discriminating power of a DNA sample depends on the temperature at which the agar mixture is incubated. At 40° C, 70 per cent of fragments are bound in a within-species incubation, but the duplexes formed are very imperfect, judging by the shape of their melting curves[3]. As the temperature is raised, the proportion of fragments bound decreases, and the duplexes approach nearer to the native condition. The decrease in binding is proportionately greater in a between-species than in a within-species combination, from which it follows that the discrimination improves as

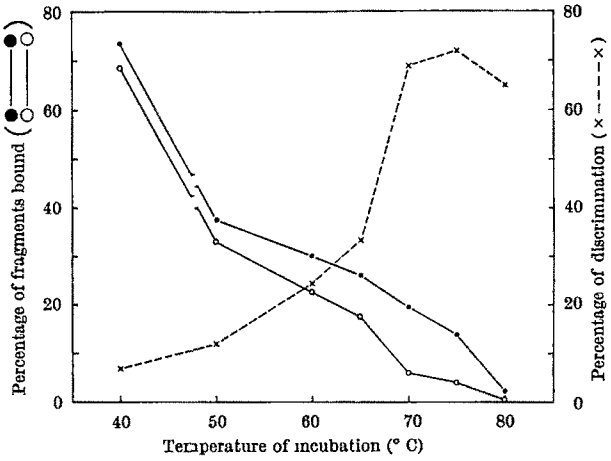

Fig. 1. The effect of temperature of incubation on the binding in DNA-agar of DNA fragments from the same (●——●) or another (○——○) species. Both mouse and rat fragments were tested at each temperature, and the results from the two species averaged to give the percentage of fragments bound. "Discrimination" (× - - - ×) is defined as the percentage by which between-species falls short of within-species binding

the temperature increases (Fig. 1). In our mouse–rat system, it is about 30 per cent on a first cycle at 60° C (Table 1), but by 70°–75° C (the highest temperatures at which the technique is satisfactory) it has risen to 70 per cent. At 70° C, fractionation by successive between-species incubations no longer improved discriminating power.

The poor discrimination at low temperatures does not mean that no specific binding has occurred, but is due rather to the masking effect of relatively non-specific binding. This can be shown by eluting the bound fragments at successively higher temperatures (Table 2). Whether the temperature of incubation is 40°, 50° or 60° C, discriminating ability is confined to those duplex regions stable at 60° C, and remains in the neighbourhood of 30 per cent.

Table 2. Binding Ability and Discriminating Power of DNA Fragments Stably Bound at Various Temperatures

Temperature of incubation (° C)	Temperature of elution (° C)	Percentage of fragments bound: Within-species	Between-species	Discrimination (per cent)
60	75	26·8	19·9	*26*
50	60	13·5	15·5	−15
	75	20·9	14·5	*31*
40	50	40·7	40·7	0
	60	13·7	14·7	−7
	75	16·7	11·7	*30*

Unbound fragments were washed off in high salt at the temperature of incubation; the temperature was then raised in steps, the eluted fragments washed off in high salt at each successive temperature below 75° C, and finally in low salt at 75° C.

The greater sensitivity to temperature of between-species, as compared with within-species binding which we have found, must in part reflect the fact that at higher temperatures, matching sequences will need to have longer complementary runs if they are to give stable binding. 'Species-common' and 'species-specific' sequences must be in continuity with one another, rather than segregated, and must constitute a gradation of increasingly imperfect matching between species. The greater thermal stability of the within-species duplexes might also indicate a higher cytosine-guanine (C-G) content. To investigate this possibility we tested the binding ability in DNA-agar of fragments separated on a hydroxyapatite column[5,6].

Binding Behaviour of Hydroxyapatite Fractions

When DNA fragments are eluted at increasing temperature and constant salt concentration from a hydroxyapatite column, the successive fractions show an increasing

C-G content[5]. Fig. 2 summarizes the results of a number of experiments in which the within- and between-species binding ability of successive thermal fractions of mouse and rat DNA fragments was tested. In between-species incubations, the results for mouse and rat fragments were very similar, and have been combined. There was no indication that within-species duplexes were richer in C-G than between-species ones; the greater thermal stability of the former is therefore presumably due entirely to the greater mean length of the complementary sequences involved in duplex formation.

Fractions with a high A-T content consistently bound less well on DNA-agar than did those from the intermediate or high C-G regions of the thermal chromatogram. In addition, the mouse fragments incubated with mouse DNA-agar showed a region of high binding towards the centre of the range, declining not only towards the high A-T but also towards the high C-G fractions (Fig. 2). This feature was not evident in the between-species or in the rat within-species incubations. It was characteristic of mouse DNA fragments incubated with homologous DNA-agar at 40° C and 70° C, as well as at 60° C (Fig. 3). A consequence of this was that the discriminating ability of mouse DNA fragments showed a strong and highly significant ($P < 0.001$) negative regression on the temperature of elution from hydroxyapatite (Fig. 4). High A-T fractions discriminated well, high C-G ones very poorly.

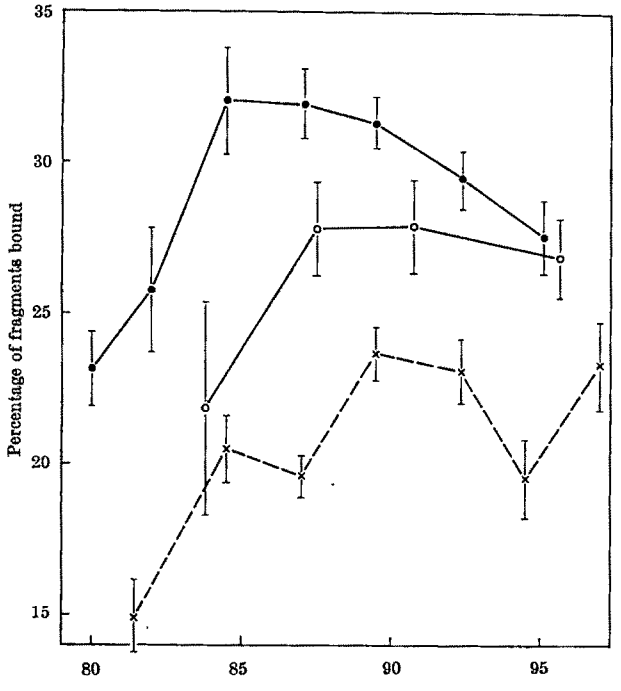

Fig. 2. Percentage binding, ± *S.E.*, of mouse and rat DNA fragments eluted at increasing temperatures from a hydroxyapatite column at constant phosphate concentration. The two between-species combinations gave very similar results, and have been combined. The total number of estimations carried out was 62, 23 and 56 for the mouse/mouse (●), rat/rat (○) and between-species (×) combinations respectively; in some cases estimates from different elution temperatures have been pooled so as to ensure that no points are based on one or two observations only. For calculating means and standard errors, the percentages were first subjected to angular transformation

The complementary fractionation procedure, whereby DNA fragments are eluted from a hydroxyapatite column at increasing phosphate concentration, at a constant temperature, fractionates DNA according to its secondary structure[5]. We find that, at 70° C, a small fraction of DNA, after denaturation, elutes in the native position (0·16–0·20 M) while the remainder elutes at lower salt concentrations (0·07–0·12 M) in the single-stranded position. We have termed these fractions "stable" and "labile", respectively[6].

Melting curve experiments on mouse DNA show that the stable fraction is partly duplex in nature, but that it is not identical with native DNA[6]. This is strikingly

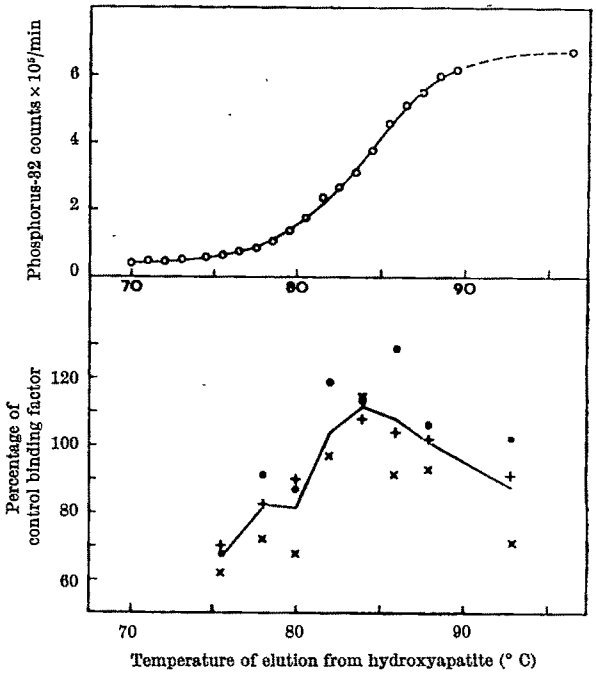

Fig. 3. The effect of temperature of elution from a hydroxyapatite column on the percentage of fragments of mouse DNA bound on mouse and rat DNA-agar during overnight incubation at 40° (+), 60° (●) and 70° C (×). For each incubation temperature the binding ability of each thermal fraction is expressed as a percentage of the binding ability of the unfractionated DNA fragments incubated in agar at the same temperature

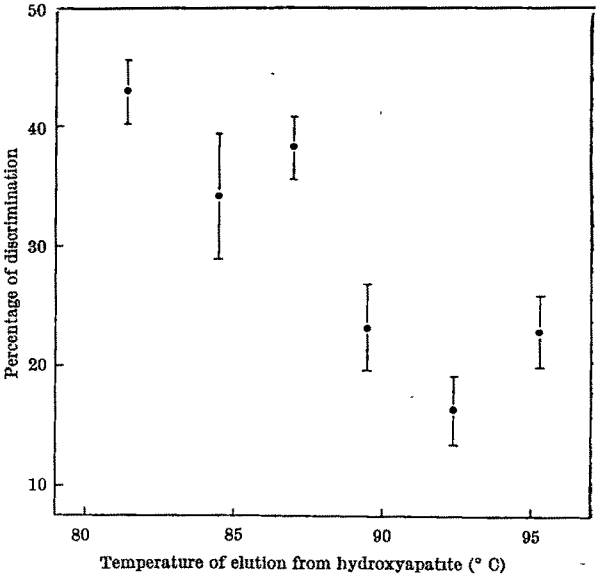

Fig. 4. The relation between the discriminating power, ± *S.E.*, of mouse DNA fragments, and their temperature of elution from a hydroxyapatite column. The points are based on a total of forty-one estimates, comprising all those experiments included in Fig. 2 where mouse DNA fragments were tested simultaneously on mouse and rat DNA-agar

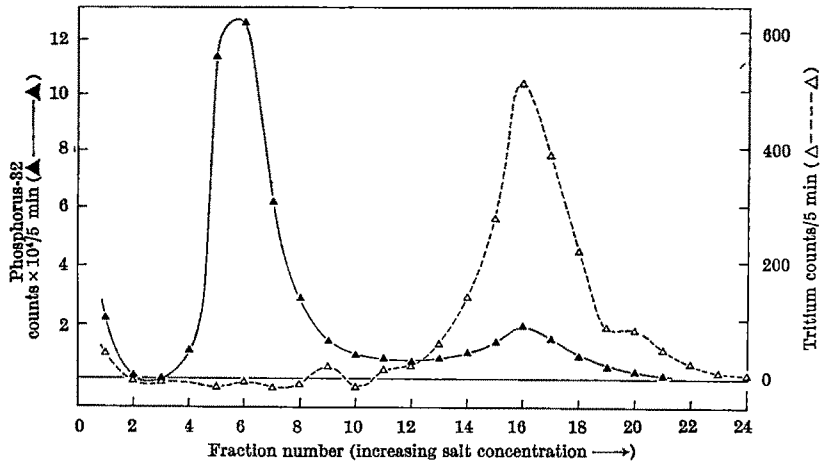

Fig 5. Hydroxyapatite fractionation at 60° C and increasing phosphate concentration (0·03–0·30 M phosphate), of native and denatured fragments of mouse DNA labelled with tritium (△) and phosphorus-32 (▲) respectively

confirmed by its binding ability on incubation with DNA-agar. Native and denatured mouse DNA, labelled with different isotopes, were fractionated simultaneously on a hydroxyapatite column (Fig. 5). The fractions corresponding to the native and single-stranded peaks were then incubated with homologous DNA-agar, and the results set out in Table 3 were obtained. The native DNA, as expected, showed very little binding; but the stable fraction contained in the same incubation mixture bound with remarkable efficiency. The labile fraction bound only about half as well as the stable fraction.

Table 3. BINDING ABILITY OF HYDROXYAPATITE FRACTIONS WHEN INCUBATED WITH HOMOLOGOUS (THAT IS, MOUSE) DNA IN AGAR GELS AT 60° C

Exp.	Hydroxyapatite fraction taken for incubation with DNA-agar	Denatured (phosphorus-32) Labile	Denatured (phosphorus-32) Stable	Native (tritium)
(1)	0·07–0·11 M	17·7	—	—
	0·14–0·17 M	—	42·8	3·7
	0·17–0·21 M	—	30·9	3·6
(2)	0·14–0·21 M	—	42·4	3·1

The fractions were taken from a hydroxyapatite column at 60° C, loaded with a mixture of native DNA labelled with tritium, and denatured DNA labelled with phosphorus-32. Figures represent the percentage of labelled DNA bound to the DNA-agar gel.

Table 4. EFFECT OF TEMPERATURE OF FRACTIONATION ON THE SIZE OF THE STABLE FRACTION OF MOUSE DNA, AND ITS BINDING ABILITY, WHEN INCUBATED WITH HOMOLOGOUS DNA IN AGAR GELS AT 60° C

Temperature of hydroxyapatite fractionation (° C)	Percentage of radioactivity in stable fraction (0·3 M)	No of DNA-agar incubations	Average binding (per cent)
50	22·8	3	51·9
60	15·0	2	50·8
70	12·2	3	51·2
Unfractionated	—	6	28·9

Table 5. EFFECT OF THE TEMPERATURE OF HYDROXYAPATITE FRACTIONATION ON THE DISCRIMINATING POWER OF MOUSE DNA FRAGMENTS

Temperature of fractionation on hydroxyapatite (° C)	Discrimination (per cent) shown by Labile	Discrimination (per cent) shown by Stable
40	42·0	58·6
50	32·5	65·2
60	28·5	77·9
70	23·4	80·7

A sample of DNA deliberately cross-linked by treatment with nitrous acid[6,7] proved to have a lower binding ability than control material; the fraction that eluted in the native position bound very poorly indeed (< 10 per cent), in contrast to the stable fraction of untreated DNA.

If the temperature at which the hydroxyapatite fractionation procedure is carried out is reduced to 50° C, more single-stranded material is included in the stable fraction[6], but this does not affect its binding ability (Table 4). In another experiment, stable and labile fractions of mouse DNA fragments from hydroxyapatite chromatograms run at 40°, 50°, 60° and 70° C were incubated with mouse and rat DNA-agar. The labile fractions bound relatively poorly, as expected, and showed less discrimination as the temperature of fractionation increased (Table 5). The stable fractions, on the other hand, all bound well in the within-species situation, but showed increasingly poor binding with the rat DNA as the temperature of fractionation increased. This led to a strikingly high level of discrimination on the part of the 70° C hydroxyapatite stable fraction.

When rat DNA from a primary embryonic cell culture is subjected to 70° C hydroxyapatite fractionation at increasing phosphate concentration, the fraction which elutes in the native position is smaller than in the case of mouse DNA (a mean of 3·9 per cent against 8·6 per cent from seven rat and seven mouse fractionations; $P < 0·001$). In marked contrast to the findings with mouse DNA from either *L*-strain or embryonic cells, the small stable fraction from rat DNA showed low binding—lower than did the labile fraction (Table 6). The discriminating power of the two rat fractions was similar. Evidently our fractionation procedure, which for mouse DNA results in segregating the "discriminant" fragments in the stable fraction (Table 6), does not exert any detectable differential effect on the discriminant fragments of rat DNA.

Table 6. DISCRIMINATING POWER OF 70° C HYDROXYAPATITE FRACTIONS OF MOUSE AND RAT DNA INCUBATED IN A DNA-AGAR GEL AT 60° C

Source of fragments: Species	Source of fragments: Cells	Hydroxyapatite fraction	Percentage of binding in agar containing: Mouse DNA	Percentage of binding in agar containing: Rat DNA	Discrimination (per cent)
Mouse	Embryonic	Stable	43·1	9·2	79
	L-cells	Stable	45·1	8·7	81
		Labile	26·1	20·0	23
Rat	Embryonic	Stable	14·0	21·6	35
		Labile	19·6	30·5	36

The two hydroxyapatite fractionation procedures can be combined by first eluting DNA from a hydroxyapatite column at increasing temperatures, and then subjecting these thermal fractions to a second fractionation at increasing phosphate concentration. When the stable and labile components of the various thermal fractions of mouse DNA were incubated with mouse and rat DNA-agar, we obtained the results summarized in Fig. 6. The labile components from all elution temperatures showed low binding and a relatively constant degree of discrimination; the stable components showed very low binding in between-species incubations, but a peak of within-species binding in the fraction eluting at 85° C. This suggests that the similar peak seen in Fig. 2 results from the stable component of the fraction. In other words, both fractionation procedures have been sequentially effective in segregating the discriminant fragments, leading to an eventual level of discrimination (Fig. 6) of more than 90 per cent.

It has already been stated that our preparations of mammalian DNA fragments are initially heterogeneous. Fragments, bound on homologous DNA-agar and later

eluted, show a higher binding capacity when re-incubated on a fresh sample of DNA-agar than did the initial population; conversely, fragments which failed to bind on a first incubation, bind poorly on subsequent incubations[3]. When bound and unbound fragments of mouse DNA from a 60° C DNA-agar incubation were subjected to hydroxyapatite fractionations, more of the bound than the unbound were included in the high phosphate fractions (27·2 per cent compared with 15·5 per cent). The heterogeneity revealed by incubation on DNA-agar is therefore not independent of that revealed by the hydroxyapatite procedure.

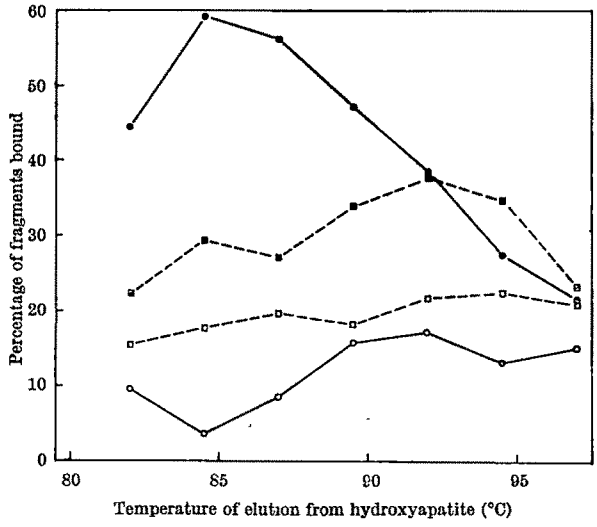

Fig. 6. The within- (● and ■) and between-species (○ and □) binding ability of stable (● and ○) and labile (■ and □) components of various thermal fractions of mouse DNA from a hydroxyapatite thermal chromatogram. Mouse DNA fragments were first eluted from a hydroxyapatite column at constant phosphate concentration (0·06 M phosphate) and increasing temperature; successive elution fractions were pooled to give a total of seven samples, which were then separately fractionated on a hydroxyapatite column at 70° C and an increasing phosphate concentration. The 0·07–0·12 M (labile) and 0·16–0·20 M (stable) fractions of each were recovered, and incubated overnight with mouse and rat DNA-agar at 60° C

Earlier evidence[3] suggested that failure to bind might be partly due to the presence of intra-strand secondary structure, stable at the temperature of incubation in agar, and associated with C-G rich regions of the genome. This interpretation is supported by the binding capacities of the various thermal chromatogram fractions illustrated in Fig. 2. If C-G regions were the main contributors to DNA duplex stability at 60° C in 0·3 M sodium chloride, then we would expect, unless there was some impediment, that the binding efficiency of thermal fractions should increase as the temperature of fractionation and thus their C-G content increased. But this was not so: above a point midway up the chromatogram, binding efficiency levelled off or even, in the mouse, decreased. Our finding of a DNA fraction with both a high degree of secondary structure and a high binding capacity does not necessarily invalidate this view, because here too it is the lower and middle temperature components of the stable material which bind best (Fig. 6).

Conclusions

It seems unlikely that our failure to isolate a fraction of rat DNA with high binding and discriminatory abilities reflects any fundamental distinction between the genetic material of rats and mice. In the experiment summarized in Table 6, mouse and rat DNA differed little, after fractionation, in the overall degree of binding and discrimination, when the relative size of the stable fraction is taken into account. What did clearly differ (Table 6) was the extent to which the discriminant fragments have been successfully segregated; this is presumably dependent on the precise fractionation technique used. On the other hand, we have on a number of other occasions observed that unfractionated rat DNA fragments discriminate somewhat less well than mouse fragments[4]. It is possible that some virus-like contaminant in the genetic material of the mouse contributes to the superior discrimination. The very rapid renaturation undergone by the stable fraction might, in particular, suggest a viral origin. This rapid renaturation occurs whether or not the stable material has been isolated from the rest of the DNA; in an analogous situation, the rate of renaturation of *T4* phage DNA is not affected by a 500-fold excess of mouse DNA (ref. 8).

On the other hand, when a stable fraction is isolated from high molecular weight DNA at 70° C, only about 25 per cent of it shows a sharp spectrophotometric melting transition; the remainder is single-chain DNA which must be linked, presumably by covalent bonds, to the stable component. No such linkage would be expected if the stable material were viral or cytoplasmic in origin. More recent experiments[9] have shown that the stable fraction discussed in this paper renatures at the same rate as, and is therefore presumably identical with, the satellite fraction isolated by Britten[10]. The rapid renaturation of both fractions is thought to be due to the repetition, many times over, of a sequence perhaps only 250 base-pairs in length. The existence of a large amount of nucleotide sequence repetition in the DNA of higher organisms, if confirmed, would have important evolutionary implications.

The binding ability of the stable fraction of mouse DNA is surprising, because the reformation of duplex structure might be expected to reduce the number of hydrogen-bonding sites available. The imperfections in duplex structure revealed by melting curve experiments must, however, expose a certain number of sites, and it is presumably these which are responsible for binding on DNA-agar. This implies that partially renatured DNA can be stabilized in DNA-agar by the specific binding of the unpaired bases in a relatively short segment.

However, we have also seen that the high binding ability is only manifested in within-species incubations, and then only by fragments eluting over a certain portion of the hydroxyapatite chromatogram. Fractions of mouse DNA eluted at higher temperatures bind worse with mouse but better with rat DNA than do those eluted at lower temperatures. For this reason, use of the stable component of the thermal fraction eluting at 85° C achieves a higher level of discrimination between mouse and rat DNA than any other method tried so far. Either the species-specific sequences must be rather rigidly segregated into this particular fraction, or the degree of complementarity required for stable binding by the exposed sites in the stable fraction of mouse DNA is so stringent that they are unlikely to be satisfied by more than a small minority of sequences present in DNA of the other species.

INCREASED ANGIOTENSIN FORMATION IN RESPONSE TO CAROTID OCCLUSION IN THE DOG

By DR. R. L. HODGE, DR. R. D. LOWE and PROF. J. R. VANE

Department of Pharmacology, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, and Department of Medicine, St. Thomas's Hospital Medical School, London, S.E.1

A FALL of renal arterial pressure raises the rate of secretion of renin[1] and its concentration in the blood[2,3]. A reduction of blood volume brought about by severe haemorrhage also raises the concentration of renin in blood[4,5], an effect thought to be mediated by the local effect of the fall in renal arterial pressure. Recent evidence suggests that this interpretation is not correct. Thus in dogs a reduction of renal arterial pressure by clamping the aorta fails to increase the concentration of circulating angiotensin, though an increase is brought about by an equivalent fall of systemic arterial pressure caused by haemorrhage[6]. We have found[7] that in dogs haemorrhage causes an increase in the concentration of circulating angiotensin even when there is no fall of arterial mean or pulse pressure. These results suggest that the secretion of renin is modified by nervous reflexes, and Vander[8] showed that stimulation of the renal nerves raises the concentration of renin in the blood. We have also shown that the rise of angiotensin concentration during haemorrhage is prevented by blocking the renal nerves with lignocaine[9]. The experiments described here provide direct evidence that the concentration of angiotensin in blood is affected by cardiovascular reflexes.

Dogs of both sexes, weighing 18–32 kg, were used. Anaesthesia was induced with halothane, maintained with chloralose (100 mg/kg intravenously) and supplemented with pentobarbitone (60–120 mg intravenously) as necessary. Cannulae were inserted into the trachea, a femoral artery and a femoral vein; an animal was mechanically ventilated and given heparin (1,000 U/kg intravenously). Mean arterial pressure was recorded by a mercury manometer, and in some experiments the undamped pressure was recorded photographically from a Statham pressure transducer (type *P23Db*) and amplifier. The bladder was catheterized and the output of urine recorded by drop counter. For each millilitre of urine excreted, an equal volume of 0·9 per cent saline w/v was automatically injected intravenously. Both common carotid arteries were dissected in the neck and mobilized for temporary occlusion with bulldog clamps.

The concentration of angiotensin in circulating blood was assayed continuously by the blood-bathed organ technique, developed for catecholamines by Vane[10,11] and modified for angiotensin by Regoli and Vane[12,13]. Femoral arterial blood was pumped at 15 ml./min to superfuse in series three assay tissues and was returned to the femoral vein by gravity. Contractions of the tissues were recorded on a kymograph with frontal writing pendulum levers[14] of 16 : 1 magnification and an initial load of 1–3 g. The assay tissues were chosen from: *rat stomach strip*[15], which distinguishes between angiotensin (which causes a small contraction) and catecholamines (which cause relaxation); *chick rectum*[16], which relaxes in response to adrenaline, is less sensitive to noradrenaline and is insensitive to angiotensin; *rat colon*[12], which is highly sensitive to angiotensin (responding by contraction) and feebly sensitive to catecholamines (responding by relaxation). The specificity of the assay, which is described in detail elsewhere[9,13], depends on the differential responses of the three tissues and on the demonstration that a response characteristic of a change of endogenous angiotensin concentration no longer occurs when the kidneys are excluded from the circulation. Angiotensin can be distinguished from histamine, acetylcholine, 5-hydroxytryptamine, bradykinin, vasopressin, oxytocin, catecholamines, adenosine and its derivatives, corticosteroids, and many other compounds.

The response of the tissues to changes of concentration of endogenous angiotensin was calibrated by infusions of synthetic angiotensin to match the response as follows: to determine the *rate of generation* of angiotensin in the dog, angiotensin (Val_3—Hypertensin, II Asp.β.amide, 'Hypertensin Ciba') was infused intravenously at 0·1–2·0 μg/min. To determine the concentration of angiotensin in blood, angiotensin was infused at 3–15 ng/min directly into the blood superfusing the tissues.

Occlusion of the carotid arteries always caused a rise of blood pressure. This varied from 10 to 120 mm mercury; occlusion for 5 min or less caused no detectable change of

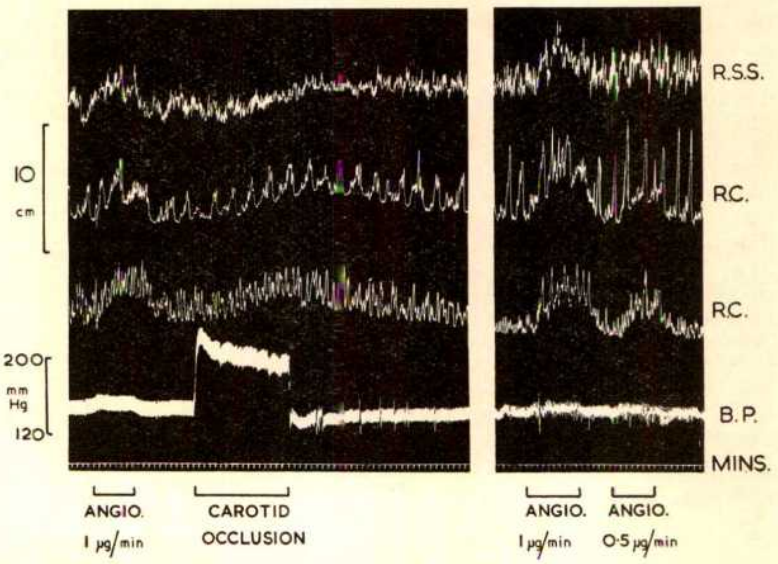

Fig. 1. Dog No. 73 (27 kg). The kymograph tracing shows the movements of a rat stomach strip (*R.S.S.*) and two rat colons (*R.C.*) superfused with carotid arterial blood from the dog. Blood pressure (*B.P.*) in mm mercury and time in min. An infusion of angiotensin (angio) at 1 μg/min intravenously shows the sensitivity of the system. During the period of carotid occlusion, the contractions of the blood-bathed organs indicated an increase in the generation rate of angiotensin of 0·5 μg/min

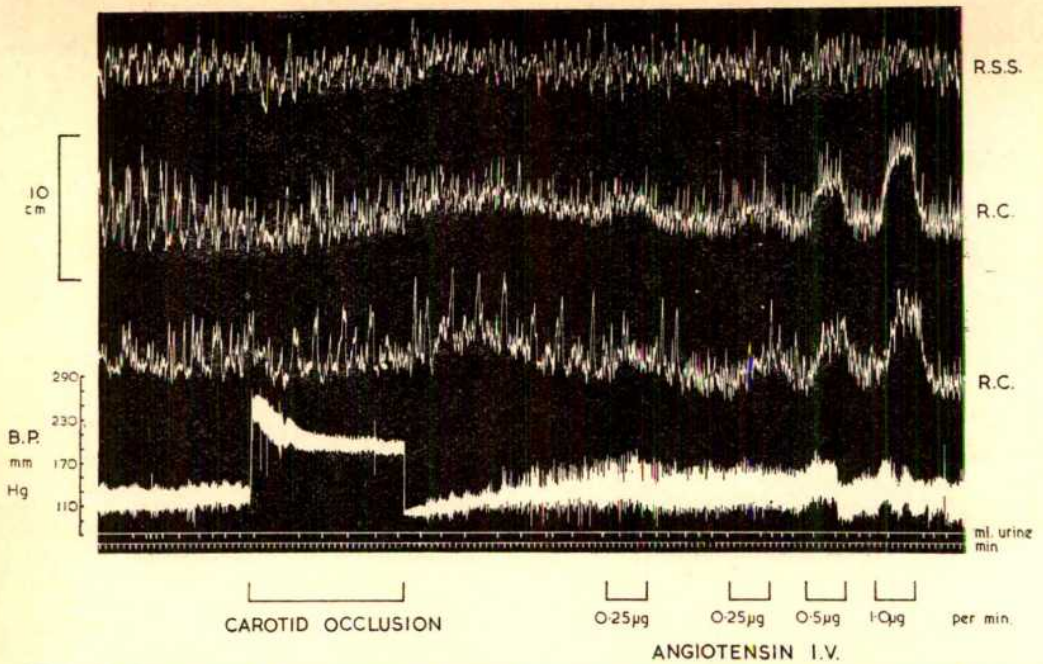

Fig. 2. Dog No. 75 (24 kg). Record as in Fig. 1, with the addition of urine output in ml. The carotid occlusion caused an increase in the angiotensin concentration which was maximal after the release of the occlusion. The peak increase corresponded to a generation rate of between 0·25 and 0·5 μg angiotensin/min

angiotensin concentration (14 dogs); longer periods of occlusion (7–26 min) caused a rise in the concentration of circulating angiotensin in ten out of seventeen animals. One of these experiments is illustrated in Fig. 1, which shows a slow rise of angiotensin concentration during occlusion, followed by a slow fall after its release. This time course is typical of the effect of injections of renin, which has a half-life in the circulation of 15–20 min[13]; angiotensin itself has a half-life of less than 3 min[9]. In two of these ten dogs, carotid occlusion was repeated after the vagus nerves had been cut in the neck; in both dogs the second occlusion caused a greater increase of blood pressure and of angiotensin concentration. In six of the ten dogs the angiotensin concentration reached a maximum after release of the occlusion (for example, Fig. 2). Of the seven dogs in which carotid occlusion was ineffective in causing a rise of angiotensin concentration, haemorrhage was effective in four and ineffective in three.

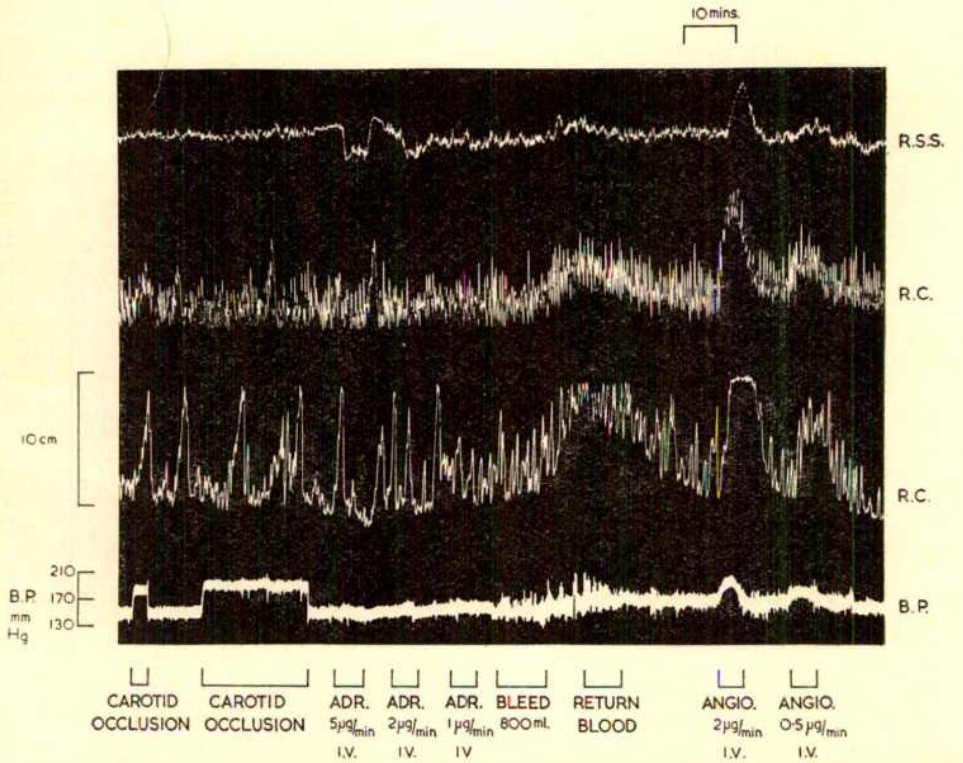

Fig. 3. Dog No. 64 (31 kg). Record as in Fig. 1. Carotid occlusion failed to change the blood angiotensin concentration, although subsequent haemorrhage was effective. Note the different responses of the tissues to intravenous infusions of adrenaline (*ADR*) and angiotensin

Table 1. SUMMARY OF RESULTS

The experiments have been arranged according to the rise in blood pressure induced by carotid occlusion (duration 7–36 min)

Dog No.	Weight (kg)	Duration of occlusion (min)	Mean rise of blood pressure due to carotid occlusion (mm mercury)	Increase of angiotensin generation rate due to carotid occlusion (μg/min)	Rise in blood pressure (mm mercury) produced by angiotensin infusion at the rate shown in the preceding column
68	26	15	110	1·0	8
68	27	15	100	1·0	14
37	26	10	90	0·1	5
73	27	18	80	0·5	6
74	30	24	80	0	0
75	24	26	74	0·25	2
67	26	16	72	0·2	6
65	28	18	72	0·1	2
72	9	7·5	70	0·2	4
70	23	12	70	0	0
61	26	7	60	0	0
36	23	10	52	0	0
41	16	8	50	0·1	2
69	22	18	50	0	0
66	21	11	38	0	0
64	31	18	36	0	0
38	20	8	10	0·1	2

To determine whether the observed increase of angiotensin concentration arose from an increase in its rate of generation, the rate of destruction of infused angiotensin was measured before and during carotid occlusion in two dogs. Angiotensin was infused intravenously at the same rate before and during carotid occlusion. The resulting increases in concentration were similar in the two circumstances, indicating that its rate of destruction was unaltered. Assuming that synthetic and endogenous angiotensin are inactivated at the same rate we can conclude that the rise of angiotensin concentration during carotid occlusion resulted from an increase in its rate of generation.

The results of the experiments are summarized in Table 1. The increased blood angiotensin concentration in response to carotid occlusion was equivalent to an increased generation rate of 0·1–1 μg/min: infusion of synthetic angiotensin at these rates had detectable effects on arterial pressure which were, however, quantitatively unimportant in contributing to the rise of blood pressure during carotid occlusion.

The results show that, in anaesthetized dogs, occlusion of the common carotid arteries can cause a rise of the concentration of angiotensin in blood. This rise was the result of an increase in the rate of generation of angiotensin, presumably owing to an increased rate of secretion of renin, and could account for the increase of aldosterone secretion rate which occurs during carotid occlusion or constriction[17,18].

The cardiovascular effects of carotid occlusion in the dog result entirely from a fall of pressure in the carotid sinus, which causes complex reflex circulatory adjustments resulting in a rise of arterial pressure[19]. The renal vasomotor nerves contribute to the general increase of peripheral resistance so that the effects on the kidney may include changes of volume; of afferent arteriolar pressure; of glomerular filtration rate and filtration pressure; and of renal blood flow. Any of these could be the effective stimulus to the release of renin, whether this is brought about by cardiovascular reflexes or by changes of renal arterial pressure caused, for example, by partial occlusion of the renal artery. It therefore does not seem necessary to postulate the existence of nerves the special function of which is to regulate the secretion of renin.

The role of carotid sinus reflexes in the control of renin secretion remains to be elucidated. Such reflexes cannot be the only ones mediating the changes of angiotensin concentration during haemorrhage. Thus, despite a smaller fall of sinus pressure, haemorrhage caused a greater rise of angiotensin concentration (for example, Fig. 3) than did carotid occlusion. Furthermore, none of the systemic arterial baroreceptors is likely to be important in causing the increase of angiotensin generation rate during slow haemorrhage, as this can occur without change in systemic arterial mean or pulse pressure[8].

The significance of the results described here lies in the demonstration that a cardiovascular reflex can bring about increased generation of angiotensin despite a rise of renal arterial pressure. Thus in the control of the renin-angiotensin system, reflexly induced changes in the kidney can override the direct effects of changes of renal arterial pressure.

SPECTROPHOTOMETRIC DETECTION AND MEASUREMENT OF SENSITIZING ANTIBODIES

By DR. D. ALLAN and M. MALKINSON
Department of Veterinary Pathology, University of Liverpool

METHODS for detecting tissue-sensitizing antibodies in the sera of chickens experimentally infected with *Salmonella gallinarum* have already been described. Buxton and Allan[1] recorded experiments demonstrating the presence of cytophilic antibodies on circulating chicken leucocytes, while techniques were described by Allan, Buxton and Thomlinson[2], using an established line of *ERK* cells to detect antigen–antibody reactions *in vitro*.

In all these techniques an eosin–*y* dye exclusion method, modified from that of Hanks and Wallace[3], was used to detect the resultant cytopathic effect[1] (CPE). This, like other dye-exclusion techniques, is open to certain criticisms, and these have been ably illustrated in experiments carried out by Black and Berenbaum[4]. The main criticism of dye-exclusion methods for estimating CPE is that such estimations are achieved by subjective means. A proportion of cells invariably shows intermediate morphological changes when dye exclusion is not conclusive, and interpretation becomes speculative. Consequently, an alternative technique for estimating CPE based on more exact methods of assay seemed desirable.

Ultra-violet spectrophotometry, because it precludes the necessity of including colour reactions, seemed likely to produce a direct and uncomplicated method of assay.

Table 1

0·5 ml. volumes incubated with cells; *A* for 30 min followed by *B* for 20 min	Tubes containing an equal volume of HeLa cells of known concentration					
	1	2	3	4	5	6
Chicken antiserum	A	A	—	—	—	—
Antigen in PBS	B	—	B	—	B	—
Chicken negative serum	—	—	A	A	—	—
PBS alone	—	B	—	B	A	A,B

Romeyn and Rigby[5] measured immune cytolysis of guinea-pig peritoneal exudate cells (chiefly mononuclears) and Ehrlich's ascites tumour cells, by monitoring cell-free supernatants for nucleic acid, at a wave-length of 260 mμ, following incubation of the cells with specific antisera. By this means an *in vitro* type 2 reaction[6] was produced and complement was titrated.

As the intention was to measure tissue sensitizing antibodies in sera, the possibility was considered of passively sensitizing a suspension of an established line of either *ERK* or HeLa cells *in vitro*, washing them, exposing them to a Westphal-type antigen and measuring the release of cellular ribonucleic acid into the supernatant suspending medium at a wave-length of 260 mμ. In other words, an attempt was to be made to induce passively *in vitro* a type 1 reaction[6].

As a preliminary step, HeLa cells were examined microscopically for cellular RNA by staining with methyl-green pyronin, using perchloric acid as a substitute for ribonuclease in the histochemical detection of RNA (refs. 7–10). These preliminary observations were encouraging[11] and led to the design of a test which it was thought might measure release of cellular RNA following controlled passively induced type 1 reactions[6] on *in vitro* cultured cells. In this way it was hoped to calculate a cytopathic index based on the absorbancies of supernatants from experimental and control HeLa cell suspensions, which would allow the titration of sensitizing or cytophilic antibody in sera under test.

The test was initiated by dispersing a number of aliquots of thrice-washed HeLa cells of known concentration, suspended in phosphate buffer-saline (PBS), into tubes. Some of these cells were incubated with 0·5 ml. of a 1 : 2 dilution of chicken serum under test, others with 0·5 ml. of a 1 : 2 dilution of known negative chicken serum, and others were incubated with 0·5-ml. PBS. After 30 min at 37° C the cells were washed as before in PBS, some were further incubated for 20 min at 37° C, resuspended in 1-ml. suspensions of antigen in PBS, and some in 1-ml. volumes of PBS alone (see Table 1).

After the second period of incubation (*B* in Table 1) all tubes were centrifuged at 236*g* for 2 min, and to the supernatants were added 1-ml. volumes of 2 N Analar perchloric acid. This precipitated any protein and freed nucleic acid and nucleotides by hydrolysis. The supernatants were incubated with perchloric acid for 30 min at 60° C and were then centrifuged at 1,720*g* for 30 min to separate the acid-soluble nucleic acid and nucleotides for monitoring at 260 mμ. Analysis of the results of several hundred absorbance readings consistently showed that minimal release of cellular RNA from HeLa cells occurred owing to manipulation of the cells during the experiment (tube 6, Table 1). Absorbance of supernatants from cells in tubes 2, 3, 4 and 5 (Table 1) were all significantly less than from cells in tube 1 which had been passively subjected to a type 1 reaction[6].

Table 2. CYTOPATHIC INDICES OF WHOLE SERUM AND 'SEPHADEX' FRACTIONS OF CHICKENS ARTIFICIALLY INJECTED WITH *E coli*

H: H agglutinating antibody. HA: O haemagglutinating antibody. AG: O antiglobulin haemagglutinating antibody.

It was possible, in consequence, to calculate cytopathic indexes from data which were so controlled that the only variable was the sensitizing activity of the chicken antiserum. The formula used was:

$$\text{Cytopathic index (CI)} = \frac{E\ 260\ \text{tube}\ 1 - E\ 260\ \text{tube}\ 5}{E\ 260\ \text{tube}\ 1} \times 100$$

Tube 5 was deliberately chosen as the control, as it consistently gave slightly higher absorbancies than tubes 2, 3, 4 and 6 (see Table 1).

To determine the efficiency of this cytopathic test a series of experiments was carried out in which serum responses to oral infection of individual birds were followed. As a result, it was shown that sensitizing activity was present in these sera. The next step was to see if serum fractions possessed cytophilic properties and if it was possible to characterize sensitizing antibodies. Accordingly, thirty Light Sussex 5-week-old cockerels were obtained and divided into six groups. One group was killed immediately and maximum serum samples recovered from each bird. These are the samples of day 0. The remaining five groups immediately received 1×10^6 live *E. coli* 02 organisms into the posterior air sac. Serum samples were recovered by killing one group from the remaining five at daily intervals to give serum samples for days 1–5. These sera were used passively to induce type 1 antigen–antibody reactions[4] with *E. coli* 02 polysaccharide at a concentration of 60 μg/ml. on suspensions of HeLa cells.

Cytopathic indexes were calculated for these whole serum samples, and detailed results of these can be seen in Table 2. Fig. 1 illustrates the mean cytopathic index for each day of the experiment, and these show a typical secondary response to infection with live organisms. The presence of antibodies in the sera before experimental infection is of interest as *E. coli* 02 is a normal inhabitant of the alimentary tract of the chicken. The mean haemagglutination and anti-globulin haemagglutination titres (Table 2) follow similar patterns to the mean cytopathic index figure except that the minimal mean antiglobulin haemagglutination titre was reached one day later, that is, on day 2. It is of interest to note that Buxton and Allan[1] showed that antiglobulin haemagglutinins in sera from birds orally infected with *Salm. gallinarum* were capable of sensitizing leucocytes from normal chickens. When challenged with *Salm. gallinarum* polysaccharide, these leucocytes were damaged.

For 'Sephadex' fractionation 3 sera from each day were used. A 5-ml. volume of each serum was used, with the exception of birds 5 and 6, when 2·5 ml. of each of these sera were fractionated together. The fractions were bulked and reduced to a fixed volume by overnight dialysis at 4° C against polyethylene glycol ('Carbowax', Union Carbide Co.). By this method a tenfold concentration was achieved, and the ultra dialysate was used in place of whole serum to induce a type 1 reaction[3] on HeLa cells.

The concentration of the 'Sephadex' fractions followed three patterns: (*a*) Day 0 and day 1: consecutive pairs of fractions totalling 10 ml. were reduced to 1 ml. (*b*) An exception to this was bird 7 on day 1, when each individual fraction of 5 ml. was reduced to 0·5 ml. (*c*) Days 2, 3, 4 and 5: five consecutive fractions totalling 25 ml. were reduced to 2·5 ml.

Fig. 2 shows the profile of a typical fractionated serum taken from each day. The absence of peak I in day 0 is

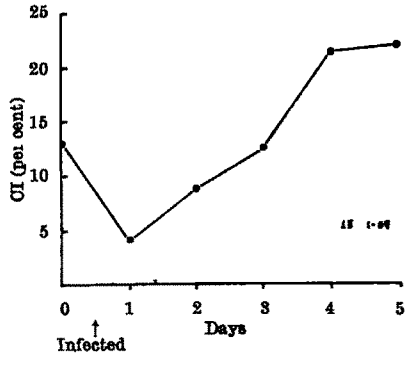

Fig 1

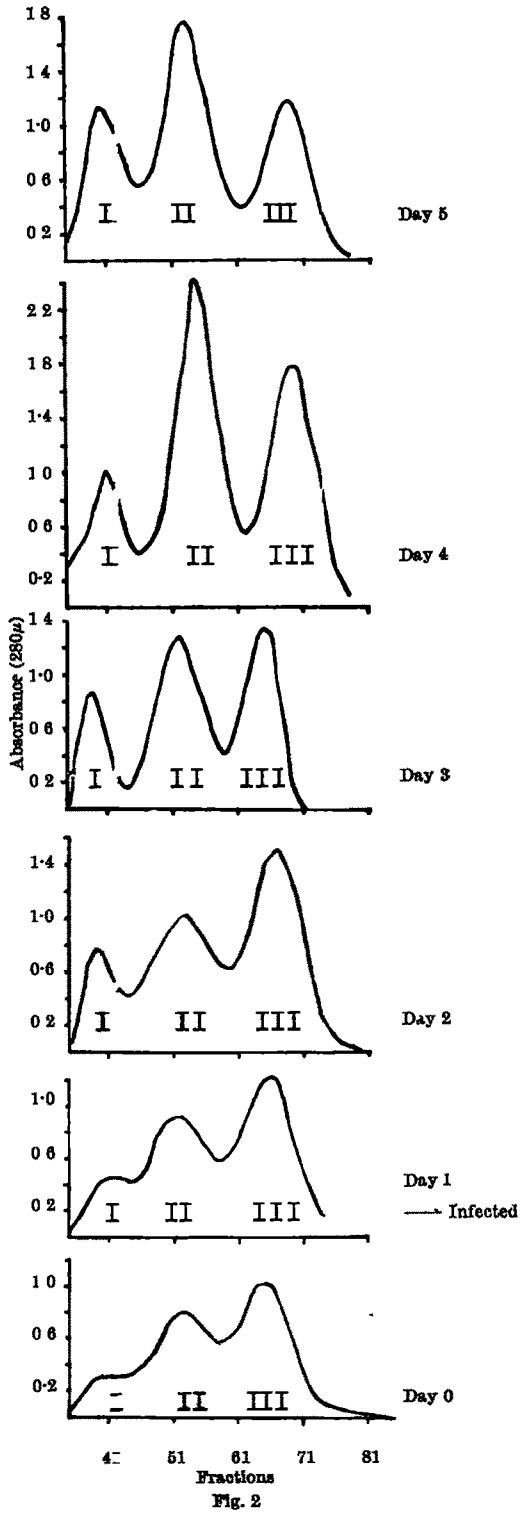

Fig. 2

indicative of the low IgM levels in normal 5-week-old chickens. The rapid increase in formation and height of peaks I and II as a result of infection is readily discernible. The consistent reliability of 'Sephadex G 200' as a separating medium meant that it was possible from day 2 onwards to bulk the fractions from each serum in the same manner (*vide supra*, and Table 2).

Table 2 sets out the cytopathic indexes of all the fractions tested. It will be seen that the sera from days 0 and 1 show sensitizing activity throughout the initial fractions which correspond to peaks I and II on the respective serum protein profiles (Fig. 2). In contrast, sera from days 2 and 3 show activity confined to the IgM peak only. Sensitizing activity gradually reappeared throughout the whole range of fractions during the last 2 days, with the cytopathic indexes becoming approximately equivalent.

When the whole sera were subjected to 2-mercaptoethanol treatment, it was found that all haemagglutinating activity was removed while the antiglobulin haemagglutinating titres were reduced to 1 : 8 or less.

From these experiments it appears that first IgM and then IgG antibodies may be sensitizing and concerned in cell damage. Turner, Jenkins and Rowley[12] showed that mice vaccinated with living *Salm. typhimurium* produced two types of immunoglobulin. The first phase of production was characterized by a 19*S* macroglobulin response which lasted for about 4 weeks, leaving a 7*S* IgG antibody which persisted for about 6 months. Rowley, Turner and Jenkins[13] also showed that passive transfer of immunity to mouse typhoid was possible by transfer of phagocytic cells from immune mice. This resulted from a cell-bound antibody that could be eluted from these cells and was shown to be 19*S* IgM.

The fact that both IgM and IgG immunoglobulins are capable of sensitizing heterologous HeLa cells may to some extent be explained by a report of Brambell[14]. This suggested that uptake of globulins by cells, whether passively as in type 1 reactions[6] or actively, depends on the presence of "recognition units" on the immunoglobulin molecules which match receptors on the pinocytotic vesicles of the tissue cells involved in the adsorption process[14].

From the experimental results obtained by the cytopathic test described in this article, it seems that this test is capable of detecting 7*S* IgG activity at an earlier period in the immune response than conventional *in vitro* methods.

The emergence of 7*S* IgG antibody as a more potent cell sensitizing agent may be related to a higher circulating serum level. However, recent reports indicate that homologous $7S\gamma_1$ is more effective than $7S\gamma_2$ in sensitizing skin in passive cutaneous anaphylaxis (PCA) tests in guinea-pig and mice[15,16].

Roe[17] stated that the uncertainty in interpreting the ultra-violet absorption spectra of macronuclear material when the conditions of examination are difficult to control has made many workers sceptical about possibilities of obtaining quantitative results from the microspectroscopy of biological cells. The knowledge that nucleic acid is present in high concentration, and may undergo local changes in *p*H or in ionic environment with changing cell metabolism, and at different stages of cell division, leads to the conclusion that quantitative information may be difficult to obtain[17]. By using an established cell line such as HeLa in the carefully controlled environment of the cytopathic test just described, it is possible to fulfil Roe's criteria and thus present quantitative results which, at least under the same experimental conditions, appear quite valid.

EFFECT OF SULPHYDRYL REAGENTS ON A MECHANICAL PROPERTY OF SKIN

By MRS. MARGARET L. R. HARKNESS and DR. R. D. HARKNESS
Department of Physiology, University College, Gower Street, London, W.C.1

INVESTIGATING the effect of various treatments on the tensile strength of the skin of the rat's tail, with the object of defining more precisely the mechanical linkages holding it together, we had occasion to try thioglycollate and this was found to produce a large reduction in tensile strength. We have since tried a number of other thiol reagents and found they all have this effect.

The experiments were carried out on the tail skin of rats 40–60 days old. This skin was cut into rings, and loaded stepwise to the point of rupture at a constant rate (breaking time 3–5 min in untreated skin[1,2]). The tensile strength of this material is almost entirely due to the dermis, the effect of the epidermis being relatively unimportant[1,2]. It has therefore, in general, been ignored. However, some of the results have been checked on epidermis-free skin.

Usually, rings of skin were treated with the reagent under investigation overnight or for longer periods in the refrigerator at about 4° C. Fig. 1 shows effects of treatment with thioglycollate, mercaptoethanol cysteamine, cysteine and reduced glutathione (in 0·1 M concentration, except for glutathione), at different hydrogen ion concentrations obtained by adjusting the *p*H with hydrochloric acid or sodium hydroxide. Lower concentrations (not shown in Fig. 1) of glutathione (2·5 mM) and cysteine (10 mM) have also produced similar effects. In Fig. 1 the effect of alteration of *p*H in buffered physiological saline alone is shown as a dotted line (from ref. 2). The effect of the experimental reagents is to move this curve in the direction of higher *p*H, and large reduction in tensile strength is produced by them in the range of *p*H from 6 to 7·5. It should be noted, however, that the curves represent effects at standard times and not necessarily final equilibrium conditions.

Compounds related to two of the above but containing oxygen instead of sulphur (ethylene glycol and ethanolamine) had no significant effect (at *p*H 7). The normal effect of *p*H on tensile strength appears to be relatively insensitive to changes in the composition of the buffer[2]. It is much the same in 0·1 M *tris* or acetate as in the

physiological saline buffered with phosphate, or bicarbonate, we have generally used. Other substances which in single tests have not had an effect like these thiols are ascorbate and oxalate. To this extent the effects of thiols appear to be specific.

The effects are not confined to tail skin. We have obtained them on ankle and wrist skin with cysteamine.

The method of adjusting the hydrogen ion concentration leads to small variations in ionic strength, but there is no reason to suppose these have more than second-order effects[3] except perhaps at the lowest *p*H value for mercaptoethanol which represents a simple solution.

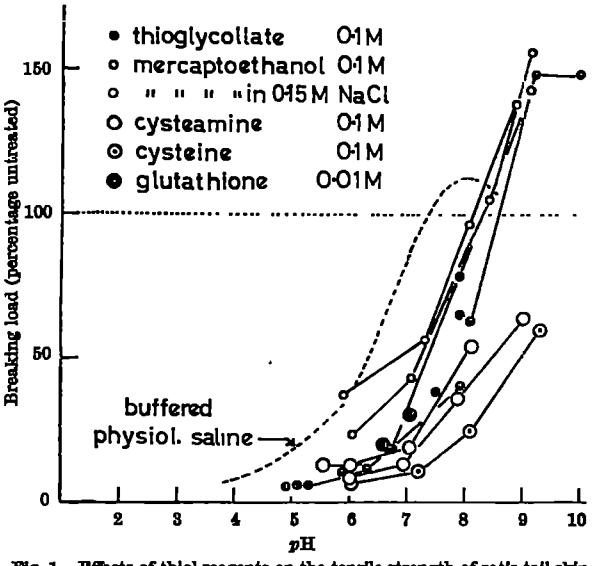

Fig. 1. Effects of thiol reagents on the tensile strength of rat's tail skin. Rings of skin were treated at 4° C, overnight, or for three days (glutathione) in 10 ml. of solution. Reagents were in simple aqueous solution or physiological saline buffered with phosphate (glutathione, in sodium chloride 0·13 M and 0·02 M phosphate; this was also boiled out and gassed with nitrogen). EDTA was added to some of the solutions to a final concentration of 1 mM. The *p*H values are those obtained by measurement after removal of skin sample for test. The lines join means of pairs of skin samples from individual tails. The dashed line shows the simple effect of *p*H in physiological saline (ref. 2). Reagents were obtained from commercial sources as follows: thioglycollic acid, Light; mercaptoethanol cysteamine, Light and B.D.H.; cysteine, B.D.H; reduced glutathione, B.D.H.

It has been suggested to us that the effects of these reagents might be produced by activation of proteolytic enzymes, but this seems unlikely in view of the following: (1) Previous treatment of the skin with acetone did not prevent the effect. (2) Treatment with cysteamine at room temperature for 0·5 h, followed by 10^{-2} M iodoacetamide for 2 h (which should activate and then inactivate an enzyme), did not prevent the effect. (3) The effect was at least partly (up to about 70 per cent) reversible by leaving in phosphate-buffered physiological saline in the refrigerator. After reversal, the effect, so far as we have investigated it, can be repeated (indicating that the reversal is a true one and not due to formation of new linkages).

Also it is difficult to explain the increase in tensile strength found at high *p*H values with some of the reagents on the basis of enzyme activation. However, one cannot draw definite conclusions from this increase at the moment in view of the similar effect of cyanide[3] in low concentration. There is no reason to suppose it was a contaminant of the reagents used, but an equally active material would only have to be present to the extent of one part in a thousand of the reagents to produce the effect.

The conditions of some of the experiments were similar to those used to encourage growth of anaerobic bacteria. However, the participation of such organisms can virtually be excluded from some of the effects, because, at room temperature or 37° C, those can be demonstrated in 30 min. In experiments overnight at 4° C the addition of sodium azide (10^{-3} M), an inhibitor of bacterial growth, made no significant difference.

There are a number of possible explanations of those effects of thiols. Removal of a metal ion is one. We have been able to find no effect of EDTA (up to 0·1 M); but acetyl acetone reduces the tensile strength of this skin[2], though not nearly as effectively as these thiols. Another possible effect of these could be the breaking of disulphide links, which would agree with the fact that we also have found sulphite to reduce the tensile strength of this skin.

Whatever the ultimate explanation of these effects, they do not appear to be capable of interpretation in terms of what is at present known of the structure of collagen. There is, for example, no evidence of the presence of disulphide links in its structure. We have tried cysteamine on reconstituted collagenous sausage skin (kindly provided by Ethicon, Inc.) and found no significant effect.

It is reasonable to conclude that these thiol reagents are acting on another material, between the collagen fibrils, and that this forms an essential link in the mechanical integrity of the dermis. Previously recorded effects of *p*H and other agents on the tensile strength of skin, which are equally inexplicable in terms of known properties of collagen, support the same conclusion[1,2].

We have previously suggested the possibility[1] that local changes in hydrogen ion concentration could be the basis of a mechanism by which cells could mould connective tissues and move through them. These effects of thiol reagents could be used for the same purpose, with less or no alteration of *p*H from normal. They also suggest that more attention might usefully be concentrated on the role of non-collagenous materials in mechanical properties of other soft tissues, for example in wounds.

We thank Miss Ines des Tombe for skilled technical assistance, and the Medical Research Council for a grant.

SUBSTRATE- AND INHIBITOR-INDUCED CHANGES IN THE OPTICAL ROTATORY DISPERSION OF ASPARTATE TRANSCARBAMYLASE

By E. A. DRATZ and Prof. M. CALVIN

Department of Chemistry and Lawrence Radiation Laboratory, University of California, Berkeley, California

One of the main homeostatic control processes in cells is the modulation of the activity of certain enzymes by small metabolites and catabolites. Allosteric enzymes[1] show large changes in catalytic activity in the presence of effectors (inhibitors or activators) that are often not stereochemically related to the substrate or product of the enzyme of interest. A model for the allosteric enzyme regulation mechanism, based largely on kinetic evidence,

has been proposed by Monod, Changeux and Wyman[2]. This model proposes that small molecule effectors alter enzyme catalytic activity by bringing about conformational changes in the enzyme structure. Independent evidence for or against the alteration of protein conformation by allosteric effectors is important for assessing the correctness of the point of view of this model. This article reports some results on optical rotatory dispersion which demonstrate changes in the conformation of the enzyme aspartate transcarbamylase caused by substrate and by an allosteric inhibitor.

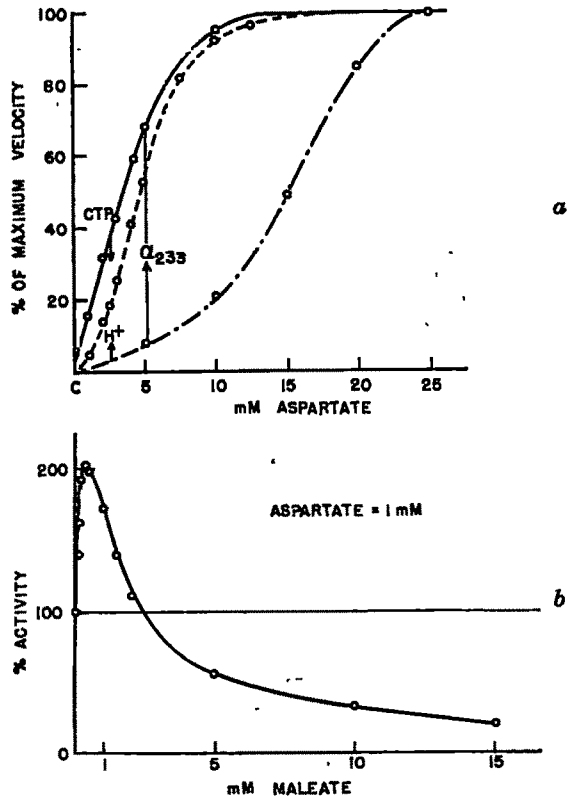

Fig. 1. *a*, The effect of CTP and *p*H on the reaction velocity substrate dependence of ATCase. 3·6 mM carbamyl phosphate and 40 mM buffer present in all samples. ———, *p*H 6·1; - - - -, *p*H 7·0 or *p*H 6·1 plus 2×10^{-4} M CTP; —·—·, *p*H 8·6. All the curves (except the *p*H 6·1 plus 2×10^{-4} M CTP curve) are taken from ref. 3. The arrows on the graph are explained in the text. *b*, The effect of the substrate analogue, maleate, on the reaction velocity of ATCase. 1 mM aspartate, 3·6 mM carbamyl phosphate, and 40 mM potassium phosphate; *p*H 7. Curve taken from ref. 3

Aspartate transcarbamylase (ATCase)[3] is one of the best characterized examples of an allosteric enzyme and is suitable for physical investigation because it can be highly purified. ATCase is the first enzyme in the pyrimidine biosynthetic pathway. Aspartic acid and carbamyl phosphate are coupled by ATCase to form carbamyl aspartate which is transformed by a series of enzymatic reactions to the pyrimidine nucleotides, uridine triphosphate (UTP) and cytidine triphosphate (CTP). As first shown by Yates and Pardee[4], cytidine derivatives exert a regulatory influence on the activity of the enzyme in whole cells and in cell extracts. Kinetic measurements on purified ATCase show that CTP binds reversibly at a site distinct from the catalytic site, and inhibits the enzyme by reducing its affinity for the substrate aspartate[5]. The level of the ultimate product, CTP, is controlled by feed-back inhibition of ATCase.

ATCase has a sigmoidal substrate saturation curve for aspartate at *p*H greater than 6·1, indicating a co-operative (homotropic) interaction[2] between catalytic sites, that is, ATCase increases its aspartate affinity with increasing aspartate concentration. Fig. 1*a* shows the effect of CTP and *p*H on the substrate saturation curve of ATCase. Co-operative interactions between catalytic sites and the modification of this interaction by CTP (heterotropic interaction[2]) are examples of indirect interactions between binding sites that are characteristic of allosteric enzymes. The co-operative substrate site interaction allows non-reactive substrate analogues that are simple competitive inhibitors at high concentrations to activate the enzyme at low concentrations. Fig. 1*b* shows the activation of ATCase by a substrate analogue at low concentrations, and the competitive inhibition at high concentrations. Several substrate analogues show this effect.

The kinetic effects, in summary, are as follows: CTP promotes a decrease in the affinity of ATCase for aspartate while substrates, substrate analogues, and protons increase enzyme affinity for aspartate. At a given aspartate concentration, the aspartate affinity of the enzyme determines the catalytic activity (reaction velocity) of ATCase. The activity changes at a fixed aspartate concentration are represented in Fig. 1*a* by the arrows showing the direction of the activity shift on addition of CTP and H^+.

Materials and methods. All chemicals used were obtained from commercial organizations. The sodium salt of poly-L-glutamic acid, supplied by Mann Research, Inc., had an average degree of polymerization of about 180, estimated by the intrinsic viscosity in 0·1 M sodium chloride. The poly-L-glutamic acid concentration was estimated from the dry weight, assuming one water of hydration per residue. ATCase was a gift from Dr. John Gerhart. The enzyme assay[5] and method of preparation[21] were previously described. All enzyme solutions contained 2 mM mercaptoethanol and 0·2 mM EDTA. Potassium phosphate was used for the *p*H 7·0 and *p*H 6·1 buffers, while *tris* hydrochloric acid was used for *p*H 8·6. The buffers were 40 mM for the kinetic measurements and 4 mM for the optical measurements at less than 240 mμ. The enzyme concentrations were determined from the absorption at 279 mμ, using $A^{1\,cm}_{1\,mg/ml.} = 0{\cdot}59$. The average residue weight ($\bar{M}$) of ATCase was estimated, from a preliminary amino-acid analysis[17], to be 120.

Optical rotatory dispersion measurements were made with a Cary Model 60 recording spectropolarimeter. The rotations were independent of slit width and the specific rotations were independent of the product of (concentration) × (path length) over a ten-fold range. Lamp position adjustment and slit width adjustment were made for minimum noise-level at the wave-length region of interest. The cells, made by Pyrocell, Inc., were selected for minimum birefringence and were cleaned inside and out by soaking in concentrated nitric acid–sulphuric acid (50/50 by volume) and by exposure for 1 min to methanol–3 M potassium hydroxide (50/50 by volume). When properly cleaned, the cells could be removed and replaced in the polarimeter with no observable change in the rotation. Cells of 0·1, 1·0 and 10 mm path length were used. All measurements were performed at 4·5° ± 1·0° C. The specific rotation measurements for different samples at the same solution conditions varied 1–2 per cent. The variation probably arises from volumetric errors in sample preparation. This variation of specific rotation from sample to sample was too large to permit a satisfactory determination of the absolute specific rotations of the enzyme in the presence and absence of effectors. However, we could determine the relative rotation in the presence and absence of effector by a titration method. For the titration experiments, 2·5 ml. of enzyme solution was pipetted into a 0·1 or 1·0 mm cell and the optical rotatory dispersion spectrum measured. Ten- to twenty-lambda portions of concentrated effector solutions, previously adjusted to the appropriate *p*H, were added with a micro-pipette. The enzyme solution was mixed by slow inversion

of the cell and the optical rotatory dispersion spectrum measured. Corrections for dilution and CTP rotation were applied. The magnitude of rotation at selected wave-lengths was most precisely determined by chart recording of the rotation at each fixed wave-length for extended periods (*c.* 10 min) with a 10- or 30-sec pen time constant. After running a spectrum, the peak and trough wave-length points were repeated and the rotations were unchanged within the noise level in all cases. The specific residue rotation $[R']$ was calculated according to the relation:

$$[R'] = \frac{3}{n^2 + 2} \frac{\alpha_\lambda}{l\,c} \frac{\bar{M}}{100}$$

where α_λ is the observed rotation in degrees, l is the path length in decimetres, c is the concentration in g/ml., $\bar{M}$ is the average residue weight, and n is the refractive index of the solution at wave-length of measurement. The refractive index of water at 231 mμ[6] and 20° C was used for all wave-lengths. The Lorentz factor, $3/(n^2 + 2)$, for water at 231 mμ is 0·7635.

Absorption measurements were made with a nitrogen-purged Cary model 15 spectrophotometer. Absorption spectra were taken relative to a buffer solution of identical concentration. The phosphate buffer used for the far ultra-violet absorption measurements had a maximum absorption of one at 180 mμ in a 0·1 mm cell.

Helix content of ATCase. Optical rotatory dispersion in the far ultra-violet region of peptide bond absorption is sensitive to protein secondary structure[7,8]. Fig. 2 shows the ultra-violet optical rotatory dispersion of a model polypeptide, poly-L-glutamic acid (PLGA), in the helical (*a*) and random coil (*b*) conformations. Similar curves, differing slightly in magnitude, have previously been published by other workers[8]. Fig. 2c shows the ultra-violet optical rotatory dispersion of ATCase; the spectrum is strikingly similar in shape to that of helical PLGA, but the magnitude/residue is much smaller. The optical rotatory dispersion curve of ATCase can best be fitted with about 47 per cent of the PLGA helix specific residue rotation (Fig. 2*a*) with no contribution of the non-helical residues. To a first approximation, we conclude that about 37 per cent of the residues of ATCase are in the helical conformation. Because there may be many short regions of helix in the molecule, the actual helix content may be somewhat higher than 37 per cent owing to an expected dependence on chain-length of the rotation/residue of a polypeptide helix[8]. The only appreciable deviation of the fit of a 37 per cent PLGA helix specific residue rotation to the ATCase optical rotatory dispersion occurs in the region between 220 mμ and 205 mμ. The small deviation of the fit has a rather complicated wave-length dependence, and is thought to result from an almost complete cancellation of opposing contributions of the Cotton effects of the various non-helical residues. In an investigation of the far ultra-violet optical activity of myoglobin, using circular dichroism, Holzwarth and Doty[10] have found a similar cancellation of the contributions of the non-helical residues. For myoglobin, the circular dichroism can best be fitted by 70 per cent model polypeptide helix dichroism with no contribution from the non-helical residues[11].

Several other methods are available for helix content estimation from data for optical rotatory dispersion[12,13]. The other treatments of this problem rely on the monotonic visible and near ultra-violet data, and we feel that the most reliable method should be the direct observation of the peptide helix Cotton effects as has been done here. The exact absolute value of helix content of ATCase is not of prime importance in our work and, furthermore, we did not want to use the large amounts of material required for precise visible measurements. None of the methods for estimating the helix content is really satisfactory for proteins with low helix content, as local charge and dipole fields[14] of regions of the protein wrapped around the helical segments are not present in the reference polypeptides. It should be mentioned that PLGA may not be the ideal reference material for an estimation of helix content, and these problems have been discussed by Yang and McCabe[15].

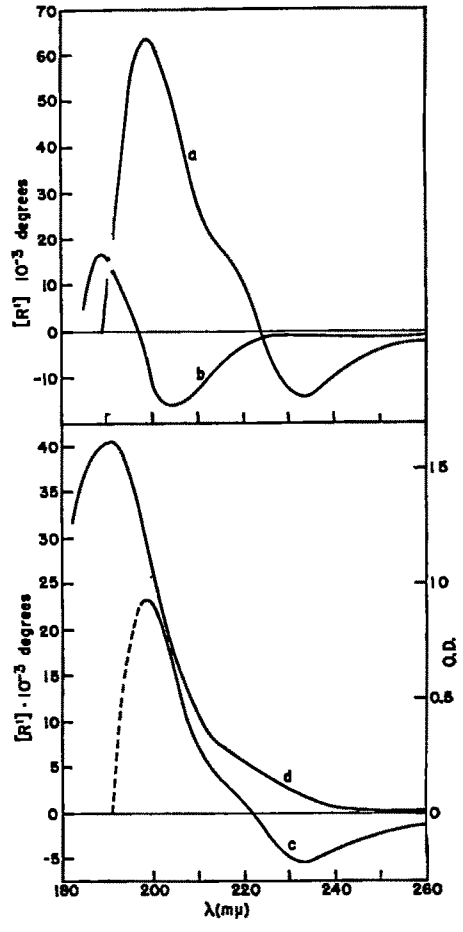

Fig. 2. Optical rotatory dispersion (ORD) and absorption. *a*, ORD of poly-L-glutamic acid, *p*H 4·8 (no added salt), helix form; *b*, ORD of poly-L-glutamic acid, *p*H 7, random coil form; *c*, ORD of ATCase, *p*H 6·1, the average residue weight is taken as 120 g/mole; the dotted portion of the curve is in a region of relatively high noise-level and is less reliable than the other data; *d*, absorption of ATCase, 2·08 mg/ml., *p*H 6·1 in a 0·1 mm cell measured versus buffer

The helix content of proteins can also be estimated from the hypochromic effect that the helical conformation exerts on the ultra-violet peptide bond absorption[16]. This method agrees well with the optical rotatory dispersion for simple polypeptides and some proteins. The use of this method for proteins is complicated by the contribution of aromatic amino-acid side-chains, as well as arginine, methionine, cysteine, amide, and carboxylate groups, to the absorption in the region of peptide bond absorption. The method is attractive because it requires small amounts of material and we felt that more cases should be tried to fully explore its possible usefulness. The side-chains contribution to the absorption of ATCase was estimated from an amino-acid analysis[17] and the amino-acid side-chain extinction coefficients given by Rosenheck and Doty[18]. The absorption spectrum of ATCase is given in Fig. 2*b*. The helix content of ATCase was estimated by this method to be 95 per cent at 190 mμ, 51 per cent at 197 mμ, and 48 per cent at 205 mμ. The 190 mμ point has the largest relative correction for side-chain absorption and is least trustworthy. The 197 mμ point has the

smallest relative correction, and Rosenheck and Doty[18] believe 197 mμ to be the most reliable.

The peptide hypochromism gives a value for the helix content of ATCase which is larger than that predicted by the optical rotatory dispersion. If the 190 mμ point is neglected, the peptide bond hypochromism indicates about 50 per cent helix. This is in acceptable agreement with the optical rotatory dispersion value of 37 per cent. We consider the hypochromism value as the less reliable, as the side-chain as well as the peptide bond absorption may be considerably perturbed by the environment inside the protein.

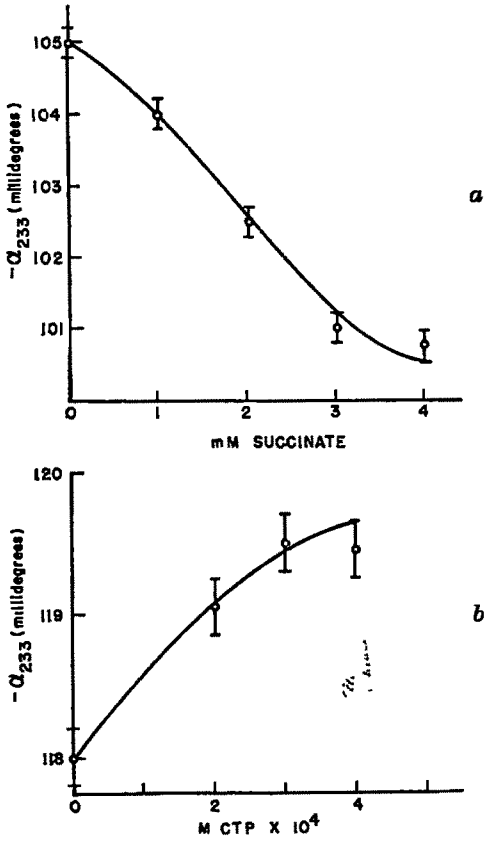

Fig. 3. The dependence of the rotation of ATCase, at the trough of the 233 mμ Cotton effect, on the concentration of CTP and substrate analogue succinate. *a*, Enzyme (1·75 mg/ml.) at *p*H 8·6, and equal portions of a mixture of 150 mM potassium succinate and 130 mM carbamyl phosphate (*p*H 8·6) added. *b*, Enzyme (2·08 mg/ml.) at *p*H 6·1, and equal portions of 20 mM CTP (*p*H 3·1) added

Substrate and inhibitor-induced changes in optical rotatory dispersion. The entire curve for optical rotatory dispersion of ATCase changes in magnitude when CTP, substrate analogues, or protons are added to the enzyme. The observed changes are small (about 5–6 per cent maximum) but can be measured over most of the wave-length range of interest. Table 1 shows the specific rotation/residue of ATCase at the trough of the 233 mμ Cotton effect in the presence of various substances that affect its kinetic behaviour. We use 233 mμ as a convenient wave-length for tabulating the optical rotatory dispersion change because the relative errors are lowest at this wave-length. These measurements were repeated several times and always showed the trends indicated in Table 1; however, the variations in the observed differences were large enough to make the magnitude of the change uncertain. We found that titration of the change in optical rotation shows the rotational changes clearly (see the section on materials and methods).

Fig. 3*a* shows the change in ATCase rotation observed on addition of small portions of a concentrated mixture of carbamyl phosphate and succinate, a non-reactive substrate analogue that is bound to the enzyme. The rotation decreases with increasing substrate concentration, while the catalytic activity increases. It is important to note here the role of carbamyl phosphate, in that carbamyl phosphate is required for the rotatory change, but causes no change by itself (within experimental error). Perhaps carbamyl phosphate is necessary for the binding of succinate. Fig. 3*b* shows the increase in rotation of ATCase as the CTP concentration increases. The catalytic activity decreases with increasing CTP concentration. The effect of added protons on the enzyme shows increased rotation (Table 1) with decreased activity (Fig. 1*a*). All measurements consistently show an inverse correlation between the magnitude of the rotation and the catalytic activity of ATCase.

Table 1. VALUES OF SPECIFIC RESIDUE ROTATION OF ATCASE AT 233 mμ IN VARIOUS SOLUTIONS FROM A TYPICAL EXPERIMENT

Sample	$[R']_{233\ m\mu}$		
*p*H = 6·1	5,240 ± 20		
*p*H = 6·1 + 10^{-4} M CTP	5,330 ± 20	Δ = 90	Δ = 350
*p*H = 8·5	5,590 ± 20		
*p*H = 8·5 + 5 mM succinate and 3 mM carb. PO_4	5,330 ± 20	Δ = 220	

The Δ values are the differences caused by solution alteration. All experiments show the same trends of effector-induced changes in the rotation. The errors shown in the table are the observed noise-level in the optical rotatory dispersion spectrum.

The changes in rotation clearly show that there is a change in the relationships of amide residues in the protein accompanying changes in the catalytic activity. Fig. 4 shows the maximum change in the optical rotatory dispersion of ATCase caused by the addition of substrate analogue. The shape of the difference curve for optical rotatory dispersion is very close to that of the polypeptide helix, indicating that, on the face of it, some residues of the protein have undergone a coil-to-helix transition. The noise-level is relatively high in the region of 200 mμ and below, and it is difficult to follow the details of the change; however, it is clear that the maximum change in

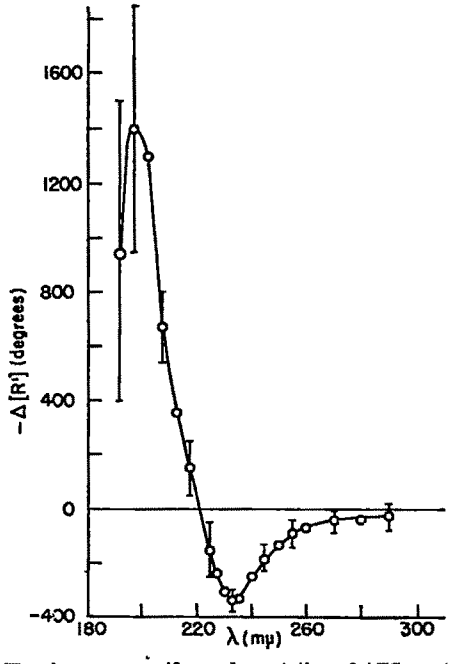

Fig. 4. The change in specific residue rotation of ATCase at *p*H 8·6 brought about by 4 mM potassium succinate and 4 mM carbamyl phosphate. The difference is presented as (enzyme + effector)–(free enzyme)

this region relative to the maximum change at 233 mμ is consistent with a change in helix content.

Care must be taken in assigning such small changes to any particular structural alteration, and alternative explanations must be carefully examined.

(1) Small molecules can acquire optical activity when bound to an optically active large molecule[18,19]. If the optical rotatory dispersion changes observed arose from induced optical activity in the bound effectors, specific rotations in excess of 10^6 degrees/mole of bound substrate analogue would be required to explain the observed change in rotation (even if as many as ten substrate analogues/mole of enzyme were bound). Specific rotations of this magnitude are much larger than can reasonably be expected. Furthermore, induced Cotton effects will be centred very close to the absorption maxima of the bound molecules. CTP has a weak optical rotatory dispersion spectrum with a Cotton effect centred at 270 mμ. An induced Cotton effect in CTP would show up in the 270 mμ region and could not give rise to a change in optical rotatory dispersion with the wave-length dependence observed. Substrate analogues, succinate and malate, have somewhat different absorption spectra and both produce a change in the optical rotatory dispersion spectrum of the same shape. Because the same changes in optical rotatory dispersion are caused by substances with different absorption spectra (CTP, succinate, malate) we can rule out Cotton effects induced in the bound molecules as the source of the changes.

(2) Effector-induced alterations in the non-helical regions of the protein structure could change the charge and dipole environment around the helix and give rise to an altered helix optical rotatory dispersion. Changes in the charge and dipole fields would be expected to have the largest effect on the helix optical rotatory dispersion in the electronically forbidden n/π^* region around 225 mμ[9,10,14] and to be less important in the electronically allowed $N-V$ peptide bond transition in the region of 190 mμ[10,14]. It is very unlikely that alterations in the static fields would produce the same percentage of change in the optical rotatory dispersion at 200 mμ and at 233 mμ as is observed. We can conclude with some confidence that the change in the optical rotatory dispersion does not result from alterations in the non-helical regions of the protein. (The non-helical regions may well change under the influence of the allosteric effectors, but this is not the source of the changes in optical rotatory dispersion we observe.)

(3) In principle, one other possible explanation for a change in optical rotatory dispersion with the wave-length dependence of the helix-coil type is a change in the local refractive index resulting from swelling or shrinking (change in internal hydration), thereby altering the local electric field of the light inside the protein and leading to an altered amplitude of optical rotatory dispersion. If we assume a Lorentz local field, a very large change in refractive increment for the protein (of the order of 6 per cent maximum) would be required to explain the observed effect. A change in refractive increment of this magnitude is extremely unlikely.

In summary, the addition of allosteric effectors causes a physical change in the protein structure. The interrelationships of the amide residues clearly change, and, although static field and hydration effects are not strictly excluded, the allosteric transition is most probably accompanied by a change in helix content of the enzyme.

ATCase appears to be composed of six sub-units, four regulatory and two catalytic, the interaction of which controls the catalytic activity[20,21]. The helix-coil transition that has been found could change the geometry of the sub-units and thereby affect the sub-unit interaction. It has been observed that substrate analogues induce a small change in the sedimentation coefficient of ATCase[17]. The magnitudes of the change in optical rotatory dispersion and sedimentation are both small. The molecular weight of ATCase[21] is about 3×10^5, which corresponds to about $2{\cdot}6 \times 10^3$ residues, about $8{\cdot}3 \times 10^2$ (37 per cent) of which are in a helical environment. The number of residues involved in the allosteric helix-coil transition can be estimated to be about 40–50 residues from the maximum change in rotation of about 5–6 per cent. This small alteration of the enzyme structure occurs during a change of substrate affinity of two orders of magnitude or more. It is not surprising, however, that small alterations of enzyme structure could lead to large changes in activity by affecting the shape, polar environment, or charge on the catalytic site. The allosteric enzyme acts like a biochemical amplifier[22] in that a small signal causes a large effect.

The estimate of the number of residues involved is a lower limit. The net observed effect could be the result of opposite transitions, one helix-to-coil and the other coil-to-helix; the difference in the number of residues would be seen by our experiments. It is also possible that a large number of residues modify their helix dimensions as compared with a smaller number undergoing a complete helix-to-coil transition. The former point of view is unfavourable because helix-coil transitions tend to be co-operative.

The model for allosteric proteins put forward by Monod *et al.*[2] supposes that there are two forms of the enzyme in equilibrium. The two forms are assumed to have different catalytic activities and that the binding of substrate or inhibitor shifts the equilibrium between the two forms. The model predicts that the physical effect of the inhibitor is equivalent but opposite to that of the activator. Another possibility, which runs contrary to the model under consideration, is that the inhibitor and activator cause the same kind of physical change but do so in different parts of the molecule. Our results show that the change occurring on addition of inhibitor is opposite (and approximately equal to) the effect of activator. In terms of Monod, Wyman and Changeux's model, the evidence from optical rotatory dispersion would imply that the catalytically more active form is the less helical form.

An investigation of the responses of the separated regulatory and catalytic sub-units[21] to the allosteric effectors would be desirable to separate their rotatory contributions. Correlation of the binding of effectors with the physical change produced by the effectors is central to the understanding of the mechanism of this enzyme.

The work described here was sponsored, in part, by the U.S. Atomic Energy Commission. We thank Dr. J. C. Gerhart of the Molecular Biology Department, University of California, Berkeley, for samples of aspartate transcarbamylase and carbamyl phosphate, many useful discussions and for access to unpublished results.

ASTRONOMY

Expected Number of Blue-shifts and Red-shifts of Ejected Sources

IT has recently been suggested[1] that the quasi-stellar radio sources are objects that have been ejected by relatively nearby peculiar galaxies. If their large red-shifts are due to the Doppler effect, we shall show that one would, in fact, expect to see many more objects with spectral shifts towards the blue than those with shifts towards the red.

We make the following assumptions: the explosion centres are distributed randomly in space; the distribution of the ejected objects is isotropic; the explosion centres are at rest with respect to the observer (we neglect the small red-shifts of the parent galaxies); the geometry over the volume of space considered is Euclidean; the spectra of all the ejected objects are the same over the region of interest and are representable by a simple power law; and the proper luminous lifetime of the ejected objects is small compared with the time taken for light to travel from here to the ejection centre.

The Doppler shift $(1 + z) = \lambda_{obs}/\lambda_{emitted}$ is given by equation (1) (see, for example, ref. 2).

$$(1 + z) = \frac{1 + v/c \cos\theta}{(1 - v^2/c^2)^{\frac{1}{2}}} \tag{1}$$

where v is the ejection speed, and θ is the angle between the line of sight and the velocity vector. The probability that an object is ejected into a given element of solid angle is just $d\Omega/4\pi$, as the ejections are assumed isotropic. Thus, if $P_0(z)dz$ is the probability of an ejection in the interval $[z, z + dz]$, we have:

$$P_0(z)dz = \frac{d\Omega}{4\pi} = \tfrac{1}{2} \sin\theta \, d\theta \tag{2}$$

and from equation (1):

$$dz = \frac{-v/c}{(1 - v^2/c^2)^{\frac{1}{2}}} \sin\theta \, d\theta \tag{3}$$

so, letting $1 + z_m = [(1 + v/c)/(1 - v/c)]^{\frac{1}{2}}$ be the maximum observed red Doppler shift (note that the maximum blue Doppler shift is $(1 + z_m)^{-1}$), we obtain:

$$P_0(z)dz = \frac{1 + z_m}{z_m (2 + z_m)} \, dz \tag{4}$$

For a given proper lifetime, the observed lifetime is proportional to the Doppler shift (the Doppler shift is very nearly constant, because the last assumption ensures that the angular distance travelled by the object is small), and for this reason, the probability of observing an object with Doppler shift $(1 + z)$ is enhanced by a further factor $(1 + z)$. Thus if $P(z)$ is the distribution function taking this effect into account, we have:

$$P(z)dz = \frac{2(1 + z_m)^2}{(1 + z_m)^4 - 1} (1 + z) \, dz \tag{5}$$

Let the intrinsic luminosity of each source be $L_0(\nu_0)$. Then the flux crossing a shell of radius R_0 (in the frame of the emitter) in the frequency interval $(\nu_0, \nu_0 + d\nu_0)$ is:

$$F_0(\nu_0)d\nu_0 = \frac{L_0(\nu_0)d\nu_0}{4\pi {R_0}^2} \tag{6}$$

The flux seen by an observer with a Doppler shift $(1 + z)$ relative to the emitter is:

$$\begin{aligned} F(\nu)d\nu &= (1 + z)^{-2} F_0(\nu_0)d\nu_0 \\ &= (1 + z)^{-1} F_0[\nu(1 + z)] \, d\nu \end{aligned} \tag{7}$$

The factor $(1 + z)^{-2}$ can be understood either by considering a flux of photons, both the energy and rate of passage of which are reduced by $(1 + z)^{-1}$ (the area enclosing a given bundle of rays can be easily shown to be invariant; see, for example, ref. 3), or by directly transforming the Poynting vector. The distance R to the emitter measured by the observer can be easily shown to be:

$$R = \frac{R_0}{1 + z} \tag{8}$$

so we can write:

$$F(\nu) = \frac{L_0 [\nu(1 + z)]}{4\pi R^2 (1 + z)^3} \tag{9}$$

We assume that $L_0(\nu_0) = C\nu_0^{-\alpha}$ for each source (C may differ from source to source). The relation between the monochromatic apparent magnitude m and the proper monochromatic absolute magnitude M is:

$$m = M + 5 \log R + 2{\cdot}5 \log [(1 + z)^{3+\alpha}] \tag{10}$$

Let $n(m,z)dm dz d\Omega$ be the number of objects with apparent magnitude in $[m, m + dm]$ and with red-shift in $[z, z + dz]$ in the solid angle of sky $d\Omega$. Let $N(M,z)dM dz$ be the number of objects with absolute magnitude in $[M, M + dM]$ and with red-shift in $[z, z + dz]$ in a unit volume of space. Thus,

$$n(m,z)dz d\Omega = \left[\int_0^\infty N(M,z)R^2 dR \right] dz d\Omega \tag{11}$$

From equation (10):

$$R = 10^{0.2(m-M)} (1 + z)^{-(3+\alpha)/2} \tag{12}$$

and

$$dR = -0{\cdot}2 \times 10^{0.2(m-M)} (1 + z)^{-(3+\alpha)/2} \times \ln 10 dM \tag{13}$$

Thus

$$n(m,z) \, dz = \left[\int_{-\infty}^{\infty} 0{\cdot}2 \, N(M,z) \, 10^{-0{\cdot}6M} \times \ln 10 dM \right] 10^{0{\cdot}6m} (1 + z)^{-\frac{3}{2}(3+\alpha)} dz \tag{14}$$

Let $\Phi(M)dM$ be the number of objects per unit volume of space with absolute magnitude in $(M, M + dM)$. Then

$$N(M,z)dM dz = \Phi(M)dM \, P(z)dz \tag{15}$$

and equation (14) becomes:

$$n(m,z)dz = \left[0{\cdot}2 \int_{-\infty}^{\infty} \Phi(M) \, 10^{-0{\cdot}6M} \ln 10 \, dM \right] 10^{0{\cdot}6m} (1 + z)^{-\frac{3}{2}(3+\alpha)} \frac{2 (1 + z_m)^2}{(1 + z_m)^4 - 1} (1 + z) \, dz \tag{16}$$

The quantity in brackets is a constant; thus the form of $n(m,z)$ is independent of the luminosity function $\Phi(M)$. Note also that $\log [n(m,z)]$ is proportional to $0{\cdot}6m$.

The ratio of the number of blue-shifted objects to red-shifted objects at apparent magnitude m is

$$\frac{n(m)_{blue}}{n(m)_{red}} = \frac{\int_1^{(1 + z_m)^{-1}} n(m,z)d(1 + z)}{\int_1^{(1 + z_m)} n(m,z)d(1 + z)} = (1 + z_m)^{\frac{3}{2}(3+\alpha)-3} \tag{17}$$

for a single ejection speed corresponding to z_m. It should be noted that our final assumption minimizes the ratio n_{blue}/n_{red}, because it enhances the probability of seeing red-shifted objects. If, however, the objects were emitted uniformly in both space and time with an infinite lifetime, n_{blue}/n_{red} would be increased by a further factor $(1+z_m)$. The coefficient α is in the vicinity of 0·7 for most of the quasi-stellar radio sources in the radio region and varies around 0·7 in the optical region[4]. Taking $\alpha = 0{\cdot}7$ we have:

$$\frac{n(m)_{blue}}{n(m)_{red}} \sim (1 + z_m)^{3\cdot 55} \qquad (18)$$

If $z_m = 2$, the ratio is 50; even for z_m as small as 0·5, the ratio is 4·2. Red-shifts for quasi-stellar radio sources as large as 2 have been observed[5], and most of the observed ones are larger than 0·5; thus one expects at least of the order of five times as many blue-shifts as red-shifts. So far, no blue-shifted quasi-stellar radio sources have been observed while many have measured red-shifts. It seems unlikely that any of our initial assumptions are violated to an extent sufficient to change our result appreciably; we thus conclude that if the red-shifts are Doppler, the quasi-stellar radio sources have not been ejected from peculiar galaxies. If, however, the quasi-stellar radio sources have been so ejected, the red-shifts are not of Doppler origin.

Determination of Direction, Frequency and Polarization of Radio Emission from Galactic OH

A MAJOR problem in the study of galactic radio emission from OH is to understand how it is that the emissions appear to be localized in very small bright regions each characterized by a particular frequency[1]; in addition, it has been found that emissions can show both linear and circular polarization[2,3]. The localization of emission at a particular frequency can readily be explained on the hypothesis of stimulated emission[4] if there are regions in which the velocities of the OH molecules are correlated over large distances. Should the velocities vary considerably along a line of sight, so will the Doppler shifts relative to some local standard and stimulated emission will not occur because the optical depth at any particular frequency would be inadequate. For a sufficient optical depth, the velocities along the line of sight must be correlated over a distance of about 10^{19} cm. In the absence of shifts of wave-length from any other cause, the velocity must be constant along the line of sight over such a distance. Only in those directions along which there is such a systematic motion will intense emission be observed. The frequencies of peaks in observed spectra indicate that velocities in different parts of a source may differ by 100 km/s (ref. 1).

Whereas linear polarization might arise from some directional effect such as could be associated with the outward movement of an ionization front bounding an H-II region, circular polarization seems to require magnetic fields. The situation does not correspond, however, to simple Zeeman splitting, because just one particular frequency is observed along a particular line of sight, instead of a complete symmetrical Zeeman pattern[1]. The observations can be accounted for, however, by a magnetic field combined with a velocity field. If the magnetic field is directed along the line of sight and is proportional to the OH velocity, and if both vary along the line of sight, then at any point, the wave-length shift for one sign of circular polarization can be just balanced by the Doppler shift, but not for the other sign nor for the linearly polarized unshifted component. In a similar way, a magnetic field at right angles to the line of sight may give rise to linearly polarized radiation.

A magnetic field proportional to the velocity is consistent with the magneto-hydrodynamic equations for a fully ionized gas, for the field is then frozen into the gas and

$$\frac{\partial \mathbf{H}}{\partial t} = \text{curl}\,(\mathbf{v} \wedge \mathbf{H})$$

If $\mathbf{v}$ is always proportional to $\mathbf{H}$ and in the same direction, $\mathbf{v} \wedge \mathbf{H}$ is zero and the situation is static.

Accordingly, let it be assumed that the OH molecules have the same velocity as the ionized hydrogen at the edge of an H-II region. The present suggestion has a number of implications. The Zeeman splitting patterns of OH (ref. 2) show that for the lines at 1,665 and 1,667 Mc/s, the velocity and magnetic field must have the following relations:

$$1{,}665\ \text{Mc/s}: \quad \mathbf{v} = \pm\, 3{\cdot}0 \times 10^2\, \mathbf{H}$$
$$1{,}667\ \text{Mc/s}: \quad \mathbf{v} = \pm\, 1{\cdot}8 \times 10^2\, \mathbf{H}$$

where $\mathbf{v}$ is in km/s and $\mathbf{H}$ is in gauss.

The Zeeman patterns of the lines at 1,612 and 1,720 Mc/s are more complex and Zeeman shifts would compensate the Doppler shifts for the relations

$$\mathbf{v} = \pm\, 0{\cdot}6 \times 10^2\, \mathbf{H}$$

as well as for each of the relations for the 1,665 and 1,667 Mc/s line.

Circular polarization would therefore not be expected to be observed along the same line of sight at both 1,665 and 1,667 Mc/s, but might be seen at 1,612 and 1,720 Mc/s if seen at either 1,665 or 1,667 Mc/s. The observed spectra seem to require velocities of the order of 100 km/s and fields of the order of 0·1 G; however, it may be that they do not have to be so closely related, nor the fields so large, for, as has previously been pointed out[4], when stimulated emission occurs, relatively small differences of population can give large differences of intensity.

Such a picture of the velocities and magnetic fields in the neighbourhood of an H-II region is much more complex than that in which an ionization front moves with a predominantly radial velocity, for the tangential velocities required by the present ideas are comparable with the radial velocities on the simple model. It is difficult, in fact, to see how such a scheme of large-scale circulation can be avoided, for if the tangential velocities are only correlated over distances much less than 10^{18} cm, no net stimulated emission will occur along any line of sight.

This communication has been concerned with the problem of the determination of the frequency, line of sight and polarization of stimulated radio emission from OH; to account for the observations it is also necessary to understand how the populations of the Λ-doublet levels

may be inverted[4] and how the intensities may change rapidly with time[5].

The X-ray Source *Sco X-3*

TAMMANN[1] has advanced the suggestion that a supernova observed by Albumazar in A.D. 827 may be connected with the X-ray source *Sco X-3* in the H II region No. 114.

Dr. Tammann depends on Lundmark[2] for the report of Albumazar. It has been shown, however, that Lundmark's notice depends on a long chain of references far removed from the original report[3]. The original report is in Ali ibn Ridwan's commentary to Ptolemy's *Tetrabiblos* and refers to an apparition seen by Ali and clearly dated April 30, 1006. Ali gives the celestial longitude of the observed object as Scorpio 15° (which need not refer to the constellation Scorpio). In fact, on the basis of a variety of medieval reports of this supernova, many of them contemporary with the event, the position of the supernova has been determined. Gardner and Milne[4] report that, on the basis of radio evidence, the remnant of this supernova is located at 14^h59^m6, $-41°42'$ (epoch 1950.0).

Thus, *Sco X-3* (17^h23^m, $-44·3°$ (1950)) is not related to the supernova to which Tammann referred.

PLANETARY SCIENCE

"Westward Drift" of the Satellite Geoid

RECENTLY, Dr. Tuman[1] compared the mean free air anomaly as calculated by Jeffreys[2] with the satellite geoids calculated by Izsak[3] and Kaula[4], and on the basis of this suggested that the satellite geoid may have a westward drift. If I were to admit that Jeffreys's geoid of 1943 was adequate for a comparison with the satellite results I might accept that Dr. Tuman's work was meaningful, yet I would still maintain that it is remarkable that Dr. Tuman failed to use better solutions of satellite geoid than Izsak's 1963 solution (many have since been published, for example, by Izsak[5], by Anderle[6] and by Guier and Newton[7]). But I must reject that attitude which maintains that Jeffreys's solution of 1943 is adequate for such a comparison. The problem that Jeffreys dealt with was a statistical one. Without observations in vast oceanic areas at the time of his analysis, it was not possible for him to be certain of how much of the gravity anomaly should be attributed to terms of degrees 2 and 3 and how much of it should be attributed to those of higher degrees. The uncertainties in his longitudinal terms were thus considerable. It is significant that the general features of Jeffreys's geoid are compatible with those of the satellite geoid, but the reliability of its detailed features—for example, the longitudinal positions of the maxima and minima of the geoidal height—requires considerable care.

The longitudinal positions of the maxima and minima of satellite geoids determined by various authors are not consistent among themselves. For purposes of comparison, a few of the available results are listed in Table 1.

Table 1

Approximate locations	Jeffreys (ref. 2)	Izsak (ref. 3)	Izsak (ref. 5)	Guier and Newton (ref. 7)	Kaula (ref. 8)	Gaposchkin (ref. 9)
Gulf of Calif. (min)	—	125° W.	115° W.	135° W.	135° W.	130° W.
Andes (max)	—	90° W.	75° W.	75° W.	—	70° W.
Guinea Basin (min)	80° W.	45° W.	50° W.	70° W.	65° W.	85° W.
South Africa (max)	20° E.	20° E.	55° E.	50° E.	50° E.	50° E.
Indian Ocean (min)	85° E.	65° E.	70° E.	75° E.	70° E.	75° E.
New Guinea (max)	165° E.	180°	155° E.	150° E.	145° E.	155° E.
West Europe (max)	10° E.	5° E.	35° W.	10° W.	0°	15° W.

Besides statistical reasons, the close agreement among the last three columns also supports the implication that they are more accurate than the others. "Drifts" of these geoids from Izsak's 1963 one are observed of 5°–30° (both in eastwardly and in westwardly directions). A comparison between Gaposchkin's solution and that of Jeffreys shows that a geoidal minimum near Guinea Basin and a maximum near South Africa "drift" eastward by 15° and 30°, respectively.

Dr. Tuman used Vogel's[10] and Egyed's[11] works to support his observations. I have already questioned[12] Vogel's work as the assumptions used in his calculation of the undulations at the core-mantle boundary are not consistent with his results. Egyed supported Vogel's hypothesis by using a much simplified model. Serious objections to Egyed's work were raised by Coode and Runcorn[13] and myself[12]. A comparison of modern information on geomagnetism with satellite geoid shows no obvious correlation such as was suggested by Vogel.

Arc Quench Gap in Vacuum

THE purpose of these preliminary experiments was to determine the effect of vacuum pressure from 10^{-1} torr (100μ) to 10^{-3} torr (0·01μ) on the stability of a d.c. arc. A pressure of 100μ is obtained in space at an altitude of 40 miles, while 0·01μ is attained at 70 miles.

During the launch phase of unmanned instrumented artificial satellites or space probes, vibration of the grounding cables interconnecting electronic modules can become severe enough for high-voltage arcing between improperly shielded copper conductors and parts of the spacecraft structure or the shroud to occur. In a number of cases, because of their advantageous strength to weight ratio, magnesium alloys are used as a structural material in a number of spacecraft applications[1].

In this preliminary laboratory investigation of d.c. arc stability, electrodes of oxygen-free high-conductivity copper and the magnesium–thorium alloy *HM21-A* were chosen as a possible combination of materials that have been used. For example, the shrouds protecting the

Ranger and *Mariner* space probes during the ascent phase of the mission were constructed of the *HM*21-*A* alloy.

As the spacecraft system with its first- and second-stage boosters travels through the thinning atmosphere during the ascent phase before jettisoning the shroud and before separation of the first stage occurred, pressure under the shroud can rapidly decrease. However, it may also reside at pressure regions that are critical for the generation of glow discharge or electrical arcing and high-voltage breakdown phenomenon for periods during which a grounding bus cable under vibration could come into too close proximity to the shroud skin and cause high-voltage arcing. This event could seriously damage spacecraft circuitry. In order to determine the separation distance for arcing of a 28-V, 20-amp d.c. current between typical spacecraft materials and the influence of vacuum pressure on their behaviour, these preliminary experiments were conducted.

The equipment used for these experiments consisted of a vacuum system with a 4-in. oil diffusion pump, a liquid-nitrogen trap above the diffusion pump, high-vacuum valve, base-plate and lead through adaptor ring and a bell jar. Electrical power, mechanical, calibrated leak, and vacuum gauging lead through into the bell jar were provided in the base-plate adaptor ring. The d.c. power supply provided 28-V, 20-amp current through a resistive load to the test specimens.

The test device is shown in Fig. 1. The test specimens were 0·5 in. square and 0·75 in. long. The upper specimen of magnesium alloy *HM*21-*AT*8 was the cathode, the lower specimen of oxygen-free high-conductivity copper, the anode. The device was made of polymethylmeth-acrylate ('Plexiglass'). A lead screw and nut provided the electrode separating motion of 0·0015 in./sec, through bevel gears, a stub shaft and magnetic drive.

The system was pumped to high vacuum ($\sim 10^{-5}$ torr), the bell jar was cut off by a valve, and dry air was admitted through the calibrated leak while throttling the pumping system valve to achieve the pressure required (for example, 3×10^{-2} torr or 30μ). With the electrodes touching, power of 28 V, 20 amp d.c. was applied, the electrodes were separated slowly (0·0015 in./sec), while observing the quenching of the arc. The moment the arc was quenched, separation was stopped, the power turned off, air admitted to the system, and after removal of the bell jar the electrode separation measured with a feeler gauge.

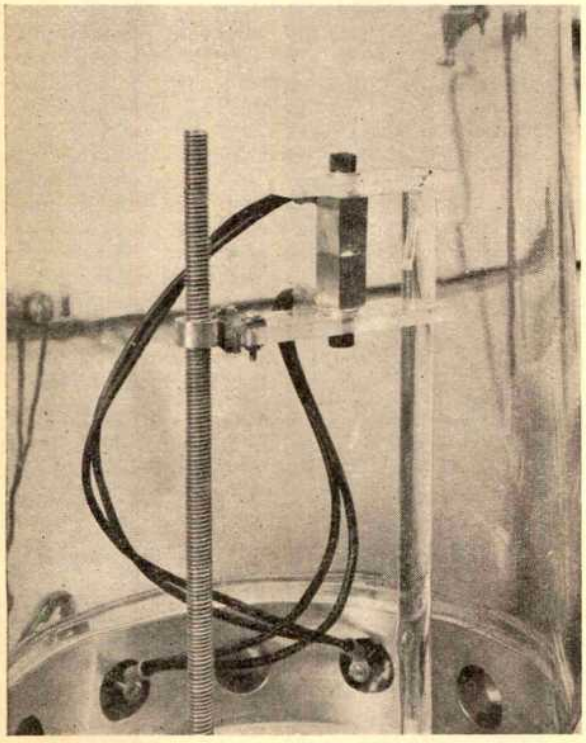

Fig. 1. Arc quench gap electrode separation device

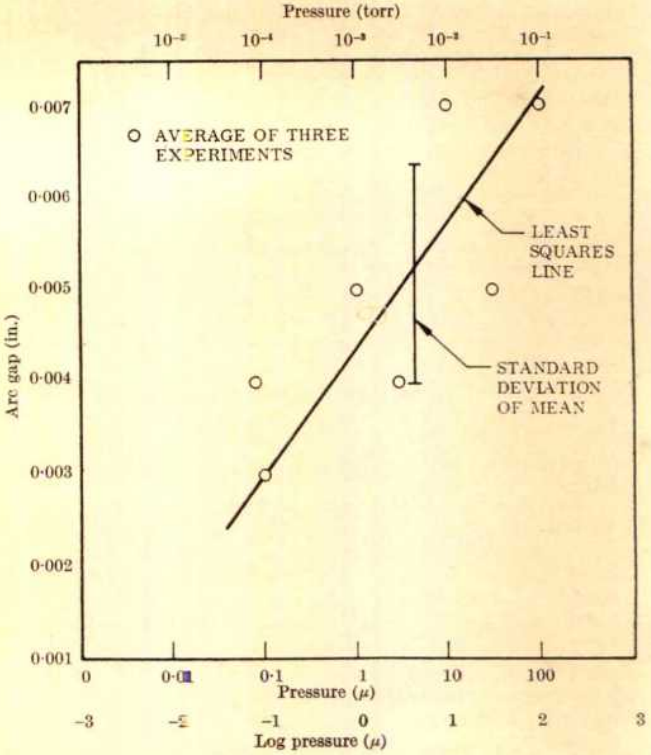

Fig. 2. Arc quench gap in vacuum, 28 V, 20 amp d.c., copper anode, *HM*21-*AT*8, magnesium alloy cathode

The surfaces of the electrodes were electrolytically cleaned after each test. Surface contamination was checked after each test. The contamination of the anode increased with decreasing pressure.

The electrode separations at arc quench are shown in Table 1. The maximum value was 0·008 in. at 10^{-2} torr (10μ), the minimum was 0·002 at 10^{-4} torr (0·1μ).

Three experiments were performed at each pressure in random sequence, for example, 10^{-4}, 10^{-2}, 10^{-1}, 10^{-3} torr, etc. The average of each of the three was plotted with arc gap as ordinate versus the log value of the pressure in

Table 1. Effect of Vacuum Pressure on D.C. Arc Quench Gap at 28 V-20 Amp

Test No.	Pressure (μ)	Pressure (torr)	Arc distance (in.)
4	100	10^{-1}	0·007
5	100	10^{-1}	0·007
6	100	10^{-1}	0·006
7	10	10^{-2}	0·008
8	10	10^{-2}	0·007
9	10	10^{-2}	0·006
19	3	3×10^{-3}	0·005
20	3	3×10^{-3}	0·004
21	3	3×10^{-3}	0·004
18*	3	3×10^{-3}	0·002
22*	3	3×10^{-3}	0·001
15	1	10^{-3}	0·003
16	1	10^{-3}	0·005
17	1	10^{-3}	0·005
18*	1	10^{-3}	0·002
12	0·1	10^{-4}	0·004
13	0·1	10^{-4}	0·002
14	0·1	10^{-4}	0·007
10	0·07	7×10^{-5}	0·004
11*	0·04	4×10^{-5}	0·001
23	30	3×10^{-2}	0·005
24	30	3×10^{-2}	0·004
27	30	3×10^{-2}	0·005
33*	1,000	1	0·002
34*	1,000	1	0·002

* In these tests the electrodes were separated, and the distance required to initiate the arc as electrodes were moved towards one another was measured.

microns, and a straight line was obtained (Fig. 2). A least squares estimate gave the equation:

$$A = 4{\cdot}39 \times 10^{-3} - 1{\cdot}36 \times 10^{-3}\ P$$

where A was arc gap inches and P the log of the pressure in microns.

A mean arc gap of $0{\cdot}0052 \pm 0{\cdot}0012$ in. was found at a pressure of 5μ.

Under the conditions of this experiment, an initiated arc can be sustained at an electrode distance of less than 0·004 in. and quenched at about 0·007 in.

The electrode separation required to initiate an arc was smaller than that to quench one. The average value over a range of pressure $1\text{–}4 \times 10^{-5}$ torr (1,000–0·04μ) was 0·0015 in. with a maximum of 0·002 in. and a minimum of 0·001 in.

The arc length at quench was measured by slowly separating a copper anode and a magnesium alloy (*HM*21-*AT*8) cathode, which were in contact in vacuum. Vacuum pressures were from 10^{-1} torr (100μ) to 10^{-3} torr (0·01μ).

The arc length at blow-out varied from a maximum of 0·007 in. (100μ or 10^{-1} torr) to a minimum of 0·001 in. (0·01μ or 10^{-5} torr).

An Iron-bearing Nepheloid Layer near Key West, Florida

VERY little is known about the suspended matter contributing to those turbid zones in the sea which occur well above the bottom. Recently, however, Ewing and Thorndike[1] reported a layer containing 2·5 mg/l. of lutite at 4,030 m in the Sargasso Sea 160 m above bottom. They did not indicate any further characterization of their material.

In connexion with suspended-matter analyses in near-surface waters to the south of Key West, Florida, it was observed on both occasions when deeper casts were made that some of the water samples taken from depths below 150 m, but 275 m or more above the bottom, were yellowish in colour and contained substantial amounts of material in fine suspension. Chemical and spectrographic analyses of this material have shown that the suspended matter is predominantly iron.

The first samples were obtained from a Nansen cast in lat. 24° 13′ N., long. 81° 41′ W., on January 22, 1965. Turbid water was found in adjacent bottles at 180 m and 215 m with clear water above and at 230 m (the deepest sample taken). The bottom was at about 490 m. The turbid water samples left an orange deposit on membrane filters which were later made available to us for analysis. Preliminary tests showed that a large amount of iron was present. An emission spectrogram of the washed suspended matter was then obtained which confirmed the predominance of iron and revealed the presence of lesser amounts of manganese and vanadium. Other elements were either absent or only occurred in trace amounts. No quantitative analyses were made.

On March 22 a cast to 305 m in lat. 24° 11′ N., long. 81° 52′ W., again resulted in yellowish turbid water samples at 245 m and 305 m, this time with clear water intervening at 275 m. The bottom at this point was about 642 m.

Under the microscope, the particles in both turbid samples were bright golden yellow and seemed to consist of loose aggregations of small spheroids uniformly less than 1μ in diameter. Material of similar appearance was obtained from the January membranes on suspension of the precipitates in distilled water. The spherules in the March samples often occurred singly but tended to aggregate loosely in what appeared to be a soft, gelatinous matrix when left undisturbed. The 245-m sample settled out only slowly over a period of many days, whereas the 305-m sample was more flocculent and appeared to contain more suspended matter. The *p*H of both turbid samples was 7·9, whereas that of the other samples from the cast was about 8·1 (8·3 at the surface). A few particles with a clear, plate-like appearance were found among the yellow material. The January membranes contained many rod-shaped bacteria, and the turbid samples were reported to have a strong organic odour (not hydrogen sulphide). No such odour was noted in the March samples, and no particles that could be identified as bacteria were seen in the turbid samples from that cast.

Volume limitations prevented extensive analyses being made of any of the samples. Two-hundred ml. of the 245-m sample was filtered on to a tared 'Millipore *HA*' membrane filter (effective pore size 0·45μ), and the dry weight of suspended matter was obtained after washing with distilled water. This amounted to 1·8 mg/l. 'Reactive' particulate and soluble iron were also determined on portions of this same sample using the procedure of Strickland and Parsons[2]. This was found to be 1·1 mg/l. in the particulate fraction, or 61 per cent of the total mass, and essentially zero in the filtrate. Total iron was later determined in a portion of the 305-m sample using the method of Lewis and Goldberg[3] but omitting the preliminary separation into particulate and soluble fractions. Total iron was thus found to be 2·0 mg/l. Total 'reactive' iron was also determined in the same sample and was found to be 1·2 mg/l., or 60 per cent of the total iron as determined after digestion in perchloric acid.

An X-ray powder analysis was undertaken of a small quantity of the washed solids from the 245-m sample. The material was mounted in a 0·3-mm-diameter silica capillary and patterns were obtained using the standard 'Norelco' 114·59-mm camera with manganese-filtered iron radiation. Analysis revealed that the material was mostly amorphous but indicated the presence of minor amounts of quartz and a plagioclase feldspar. The presence of another mineral was also indicated, but it could not be identified because of the absence of sufficient analytical data; determination of the plagioclase composition was not possible for the same reason. There was no evidence of carbonate minerals.

It is concluded that the suspended matter in this turbid water consisted almost entirely of hydrous iron oxide(s). No quantitative analysis of manganese was made, but the emission spectrogram indicated that manganese was present at a concentration of about 0·1 per cent. The concentration of vanadium was slightly less than this. The nature of the sampling operations was such that certain fundamental data, notably a temperature profile, salinity, and dissolved oxygen content, which might have provided clues to the origin of the suspended matter, were not obtained. The question of origin was further complicated by the presence in the vicinity of two abandoned dumping grounds which might, conceivably, have enhanced significantly the iron concentration in the surrounding water.

The casts themselves provided little information on the extent of clear water between the depth at which turbid water was obtained and the bottom. In the January cast, one clear sample (at 230 m) was obtained from beneath the turbid samples, but this might, of course, represent only a clear layer in an extensive turbid zone. In the March operation, however, experimental sonar gear designed for acoustic reverberation studies on suspended matter in the sea was used in conjunction with the cast. This equipment gave good indication of a layer 30–50 m thick coinciding in depth with the nepheloid zone as

sampled and with no indication that water with similar scattering characteristics lay beneath it.

The occurrence of large amounts of iron in an extensive nepheloid zone located well above the bottom is noteworthy regardless of the location of the water mass. Further sampling and characterization of this and other turbid zones should produce important information bearing on the origins of suspended inorganic matter and marine sediments.

We thank A. J. Hiller of the U.S. Naval Research Laboratory (NRL) for both the January and the March samples; R. C. Beckett of NRL was in charge of sampling operations on both occasions. We also thank S. H. Cress of NRL for the spectrogram, H. N. Giles of the U.S. Naval Oceanographic Office for the X-ray powder analysis, and L. C. Ricalzone of NRL for the acoustic information.

Late Weichselian Glaciation in the Cheshire–Shropshire Basin

RECENTLY, Boulton and Worsley[1] have interpreted the huge composite morainic suite which occurs in the Wrexham–Bar Hill area of the Shropshire–Cheshire Basin as an end-moraine marking the southern limit of the advance of an ice-sheet in the Weichselian Glaciation. This interpretation is based on a radiocarbon dating of about 28,000 years B.P. obtained from only two molluscan shells found beneath the Upper Boulder Clay in the Sandiway district of Cheshire to the north of the morainic suite. It ignores the fact that the Upper Boulder Clay is cut into and is therefore older than the highest stages of the Lake Lapworth sequence which was formed during the retreat of the Upper Boulder Clay ice-sheet. These lake stages at 330 ft. and 305 ft. have long been correlated with the Main Terrace of the River Severn and its equivalent terrace on its tributary, the River Salwarpe near Droitwich. From this terrace a radiocarbon dating of about 40,000 years B.P. was recorded[2] and, because there seems no reason to doubt this correlation, this clearly demonstrates that the Wrexham–Bar Hill morainic suite is considerably older than 40,000 years and cannot be a product of the last or late Weichselian Glaciation.

At the time of the 330 ft. and 305 ft. Lake Lapworth stages, the position of the retreating Upper Boulder Clay ice-sheet was marked by a series of meltwater channels at various points along the Mid-Cheshire Ridge (ref. 3, Fig. 4). The Peckforton Hall moraine was produced at this time—a small boulder clay moraine which contrasts markedly with the huge ridges of the earlier Wrexham–Bar Hill suite. These features provide indisputable proof of two glaciations with two completely different modes of retreat. Full details of these features found in the critical Nantwich district (*One-Inch Geological Sheet* No. 122) will be published shortly[4].

There is no definite evidence to show that the Wrexham–Bar Hill suite marked the limit of an advancing ice-sheet at any time, but on the contrary within this suite three separate ridges may be distinguished marking the successive halt-stage positions of an ice-sheet which split into two lobes across the Mid-Cheshire Ridge and retreated northwards. Similar morainic ridges in the Delamere area of Cheshire and the Chorley area of Lancashire show further pauses in this retreat northwards. At a later stage all these ridges were overridden by the Upper Boulder Clay ice-sheet which continued far to the south and overlies large areas of the outwash plain of the Wrexham–Bar Hill morainic suite in the Wem district.

Different carbonate leaching properties discovered in the Upper Boulder Clay which occur to the north and south of the Wrexham–Bar Hill morainic suite are not necessarily indicative of age differences between these deposits as suggested by Boulton and Worsley[1], but may have arisen because at the time of the 260–250 ft. Lake Lapworth stage the boulder clay to the north of the morainic suite was almost completely covered by ice and water while that to the south of the ridge was exposed to the elements in the normal way (ref. 3, Fig. 5).

Age of the Aliwal Shoal, South Africa

SPECIMENS of calcareous sandstone containing foraminifera from the submerged Aliwal Shoal, about 5 km east of Green Point on the Natal coast, 50 km south of Durban, were received from Mr. M. J. McCarthy of the University of Natal. They have been investigated with a view to determining the age of the rock. The first specimen was obtained from the damaged bow of the ship *Aimee Lykes* following a collision between this ship and the Shoal. Later, a larger specimen was collected by a diver. The specimens were gently crushed to free the grains and, from the −28, +100 Tyler mesh fraction, all the foraminifera were picked out and mounted.

The foraminifera in these samples were all severely abraded before consolidation of the rock occurred. Consequently most of the identifications are not made to species level. Of the 211 particles recognizable as foraminifera, eighty-six are not identifiable other than to record them as calcareous foraminifera—this high proportion in itself being an indication of the degree of abrasion of all the particles in the rock. The foraminifera found in the samples are recorded as follows:

Cibicides refulgens (Montfort)	16 specimens
Cibicides sp.	6 specimens
Elphidium crispum (Linné)	40 specimens
Miliolids	63 specimens
Unidentifiable foraminifera	86 specimens

The absence of *Ammonia beccarii* (Linné) from these samples, including the 'unidentifiable' specimens, is noteworthy and will be commented on later. In so far as the Aliwal Shoal samples themselves are concerned, this absence of *A. beccarii* is of doubtful stratigraphical value and this assemblage of foraminifera otherwise gives no direct indication of the age of the rock other than that it has a late Cainozoic aspect.

In order to gain an estimate of the age of Aliwal Shoal by correlation with rocks on the adjacent mainland, the samples were compared with samples from Cainozoic calcareous sandstones from various localities in the vicinity of Durban and with some Recent samples from Durban Bay and the adjacent ocean (see Fig. 1). These comparative samples were provided partly by Mr. McCarthy and partly by Prof. J. J. Frankel.

(*a*) *Fossil samples*

(1) Aliwal Shoal. *Cibicides refulgens* and *Elphidium crispum* together are about equal in number to miliolids (mainly *Quinqueloculina* spp., but too abraded to be identified). No specimens of *Amphistegina radiata* (Fichtel and Moll) have been found here.

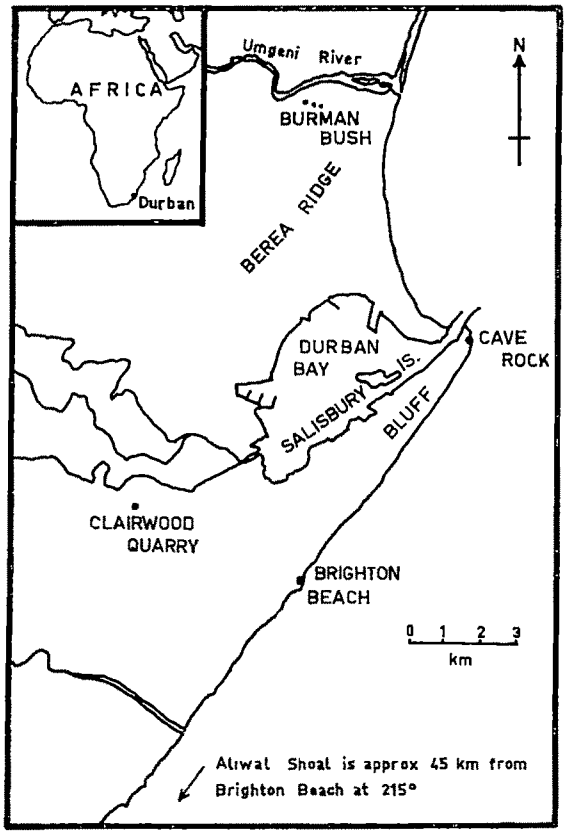

Fig. 1

(2) Berea Ridge, equivalent to sample 365 of W. J. Parr[1]. *Cibicides refulgens* and *Elphidium crispum* are common—*C. refulgens* being more numerous than *E. crispum*, whereas the reverse is the case at Aliwal Shoal. However, at Berea Ridge, miliolids are uncommon, but *Amphistegina radiata* is abundant.

(3) Burman Drive. *A. radiata* and *C. refulgens* predominate here.

(4) Cave Rock, at the Bluff, Durban—'above conglomerate'. *Elphidium crispum* predominates—only a few other species occur as single specimens, poorly preserved.

(5) Cave Rock, at the Bluff, Durban—'below conglomerate'. A large, severely abraded and unidentifiable miliolid equals *E. crispum* in abundance. Another species of *Elphidium* is also present (compare with *E. craticulatum* (Fichtel and Moll)) as well as a moderately large *Discorbis*-like form, also too poorly preserved for further identification.

(6) Clairwood Quarry. *Cibicides refulgens* predominates slightly over miliolids. No other species are present in the sample.

(7) Brighton Beach. *C. refulgens* and *E. crispum* are about equally abundant, miliolids are scarce and other species negligible.

(*b*) *Recent samples*

(8) Durban Bay, sample *DB*.1–2, collected by H. R. Belderson. Of the species relevant to this appraisal, *E. crispum*, *C. refulgens*, *Amphistegina radiata* and *Elphidium craticulatum* are all common and so is *Ammonia beccarii*. Large miliolids, *Triloculina* sp. and *Quinqueloculina* sp. are present, but less common.

(9) Durban Bay, north of North Pier, sample *D2A*, collected by H. R. Belderson. *E. crispum* is the commonest species, accompanied by *C. refulgens*, *Amphistegina radiata*, *Ammonia beccarii* and miliolids in lesser but about equal numbers.

(10) Durban Bay, harbour dredge sample from near Salisbury Island[2]. In the harbour dredging from near Salisbury Island, an entirely different facies of accessory species is present, but the commonest forms are *Elphidium craticulatum*, *Ammonia beccarii* and *Cibicides refulgens* with *E. crispum* quite common. No specimens of *Amphistegina radiata* are present. The sediment is grey mud.

(11) Sample from 11–13 fathoms off Durban Heads, collected by H. R. Belderson. *C. refulgens* predominates, with *Amphistegina radiata*, *Ammonia beccarii* and miliolids also quite common.

Within the limits of variation shown by the series of fossil samples, the samples from Aliwal Shoal have faunal and sedimentary features which link them with the calcareous rocks of localities 2–7, the chief faunal difference being the absence of *Amphistegina radiata* from some samples. This and minor lithological variations are attributed to differences in the sedimentary environments in which the rocks accumulated or from which they were derived. It is important to emphasize that all the foraminifera in the samples from these seven fossil localities are abraded and recrystallized. The Recent foraminifera are well preserved.

The foraminifera of the fossil samples also closely resemble those of the four Recent samples with which they have been compared except for one feature—the absence of *Ammonia beccarii* from all the fossil samples and its occurrence in all the Recent samples. In view of the ubiquitousness of this species in near-shore, shallow-water deposits of Recent age, its absence from the fossil samples apparently has some stratigraphical significance.

A. beccarii appears in the Tertiary sequence in south-eastern Australia in the Lower Pliocene[3]. The time of appearance of *A. beccarii* in the Tertiary of South Africa is not accurately known because of the very incomplete stratigraphical sequence of Tertiary deposits in that country. Because *A. beccarii* attained an almost world-wide distribution in the Late Cainozoic it is to be expected that it would be approximately contemporaneous in two regions of comparable southern latitude. The evidence of *A. beccarii* therefore suggests an early Pliocene or slightly older age. However, in the samples examined, two common species, *Elphidium crispum* and *Cibicides refulgens*, and one less common, *Elphidium craticulatum*, appear in south-eastern Australia in the late Pliocene and Quaternary.

From this evidence, a Pliocene age is favoured for the rock of the Aliwal Shoal and lithologically similar calcareous sandstones at the six localities near Durban with which it is correlated.

PHYSICS

Further Tests on the Ice Nucleation Potential of Meteoritic Material

SCHAEFER[1] was unable to detect any trace of ice-crystal formation when he vaporized a sample of iron–nickel meteorite by electric spark in a supercooled cloud—even in clouds as cold as −25° C. Mason and Maybank[2], who ground up and vaporized three samples of stony meteorites, and Mason[3] with three further samples also reported that they were unable to detect any production of ice-crystals at temperatures above −17° C. This communication records the results of tests on the nucleating properties of a further thirteen samples of meteoritic materials. These comprised iron–nickel types (siderites),

stony type (aerolites), plus two samples of the intermediate (siderolite) variety (all obtained from the American Meteorite Laboratory, Denver).

A fragment of each of these meteoritic samples was crushed in a steel mortar so that at least a portion of each was reduced to particles of a few microns in diameter. The crushed material was stored in small polythene bottles, from which a 'spray' of particles could be obtained by shaking and squeezing. Our refrigerator box was fitted with felt-covered sides, and the actual test chamber was a 5 l. glass flask with three outlet tubes. The temperature within it was determined by means of a copper-constantan thermocouple connected to a sensitive galvanometer. The temperature variation within the chamber was found to vary by less than 0·3° C from one place to another. A small lamp covered with a water-soaked gauze served as a source of vapour within the chamber. The chamber air, when required, could be flushed out by means of a vacuum cleaner—the suction caused clean air to enter the flask through a dust filter.

Detection of ice crystals was accomplished by means of a soap film, supported on a small copper loop which could be lowered into the test chamber by way of the central outlet tube. Owing to the rapidity with which this froze after nucleation, sugar was added to the soap solution to the extent of about 25 per cent by weight. Using this mixture, a nucleated film took 50–60 sec to freeze completely at −14° C, and slightly more than half this time at −20° C. Even at the lower temperature, film nucleation by the copper ring seldom occurred, so that it was not necessary to cover it with a plastic coating.

Before testing each substance, several observations of background ice nucleation occurrence were made. In general, fewer than one or two active nuclei were detected within a 0·5-min period of observation, but about twice this level was reached at temperatures below −19° C.

The testing technique at a particular temperature involved the production of a supercooled water droplet cloud within the chamber, and this was accomplished by turning on the vapour source lamp for 15 sec. Following this, a fresh soap film was introduced on the wire ring. The bottle containing the material to be tested was shaken and a small sample of the particles sprayed into the flask directly above the film. The threshold temperature was considered to be that at which four or five ice crystals (above background level) were observed to land on the film within 1 min of seeding the flask with the meteoritic dust sample. This was estimated to correspond to about 1 active nucleus in 10^4 inert particles. The testing sequence was carried out at least three times at any one temperature setting and the averaged result was taken as indicative of the behaviour of the specimen concerned.

The thirteen samples were first tested for activity at temperatures of −14° C to −16° C (between each sequence of trials the chamber was carefully flushed). Those that indicated activity levels above the threshol[illegible] set aside for investigation at warmer temp[illegible] that initially gave no ice crystals were test[illegible] lower temperatures until either th[illegible] was reached. Great care was [illegible] cross-contamination. [illegible]

A technique similar to that used in Mason and Maybank[2] was used to determine whether vaporization of meteoritic material by an electric spark could produce effective ice nuclei. A small fragment of an iron–nickel meteorite (*S*-5), previously observed to be inactive at −19° C, was placed between a pair of electrodes. This assembly was held at the top of the test chamber directly above a supercooled water droplet cloud and soap film detector. A 20 μF condenser, charged to 400 V, was discharged through the electrodes and meteorite. No ice crystals were observed by the film following this procedure, at least down to −19° C. The entire operation was repeated with a sample of an inactive stony, or aerolitic, meteorite (*A*-1) substituted for the iron–nickel specimen. Again, no ice nuclei were produced by the spark discharge at temperatures of −18° to 19° C.

In summary, it would seem that two of the thirteen meteorite specimens tested—one a siderite, the other an aerolite—had threshold temperatures for the onset of ice nucleation activity higher than −15° C. These may thus be considered as fairly effective sources of ice nuclei on the basis of this arbitrary division, although not so efficient as some soil components such as kaolinite and halloysite[2]. The other eleven specimens must, on this basis, be classified as ineffective. Finally, we have shown that vaporization by an electric spark is not effective in producing ice nuclei from inactive meteoritic material.

A Computer Study of the Grouping of Spheres in a Random Three-dimensional Assembly

As a part of a fundamental research programme it became necessary to investigate spatial relationships in a three-dimensional assembly of particles. Since computing time has become more readily available, there have been a number of reports on work dealing with this topic. However, these have concentrated mainly on flocculated or close-packed models. Typical studies are those of [illegible] Sutherland[1], Levine and Chernick[2] and [illegible] Lewinson[3]. In contrast the simple [illegible] basis for this computer study was as [illegible] interacting spheres was [illegible] only random contacts

random sequential manner. The selection was termed 'random sequential', because a centre which caused the sphere around it to overlap with other spheres already selected was automatically rejected and another centre tried. The final assembly of selected centres was then examined to isolate the groups of spheres associated with the predetermined contact diameter. In each model the numbers of groups having X values of 1, 2, 3, etc., were then recorded.

The model volume was taken to be a cube of side 10^4 units and each sphere was 10^3 units diameter. Three sets of models having 200, 300 and 400 spheres respectively (that is, having volume concentrations of 0·105, 0·157 and 0·209) were used. Each model was investigated at effective diameters 1,100, 1,200, 1,350 and 1,500 units. These diameters were centre–centre distances and corresponded to surface–surface separations along the line of centres of $0{\cdot}1d$, $0{\cdot}2d$, $0{\cdot}35d$ and $0{\cdot}5d$, where d was the sphere diameter.

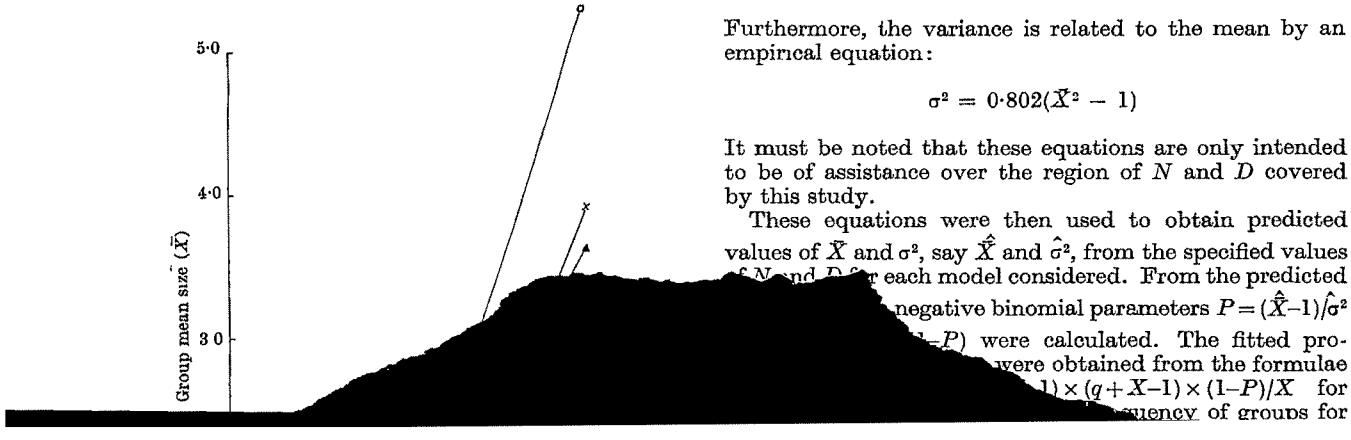

Table 1 shows the observed frequency distributions of group size X ($X = 1,2,3,..$) for all the sets of model conditions considered. The mean size $\bar{X}$ and variance σ^2 are also shown. Duplicate results are shown for the 300 sphere model and agree fairly well. Fig. 1 is a graph of the group mean size ($\bar{X}$) against contact diameter (D) for the 200, 300 (two samples), and 400 sphere models. The high computer costs of creating these types of models preclude very much replication.

The negative binomial distribution has been found to fit the observed frequency distributions of the variable $(X-1)$ quite well. This distribution is often a good fit to distributions of counts of particles. It is found that the observed mean $\bar{X}$ of a group is related to the number of spheres in the model N, and to the contact diameter, D, by the following empirical equation:

$$\bar{X} - 1 = \exp\left[10^{-3}(5{\cdot}4\,N + 5{\cdot}6\,D - 8{\cdot}96 \times 10^3)\right]$$

Furthermore, the variance is related to the mean by an empirical equation:

$$\sigma^2 = 0{\cdot}802(\bar{X}^2 - 1)$$

It must be noted that these equations are only intended to be of assistance over the region of N and D covered by this study.

These equations were then used to obtain predicted values of $\bar{X}$ and σ^2, say $\hat{\bar{X}}$ and $\hat{\sigma}^2$, from the specified values of N and D for each model considered. From the predicted negative binomial parameters $P = (\hat{\bar{X}}-1)/\hat{\sigma}^2$ $(1-P)$ were calculated. The fitted pro- were obtained from the formulae $\times (q+X-1) \times (1-P)/X$ for quency of groups for

result of random processes such as those assumed in this study or of simple flocculation under attractive forces.

The computer programme for this study was written in ALGOL and the computer used was Atlas. The programme has been extended to permit the generation of assemblies of different-sized spheres and also to consider not only the introduction of single spheres into the model but also aggregates of spheres.

It may be of more general interest to note that this computer model is a numerical attempt to solve an unsolved problem in geometrical probability, that is, the determination of the clustering properties of solid spheres distributed at random in three dimensions. Furthermore, the programme can be easily modified to consider the one-dimensional case of non-overlapping randomly placed intervals on a line or the two-dimensional case of non-overlapping randomly placed circles on a plane.

We thank Dr. Dunderdale, Mr. R. M. Driver and Mr. Hewson for their assistance both in discussions and with some of the calculations.

Radium Content of Rainwater

ATMOSPHERIC radioactivity is generally attributed to the following: (1) escape of radon and thoron into the air from radioactive material in the surface of the Earth; (2) spallation products of atmospheric gases produced by cosmic radiation; (3) radioactive fall-out as a consequence of nuclear detonations.

Most of the natural activity in the troposphere is generated by the first. It is generally believed that after formation in the ground, radon and thoron diffuse into the atmosphere. Their decay products are heavy metals which soon become attached to natural aerosol particles and eventually return to the ground by way of rain or by some other process. The presence of radium-226 in the atmosphere is not likely to arise from (1). However, in an isolated measurement, Damon and Kuroda[1] detected radium-226 in rainwater, with a specific activity of 10^{-12} c./l. Chatterjee *et al.*[2] also detected it among other α-emitting radioactive fall-out elements. It was therefore considered worthwhile to search more carefully for radium-226 in rainwater.

During the last monsoon season in Calcutta, the radium content of about fifty samples of rainwater was measured. These were collected in wide-mouthed polythene vessels at appropriate intervals (the local times of collection being noted). On average, each sample consisted of about 15 l. of rainwater. In order to avoid any possible sources of contamination, barium sulphate and other materials such as nickel or platinum crucibles were not used in the preparations. Instead, the samples were treated with pure calcium chloride (2·0 g/l. of water) and sodium potassium carbonate, so that radium, if present, could be coprecipitated with calcium carbonate. (The possibility of such a separation was envisaged by Hahn[3] and quantitatively verified by Kropf[4]). Finally, the acid-soluble carbonate was dissolved in dilute hydrochloric acid and transferred to a bubbler for estimation of radon in the usual manner. In order to eliminate any background ionization that might arise from cosmic-rays or local contamination, the measurements were carried out using the differential ion-chamber arrangement as suggested by Kropf[4].

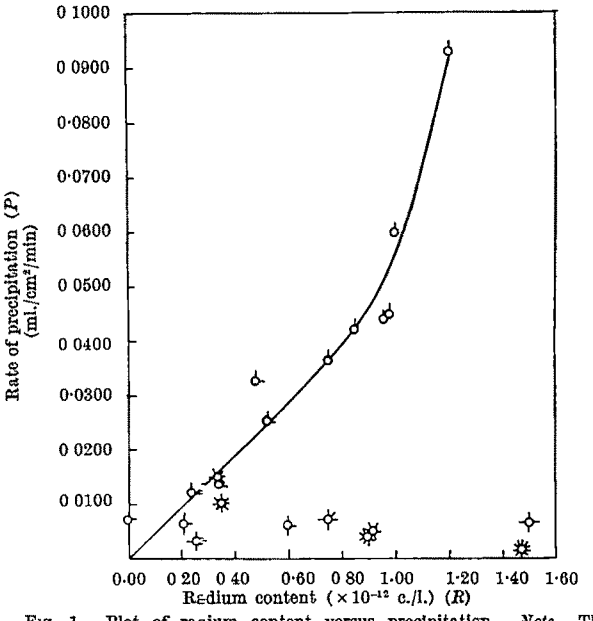

Fig. 1. Plot of radium content versus precipitation. *Note*.—The number of lines emanating from the plotting indicates the duration of rain in hours of the sample

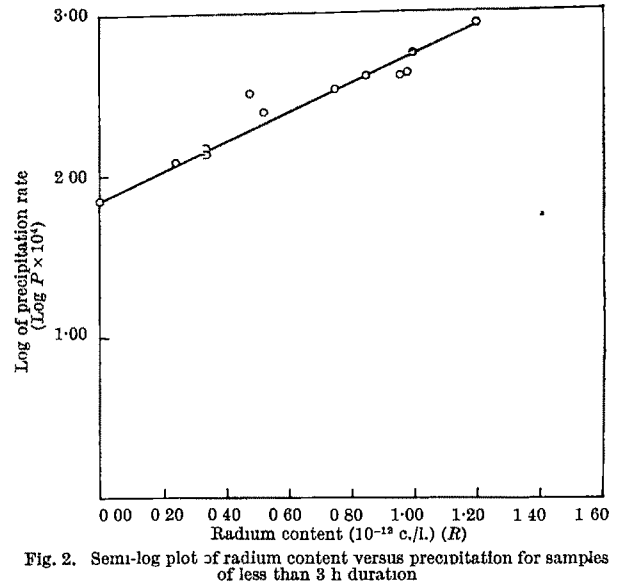

Fig. 2. Semi-log plot of radium content versus precipitation for samples of less than 3 h duration

Some twenty-five first samples were collected from separate rainfalls, while the remaining samples formed subsequent fractions. The rate of precipitation P as well as the duration of rainfall, D, corresponding to the former samples varied in individual cases. Fig. 1 is a plot of radium content (F) versus precipitation (P). If we consider all the points in the figure, there does not seem to be any decisive correlation between them. However, if we consider only samples of short duration, say for $D = 1$ or 2 h, there is a relationship which shows that as the precipitation rate increases, the radium content also increases. The relationship is not linear and a tentative curve fitting these small duration first sample data is shown in the same figure.

Fig. 2 is a plot of the same set of data with R in arithmetical scale and P in logarithmic scale. It can be seen that the points align themselves fairly closely. The linear relationship can be expressed as:

$$\text{Log } P = 0{\cdot}93\ R - 2{\cdot}15 \qquad (1)$$

An analysis of data relating to measurements of samples collected at hourly intervals during continuous rain-

falls indicates an exponential time-decay of the radium content. The negative exponent increases with the rate of precipitation, as the scavenging action becomes greater. The maximum radium content recorded was $1{\cdot}5 \times 10^{-12}$ c./l. When continuous rainfall was recorded, however, in most cases the last portion carried negligible activity ($< 10^{-14}$ c./l.).

We thank Dr. G. Ramaswamy for his help in analysing our data.

Cyclic Pattern of Metallic Crystal Structures

THE three principal crystal structures of the metallic elements, the face-centred cubic (f.c.c.), the body-centred cubic (b.c.c.) and the hexagonal close-packed (h.c.p.), follow a cyclic pattern as sub-shells are filled with electrons. The preferred structure changes from f.c.c. to h.c.p. to b.c.c. for the half-filled sub-shell. As the sub-shell continues to fill, the trend is reversed.

When a sub-shell is either empty or full, atoms pack as spheres and the f.c.c. structure predominates. The rare gases (p^6), calcium and strontium (s^2), the cobalt, nickel and copper group metals (d^{10}) and ytterbium (f^{14}) adopt this structure. The high packing density and high symmetry (low entropy) aspects of the f.c.c. structure produce the lowest energy environment for the packing of spherically symmetric atoms. The major exceptions to this occur among the alkaline earth metals where the effect of losing an s-electron to the conduction band is most pronounced.
